3. The water must be delivered under sufficient pressure to the face of the drift, and wherever hydraulic elevators are needed.
4. There must be dumping ground available for the tailing debris; or a river having sufficient current to remove it out of the way.
5. The overburden must not be of such quality or quantity as to render the cost of removal prohibitive.

Very few hydraulic mines are worked without elevating a portion of the drift material by hydraulic elevators, therefore the height of the lift must be determined. For estimating the quantity of drift and overburden the method of cross-sections is adopted as shown in Fig. 3 by sinking bore holes to bed rock at intervals of 100 feet. The difficulties found in this practice were the deviation of the bore holes from the vertical and the irregularity of the bed rock. To insure the drill had reached bed rock, and not a boulder, it would be sunk 10 feet after rock was reached in the drift. The method of cross-sections is universally adopted in estimating the drift in ancient river beds, and in one case the estimate was within 4 per cent. of the actual quantity.

In the case of shallow deposits of greater superficial extent, a plan is drawn showing the position of each bore hole or shaft

and its depth. Where these depths are fairly uniform over a particular area the average is multiplied by the area represented, giving the volume of that portion; the sum of all such volumes

and the total quantity of drift. In cases where the bottom is uneven either of the following methods are used:

1. Contour lines are drawn at regular intervals of depth; the areas enclosed are then measured by a planimeter, and the volume between every two adjacent contours is computed by multiplying the mean area by the contour interval. The use of the prismoidal formula in place of the mean-area method is a refinement generally not justifiable in this class of work on account of the comparatively few points actually determined, and, consequently, the large amount of assumption in interpolating the remaining points and contour lines.

2. The whole area is divided up by lines connecting adjacent drill holes or shafts. The interval between drill holes would depend on the funds available for prospecting purposes, the nature of the ground and the distribution of values therein. An interval of two chains (132 feet) may be taken for a preliminary test, and should the result warrant closer drill holes, a one-chain or half chain interval may be used by drilling the ground between the first series of holes. The area having been divided into small squares, and depths recorded, the volumes of all these are then computed and figured together with the value per cubic yard, and placed on the plan in respective divisions. This serves as a rough assay plan and is of more use to the management during the progress of mining operations than is a contour plan, which has little practical value. The method adopted in any case can only be decided by a careful study of the material on the spot, but generally one of the above methods, or possibly a combination of them, will be found, with perhaps certain modifications, to suit local conditions.

Perhaps the most important and most difficult problem is estimating the value of the drift. The chief methods employed are: Face sampling, tunnels, bore holes, shafts, combination of any two or more of the above, and bulk test under working conditions.

*Abstracted by E. B. W., with permission of the author, from "Notes on Tin Sluicing in Tasmania," published in Bulletin of Australasian Institute of Mining Engineers, April, 1910.

The object in each case is to treat a known quantity of drift and weigh the tin recovered. If the sample is small it is panned, or if large it is worked in a small sluice. The whole of the sample obtained should be treated, for experience has proved that small samples taken from a larger one nearly always underestimate the tin ore. The chief troubles in estimating the quantity of tin are the difficulty of obtaining representative samples owing to the irregular distribution of the ore in the drift, and secondly, in determining accurately the true volume occupied by the whole sample *in situ*. The best method of arriving at the true size of the sample is to measure all the dirt removed in suitable boxes of known capacity. In the case of tunnels the cars can be used for measuring provided they are over filled and the excess swept off by a straight edge drawn across the top of the car. Allowance must be made for the increase in bulk of the dirt after being broken down. The factor for this is best obtained by carefully measuring a regular portion of the excavation and the volume of dirt it yields. A corresponding allowance is made on the volume of the whole sample. In sampling a face, a cylindrical vessel such as a nail can of known capacity is forced into the face at points where the value is to be determined. It is then withdrawn and any loose sand is poured off. The contents of the can still retain the original volume they occupied in place, and this is carefully determined. The dirt is now tipped out and remeasured in the loose state; the increase in bulk is generally expressed at so much per cent. on the original. The mean of all the separate determinations is the figure applied to larger samples or bulk tests. In very fine wash the increase is from 20 to 25 per cent.; in coarse gravel from 30 to 40 per cent. These face samples are panned separately for tin ore. Where the depth of a deposit has been proved by drilling, the drift material from each bore hole is used as a sample for obtaining the ore contents. Its bulk should not be calculated from the dimensions of the hole, because the rubbing of the drill rods causes an enlargement in the diameter and a corresponding increase in the amount of dirt extracted. This increase may be a large proportion of the total sample. For example, a 4-inch drill hole worn to 5 inches in diameter would yield 56 per cent. more dirt than the calculated amount. The only satisfactory method, therefore, is to measure the dirt in a box or similar apparatus as described. Frequently shafts are sunk to determine the quantity of ore in shallow ground. In this case all the dirt excavated is sluiced if possible; but if not, samples are taken at regular intervals in depth and panned. The results obtained in this way have approximated closely the subsequent working, but the large sample is the more reliable.

The difficulty with prospecting by means of shafts is the necessity of keeping the water baled out, and in very wet ground this may prevent the shaft being carried down to bed rock. The bulk test under working conditions requires a plentiful supply of water, also facilities for the disposal of tailing.

A scheme of operations comprising all the above methods was employed on the Briseis-Ringarooma workings. Tunnels were driven about 350 feet apart and the first two connected by a branch drive. A sample was taken each 4 feet of the drift, and bore holes were put in 100 feet apart. In this manner 5,600 feet of driving and 2,600 feet of boring were done up to the end of 1908.

Face sampling, while it has the advantages of cheapness and simplicity, unless very carefully done does not furnish an accurate value of the ground. In fact in nearly every instance this method has given excessively high results.

Tunnels and drifts when sampled as described, give reliable information for their particular level, but it must be remembered that certain horizons are generally richer than others and the samples must be taken at all depths from top down to bed rock.

Bore holes are generally sunk vertically. Therefore in ground containing rich horizontal seams of tin the hole penetrates all layers and theoretically a more accurate sample should result. In practice, however, it is found that material falls in from the sides of the bore hole, also water in the bore hole washes fine tin down to the bottom, whence it may or may not be recovered. The sample from a bore hole is rather small. Shafts have all the advantages of bore holes and the following additional points in their favor: They give a larger sample and therefore a more accurate value; the size of the excavation allows of a thorough inspection of the ground at all depths, thus giving more exact information on the nature of the ground; if desired, fresh samples can be taken at any depth by sampling the side of the shaft, provided, of course, that the shaft is not in running or wet ground. Generally shafts cost more than bore holes, and the expense of sinking a sufficient number of them to thoroughly test a deposit may be prohibitive, and for this reason drilling is the usual practice. In the writer's opinion a few shafts should always be sunk in conjunction with drilling, both as a check and to give more accurate information as to the nature of the drill hole.

In several cases boring gave a very close approximation to the actual conditions, but in other cases the results were high, and in one or two other instances low. However honestly and faithfully the work be done, assays gotten by boring must always be accepted with caution.

As showing the advantage of large over small samples, the following figures are significant:

Case I. All the dirt taken from a drift was treated in a sluice. As an alternative test a smaller sample was taken by a shovelful from each truck. The result shows that the small sample gave only 53 per cent. of the bulk test.

Case II. Drill holes were sunk in drifts and shafts were then sunk in the same locality. The bore holes gave an assay of 2.16 pounds of tin per cubic yard, while the shafts gave 4.1 pounds; that is, the bore holes gave only 53 per cent. of the value obtained by shafts in the same spot.

Case III. Twelve blind shafts were sunk below a tunnel. Bore holes were put down on the same sites. Without exception the result of the bore holes was less than that yielded by the shafts.

Case IV. On a gold-dredging proposition the ground was bored and then dredged. Bore holes gave only 77 per cent. of the dredge returns. In this case, however, the ground was worth only 1½ grains per cubic yard and the bore holes gave 1.15 grains, a discrepancy of about ⅓ of a grain per cubic yard. The result of these tests seems to show that bore holes have a tendency to underestimate the value, also that small samples taken from the larger ones in the way described, cannot be relied upon.

Before leaving this portion of the subject, a method used with some success in gold dredging in Australia may be worth mentioning on account of its application on a fairly large scale though in a modified form in Victoria. Shafts are sunk to bed rock. The samples taken are panned, the number of colors of gold and total weight being recorded in each case. A table is then drawn up showing the average number of colors per pan at the various shafts. A number of bulk tests, 50 to 100 cubic yards, are treated from the localities of the shafts and the actual value entered opposite the previous result.

In Australia it was found that the two values bore a fairly definite relation to one another. In one case in Victoria the ground at the poorest bore hole gave the highest dredge return, the bore hole having evidently bottomed on a blank in good average ground.

Before the ancient river beds can be mined the basalt cover must be removed. At some mines this overburden is so thin it may be hydraulicked with the drift, but the companies operating on the Cascade River have an overburden sometimes 150 feet thick with the core hard columnar basalt. The Briseis company removed 4,500,000 cubic yards of overburden and drift, using for two consecutive years 30,000,000 gallons of water per day. The overburden being too high to be safely

worked as one face, was worked in benches, which was also advantageous because the debris from the top bench could be wasted in a higher place than that from the bottom bench and drift faces. The different benches were kept sufficiently ahead of the drift faces to permit all to be worked simultaneously. Water for the overburden workings is brought from the Ringarooma and Cascade rivers in 20-inch pipes, a branch going to

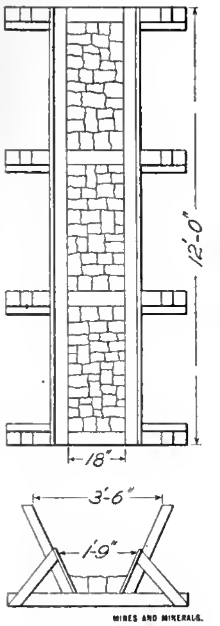

FIG. 4. OVERBURDEN TAIL SLUICE

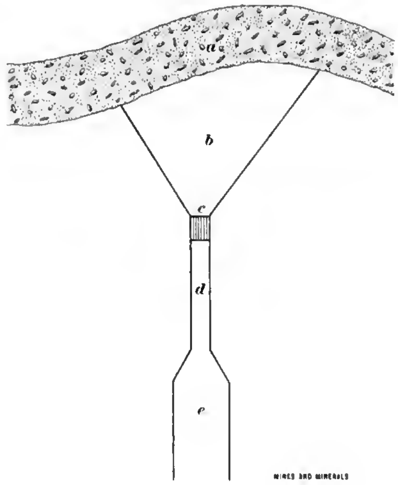

FIG. 5
a, Face; *b*, Head-Sluice; *c*, Grizzly; *d*, Feed Sluice; *e*, Sluice

each nozzle. The universal ball-and-socket nozzle, with interchangeable tips, varying from 3 to 7¾ inches in diameter, is used, in order that the "nozzle man" may readily swing the stream of water to any part of the face and regulate the quantity of water by the size of the tip. The method of working is known locally as "falling" and "washing out."

During the falling operation a 4½-inch tip is used on the nozzle and the water directed against the bottom of the face, which is gradually undermined.

When undermined sufficiently, the ground above the face will be seen to crack several feet from the edge and small pieces fall as a warning. A short time after this the undermined portion comes down and lies in a broken heap at the bottom of the face. When the ground is too hard for this practice, 3-inch holes are put down from the top and other holes put in the face. The holes are then charged with gelignite and blasting powder, the charge varying, but sometimes 10 kegs of powder are placed in a hole and discharged. This shatters the basalt so that water easily brings it down. The operation known as "washing out" is then begun and a larger quantity of water is brought into use. It is kept confined in a head sluice by wing boards, as shown in Fig. 8, where the softest portion of the overburden forms with the water a thick heavy mud which assists in transporting the larger rounded lumps of less decomposed basalt. Some of the stones removed in this manner weigh nearly 200 pounds.

Two or three men with rakes keep the sluice clear and prevent the water spreading and thereby losing its power. One man is employed on the nozzle and one on the dump. When the finer dirt has been washed out, the water is turned off and used elsewhere. The material remaining includes partly decomposed basalt which is broken with picks and washed out, and what remains is trammed out, the pieces too large to handle being broken by block holing and blasting. The sluice boxes of the special design shown in Fig. 5, are made in 12-foot sections and paved with columnar basalt. They cost about $40 per chain. When a wide face is worked, branch sluices are carried well into the face so there may be no difficulty in removing stones. The sluice is 1 foot 9 inches per chain, or 1 in 37½, and the quantity of water that can be used with safety is 10,500 gallons per minute.

The Tasmanian mining regulations limit the size of stones that may be discharged into a river, to a diameter of 2 inches. To separate the large stones the tail-sluice discharges on a large grizzly, the oversize being retained on the dump, the undersize and water sent to the river. In another case the tail-sluice discharges on to the surface dump and the water spreads so that the heavier material settles and the lighter passes on with the water to the river.

The number of gallons of water required to remove a cubic yard of overburden depends on the following conditions: Kind of material being dealt with; quantity of water used (within limits); pressure of the water; design and grade of the tail-sluices; ease of getting material into sluices; care and attention on the part of nozzle men and rakers.

In one face 321,100 cubic yards were removed with 11,630 sluice-head days, or 27.61 cubic yards per sluice head per day. Taking for example the average duty at 27 cubic yards per sluice head per day, on a sluice having a grade of 1 foot 9 inches per chain, then if the fall be 1 foot in G feet, the ratio of overburden to water in the tail-sluice is practically $\frac{1}{G}$. In such calculations the grade must always be stated, the amount of overburden being proportional to the steepness of the sluice, which in this case is 1¾ feet in 66 feet, or 1 in 37.7, so that 37.7 parts of water would remove 1 part of basalt. Since 1 sluice head $= 150$ gallons or $\frac{150}{6.25} = 24$ cubic feet of water per minute, and $\frac{24 \times 24 \times 60}{27} = 1{,}280$ cubic yards of water per day, theoretically the quantity of rock that should be removed per sluice head of water per day is $1{,}280 \times \frac{1}{37.7} = 34$ cubic yards. Practically, the result of a year's work averages 27 cubic yards, therefore the efficiency is $\frac{27}{34} = .80$. During the year but 2 per cent. of the overburden had to be trammed. As a general

FIG. 6. OVERBURDEN AND DRIFT FACE, BRISEIS TIN MINE

formula let B represent overburden; S sluice heads of water; E the efficiency .80; and $\frac{1}{G}$ the fall of the tail-sluice, then

$$B = S \times 1{,}280 \times \frac{1}{G} \times E = 1{,}280 \frac{S \times .80}{G} = \frac{1{,}024 S}{G}*$$

* For the benefit of those who desire to convert these factors to miner's inches, it is stated that the miner's inch is 1.5 cubic feet water per minute or $1.5 \times 7.48 = 11.22$ United States gallons. The British gallon is larger than the United States gallon and 6.25 British gallons make 1 cubic foot.

The formula, while not mathematically accurate, furnishes a sufficiently close approximation for most purposes of the kind.

The drift containing the cassiterite is worked in benches the same as the overburden. Fig. 6 shows the overburden *a*, the drift *b*, with the latter being hydraulicked; also the rock car and track. The stone dumped from overburden faces is shown piled at *c*; the main tail-sluice from the drift faces at *d*; and the streaming shed *e* where finally concentration is accomplished. Apart from the convenience, this method possesses the advantage, that only that portion of the drift below the level of the tail-sluices need be raised by an hydraulic elevator, which means economy of pressure water, saving in time which is occasionally lost owing to stoppages of elevators for repairs etc.

The work consists of washing the dirt from the bank, separating the stones, and allowing the water and dirt to pass through sluices to the dump. Most of the tin ore remains in the head sluice. Where two benches are close enough they are commonly worked together, the material from both passing through one sluice. The lower bench material is raised by hydraulic elevators to the sluice and, as it carries considerable water, the latter aids in transporting the thick material from the upper bench. Where a bottom face is worked singly, the mixture with elevator water is too dilute for sluices of this type, and one of the following methods may be adopted:

1. Run as an ordinary sluice on the lower level and elevate the tailing.

2. Elevate the feed and, where dirt is scarce, work with a "V" settler at the head of the sluice, returning the overflow for feedwater to the same face.

3. Work on a different principle with high riffles. In the first case, if the elevator stops the sluice is flooded, unless all water is turned off at once. In the second case, there not being much pressure in the feedwater, more skill is required. It is, however, economical where dirt is scarce.

In commencing operations on a drift face, a portion of the floor of the face is boarded off to form a rough triangular shaped enclosure All drift has to run over this area and most of the cassiterite is deposited from the water and sand passing on to the sluice. The cement gravel is broken by explosives and spalled into convenient size for handling. Then, together with any clay and stones left from overburden operations, it is thoroughly washed to remove adhering tin, and finally it is trammed out of the mine and dumped. Any cement gravel, stones, etc. still left are caught on the grizzly placed in the sluice head for the purpose. If these were not removed the heavy material would remain in the tin concentrate, while clay, being of a sticky nature when wet, is liable to carry the tin into the tailing.

The dimensions of the sluice are, width, 8 to 14 feet; length, 132 to 180 feet; laid on a grade of 2 feet 3 inches per chain. The sluice is built in 4 to 6 sections, each 24 to 30 feet long. At the end of each section riffles are provided. They are made of $3'' \times 2''$ and $3'' \times 1\frac{1}{2}''$ hard wood, corresponding in length to the width of the sluice. Timber is used throughout in the construction. Bearers and studs are 3 in. $\times$ 3 in.; chocks and struts 3 in $\times$ 1 in.; boards for bottom and sides 12 in. $\times$ $1\frac{1}{2}$ in.; battens 4 in. $\times$ $\frac{3}{4}$ in. and 5 in. $\times$ 1 in. The sluice should be perfectly level from side to side. It may be supported on trestling or built on the ground according to the requirements of the case. Feed-sluices are built exactly like the sluice, except they are narrower, being only 3 or 4 feet wide. The depth of both the feed-sluice and sluice is generally 3 feet. The change in width is made gradual, the best arrangement being as shown in Fig. 7 at *a*, where the centers of feed-sluice and sluice coincide In the other cases there is a tendency toward an accumulation of tin on one side of the sluice, which causes inconvenience in working, especially during the clean-up. Riffles are used in the feed-sluice for the same purpose as in the sluice. The distribution of the feed across the sluice is regulated by baffle boards placed at the junction of the two sluices. At this place there is generally a drop of a foot or two.

At the commencement of a run only one or two riffles are put in the sluices at each section, just sufficient to provide a sand bottom to hold any tin that may reach the sluice. As the work proceeds tin and drift accumulate in the head-sluice and the grade becomes steeper accordingly. The water then has a greater carrying capacity, and not only is fine tin liable to be carried down the sluice, but also the sand covering the tin in the feed-sluice is carried away, and when tin is exposed to the water it is transported to the sluice. To restore the original grade, a riffle is placed in the sluice at each section, in this way causing the sluice to rise correspondingly with the head-sluice. At the same time the riffles prevent any tin being carried past them, and also hold back sufficient sand to cover whatever tin is in the sluice. Work continues, the material in the head-sluice rising slowly all the time, and the sluice being riffled up at the same rate until it is nearly full; it is then run down, the tin is sunk under the drift, a couple of inches of sand being left to protect it from the water. Sluicing is recommenced in the face and operations are repeated as before. The feedwater and sand, on entering the sluice, spread out in a thin layer and flow through the sluice with a velocity just sufficient to carry the sand in suspension without washing away any particles of tin which remain in the sluice, and which eventually settle on to the working bottom of sand. This sand bottom must be kept loose and rough in order that metallic particles may not be rolled along and washed away in the tailing. To keep it in good order the sluice man constantly forks it, causing the tin to sink below the surface where it is then safe. This loosening of the sand makes the working bottom just as loose as the bed on a jig, but there is no pulsion or suction, the effect being more like that of quicksand.

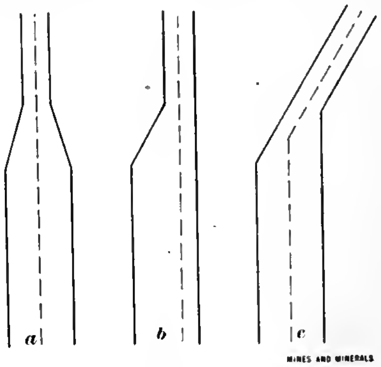

Fig. 7

Apart from the drift carried in suspension by the water, a certain amount is moved slowly along the bottom of the stream, that is, along the surface of the working bottom. This fact renders it important that the tin should be sunk below this field of corrosion which should consist of tailing only. A layer of sand 1 inch thick would probably be sufficient to protect the tin, but a 2- or 3-inch layer is the usual practice, so that if the water should from any cause form a channel in the sluice and scour out the covering drift to a depth of an inch or so, the tin would not be exposed to the water. This channeling can be avoided with reasonable care. Any slight tendency toward it can be remedied by judicious use of the sluice man's shovel, but if the trouble appears to be permanent, a readjustment of the baffle boards at the head of the sluice will generally right matters. The same trouble may be to a certain extent caused through a badly-constructed sluice or by bent or misshapen riffles. Once a good set of conditions is established as regards quantity of water, grade of head-sluice, feed-sluice, and sluice, quantity of drift or feed, etc., the aim is to keep as near to them as possible. If this can be done, the head-sluice and sluice rises at a uniform rate and the sluice is riffled up as required. The quantity of water used depends upon the width of the sluice; 1 to $1\frac{1}{2}$ sluice heads of water per foot of width is the proper quantity, according to coarseness of tin.

It is often difficult to keep the feed regular, especially when working in a cement gravel or stony face. A diminution in the quantity of drift being carried by water results in corrosion of the surface of the bed, and in time the water would cut down to the bare tin, and a loss of metal would result. If a sufficient

feed cannot be maintained, the riffles must be put in at each section of the sluice and form a series of dams which will fill with water and hold back any tin which may be escaping. The feedwater now coming from the face flows over the surface of these dams, the still water held by the riffles protecting the tin in the same way as did the sand covering. Any drift brought through with the feedwater settles as soon as it reaches dead water, and when sufficient has been collected to renew the sand covering, the upper riffles may be withdrawn one by one. The reverse trouble, that is, thicker feed, may possibly cause a loss of tin through its failure to separate out, but in any case it causes excessive deposition of sand in the feed-sluice and sluice, which necessitates the latter being run down more often than really necessary, requiring extra labor and loss of sluicing time. This running down process is a concentration of the sluice contents into a thinner but richer bed so as to reduce the level in the sluice and restore a suitable grade.

The operation is performed by from 3 to 5 men, according to the width of the sluice. The feed being turned off, clean water is admitted at the head of the sluice, and the men working in a line shovel the dirt and throw it over. The water carries light particles and the level is thus gradually lowered. A riffle is taken out wherever necessary and the process continued until the tin is fairly blackened. This is then covered by a layer of sand, and sluicing is then commenced in the ordinary way.

After passing through the sluice the debris drops into a tail-sluice constructed on a flatter grade and is carried away to the dump. The quantity of water used in sluicing is insufficient for this purpose on account of the lessened grade, and an additional supply, called tail-water, is necessary. The quantity depends on the relative proportion of sand and water in the sluicing mixture, and on the relative grades and widths of the sluice and tail-sluice. The steeper the grade of the tail-sluice the less water is required, but on the other hand the lower will be the level of its outlet, and the capacity of the dump is correspondingly reduced. The selection of the tail-sluice grade must be decided in each particular case according to local conditions. The considerations involved are: Dumping space, volume required; dumping areas available; quantity of water, if any, available for use as tail-water; cost of elevating or stacking tailing, if necessary, and amount requiring elevating.

The water supply from Briseis Mines Co.'s various flumes is distributed over a dozen or more overburden and drift faces, also to the water turbines of the tailing-pumping plant and to the electric-lighting Pelton wheels. It is necessary to record the amount supplied to each particular machine or nozzle in order that the working costs of each face and the cost of power may be obtained, also to check the efficiencies, and finally to warn the management of any leaks along the sluice or waste at the mine.

In calculating water measurements the discharge of nozzles and hydraulic elevators having circular orifices is taken simply as the product of the jet area a, the mean velocity v, and the coefficient of discharge c (=.94). The water used would be expressed by the equation

$$w = c\,a\,v = .94 \times \frac{\pi d^2}{4 \times 144} \times \sqrt{64h}$$

In the last expression d is the diameter of the nozzle in inches, and as $v = \sqrt{2gh} = \sqrt{64h}$; h represents the pressure head in feet at the jet. The value of w converted into sluice heads becomes

$$w = .94 \times \frac{\pi d^2}{4 \times 144} \times \sqrt{64h} \times \frac{60}{24} = .1025 d^2 \sqrt{h} \text{ sluice heads.}$$

Gauge cocks are provided at each nozzle so that the pressure in feet of water may be read in every change of shift or nozzle.

The method employed for monthly or quarterly measurements of drift and overburden removed is that of horizontal contours. Points are carefully selected on the face, and with the theodolite set up at a convenient known point, the bearing, angle of elevation, and distance of each point on the face are read. For the distances, stadia measurements are taken. With this information the true horizontal distances on reduced levels are found and plotted on a plan of the workings. Points for the contour lines are interpolated between those taken in the actual survey and a system of contour lines is drawn in 5-foot intervals.*.

The corresponding lines for the previous period are left on the plan, and the area removed at each level is measured by a planimeter. The areas and depths being known, the rest is simply a matter of multiplication. After an extended period of regular measurements of water used and drift removed by it, also of the grades on which the sluice was run at different times, an investigation was made into the relationship existing between these quantities. It was found that the nature of the material being dealt with had such an important bearing on the result that a coefficient had to be introduced to make a formula at all possible. Calling this k, and g the average grade of sluice throughout the run, d the cubic yards of drift removed, w the cubic yards of water used, then $d = k w \sin g$. One sluice head being equal to 1,280 cubic yards of water per day, the amount removed daily becomes $d = 1{,}280\; ks \sin g$, s being the average number of sluice heads in use. The value of k varies so widely that the formula can only be used, and then with caution, after some experience of the ground being worked. For very clean loose drift free from cement gravel and granite, the value of k approaches very nearly to 1. In decomposed basalt capable of being removed almost entirely by water, k=.75 to .80. In cement gravel faces experience is the only guide, for so long as the drift is reasonably clean a fairly good approximation may be expected.

The following example is from actual practice. Where the drift contained a little clay but otherwise was clean the value assigned to k was .95. The water used during the period was equivalent to 900 sluice-head days, and the average grade of the sluice was 2 feet 9 inches per chain, or 1 in 24. Substituting these values in the formula, $d = 1{,}280 \times .95 \times 900 \times \frac{1}{24} = 45{,}600$ cubic yards. The amount removed was estimated by survey to be 46,100 cubic yards, a difference of only about 1 per cent., which is probably within lines of accuracy of the data used.

The work of cleaning up consists in recovering from the head-sluice, feed-sluice, and sluice, the tin and gold which has become concentrated there. The first operation is to "run down" the sluice. This concentrates the tin which is skimmed off and thrown out of the sluice on to a platform. During skimming, the water is turned off, and when the sluice has been practically cleaned out, the feed-sluice is "run in," clean water is admitted at the head of the sluice and men assist by shoveling the tin with the current. The sluice being empty, the grade of the feed-sluice becomes much steeper, and the sand and tin travel much faster than during ordinary sluicing. Riffles must be put in the sluice to hold the tin. When sufficient material is in the sluice it is "run down" again and skimmed as before, and the operation continued until the feed-sluice is cleaned out. Lastly, the material in the head-sluice is "run in" in the same way, clean water with practically no pressure being drawn from the nozzle, through pipes if necessary. In order to hasten the

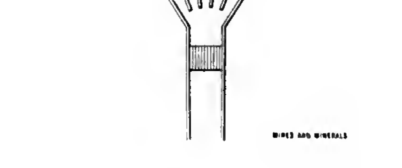

FIG. 8.

* See Tinker's Stadia Chart, MINES AND MINERALS, Vol. XXX, page 483.

operation the water is kept confined between two rows of wing-boards, *a*, *b*, Fig. 8, and, when the sand inside area 1 has been washed away, the boards *a* are shifted to a parallel position *c* alongside the last. The area 2 is then treated in the same manner as 1, and then boards *b* are moved to *d*. This is continued until the whole of the head-sluice has been treated and nearly all the sand removed. The tin mostly has remained behind, and it is skimmed and wheeled in barrows to the feed-sluice, whence it is carried by water to the sluice. Here it goes through the running down process, and when tin is skimmed off and thrown out for next treatment, work is recommenced on the face.

The tin on the plat, although often very clean, still contains sufficient sand and other impurities to make further treatment necessary before smelting. This operation, well known as streaming, is conducted in special streaming sheds. The tin is conducted there through small wooden launders 12 inches wide in which a current of water flows continuously. At some convenient place in this tin launder the gold-saving appliances are provided.

On reaching the sheds, the tin undergoes a preliminary cleaning in a small sluice outside the shed. This is 4 feet wide, 24 feet long, and in two sections. The concentrates from this are ready for the final operation.

Fig. 9. No. 2 Sluice, Two Drift Faces and Derry Overburden Face, Briseis Tin Mine

Streaming is conducted in a small sluice 2 feet wide, 24 feet long, divided into two sections, head and tail, and laid down on a grade of 8 inches per 12-foot section (1 in 18). Water is admitted at the head of the streaming sluice by a door in the launder. About a hundredweight of tin is streamed at a time. The tin is put in the race and water admitted, then the streamer, who must be a very skilful man, shovels the tin very rapidly up the sluice against the water current. After a minute or so the water is stopped, and the tin at the head of the streaming sluice is thrown out and allowed to drain before being bagged. The rest of the material accumulates at the tail of the section against the riffles. As this may contain a little fine tin, it is retreated, and tailings are then stacked outside. They contain, besides heavy sand, topazes, sapphires, titaniferous iron, and tourmaline.

After the streamed tin has drained it is placed in bags holding 1 hundredweight. Moisture determinations are made daily, 112 grams weight of the drained tin being dried and reweighed. The loss in weight is the number of grams of moisture in 112, which is equivalent to pounds per hundredweight, and in weighing the ore into hundredweight bags a corresponding allowance is made.

Reviewing the operations, it will be seen that the concentration is done in four stages. Taking a case where the ground averages 5 pounds per cubic yard, this is less than .1 per cent.

First concentration. The head-sluice would be, say, 1 to 3 per cent.

Second concentration. The sluice concentrate, 60 or 70 per cent. down to 30 at tail.

Third concentration. The preliminary streaming, over 70 per cent.

Fourth concentration. The final streamed tin, 75 per cent.

Returning to the gold sluice already mentioned, this is about 3 feet wide and 10 or 12 feet long, set on a steep grade, 1 in 4 or 1 in 6. It is made of wood, with a coarse screen of perforated metal plate at the head to separate any heavy foreign matter. The gold is saved on coconut matting, of which there are five or six sections. Most of the tin passes on to the streaming shed, but a little remains on the matting with the gold. No mercury is used in the sluice. The gold is practically all recovered from the first and second mattings, which are taken out and washed in troughs. The remaining mattings are moved up toward the head of the gold sluice, and those just cleaned are put in at the tail end for the next clean-up. The gold concentrate, after being freed from small stones and other miscellaneous articles, is treated in an ordinary prospector's dish. Mercury is now added, and the whole thoroughly mixed; some boiling water is poured in to keep the mercury lively and prevent the mass from "caking." The whole contents must be thoroughly mixed until amalgamation is complete. This can be seen by inspection of the concentrates. When no particles of free gold can be seen, and only tin and amalgam are visible, it is safe to give about five minutes further mixing and then pan off the amalgam. The tailings are panned off again to recover any amalgam lost in the first treatment, and about 1 or 2 per cent. may be recovered here. The amalgam is squeezed in chamois cloths, retorted and smelted. The tailings which are chiefly black tin, are run once again through the gold sluice, and thence to the streaming shed.

Drilling Costs in Decomposed Basalt and Drift

Depth	Total Cost	Cost Per Foot
70 feet	£3 10d.	1s.
168 feet	£14	1s. 8d.
255 feet	£27 5d.	2s. 1¾d.
440 feet	£52 10d.	2s. 4½d.

Cost, including all operations to the sacking of concentrate, 5½d. to 6½d. per cubic yard.

During one annual period the cost of each portion of the work was as follows:

	Per Cubic Yard Pence
Sluicing	.77
Hydraulicking and labor in face	1.89
Extensions and maintenance pipes, elevators, and sluices in face	.29
Cleaning up, streaming, weighing (13s. 3d. per ton)	.36
Blacksmithing, blasting, etc.	.25
Electric light	.20
Maintenance main head races	.47
Stores, timber, and explosives	.29
Maintenance main columns, salaries, office expenses, and general	1.08
Total	5.60

Duralium is a new alloy containing aluminum. It is said to be slightly heavier than aluminum and as strong as steel. It can be rolled, drawn, stamped, extended, or forged at suitable temperatures. It is less corrosive than other high aluminum alloys under the usual corrosion tests, and it is only one-third the weight of brass. It is expected that the new metal will find a steadily-increasing demand for aviation uses, while it is likely to prove an important factor in the construction of motor cars, owing to the difficulty of securing aluminum castings sufficiently reliable not to break under the strain of sudden jars and shocks caused by quick stoppages, changes of speed, and jolts upon bad roads.

CHITINA VALLEY COPPER DEPOSITS

By E. Jacobs, Victoria, B.C.

The completion of the Copper River & Northwestern Railroad from Cordova, Alaska, to the mouth of the Chitina River, opens a mining region hitherto almost inaccessible. It is expected that by the end of the year the road will have reached Kennicott, 50 miles eastward from the confluence of the Chitina with Copper River, and 194 miles from Cordova. At Kennicott the rails will be alongside the ore bunkers of the Bonanza Mine, owned by the Morgan-Guggenheim Alaska Syndicate, which is building the railroad. At present the Bonanza is about the only property in the big Chitina basin ready to ship ore regularly, the conditions in the case of this mine being exceptional.

Alaska Copper Deposits To Be Made Available By a Railroad. Peculiarities of the Country.

The Bonanza vein is exposed on both sides of a high sharp ridge from which erosion has broken a vast quantity of rock mixed with vein matter. This great natural dump is sufficiently high in copper to be worth handling in mass, so it is possible to begin regular production with comparatively little development.

On the limestone-greenstone contact, which produced the Bonanza ore body, there are in all about 30 groups of mineral claims, all located on exposures of copper ore. There are, as well, other groups elsewhere in the district. The main contact, above mentioned, has been found to occur along a distance of more than 100 miles, and the easterly end of it has not yet been reached.

FIG. 1. LOOKING BACK AT BONANZA MINE

No other property on this contact has been developed beyond the advanced prospect stage, and owing to the great cost and difficulty of getting supplies, comparatively little work has been done on other properties, and even prospecting in the district has been slight. There is little doubt that many parts of the contact have not been even superficially examined, as comparatively few prospectors have been in the district, and most of those who have prospected have been in search of placer gold, which has been found at the head of the basin, chiefly in Dan and Chititu Creeks, estimated to have together yielded between $300,000 and $400,000.

A small colored geological map of the Chitina basin, recently issued by the United States Geological Survey, shows significant conditions from the miner's point of view, while the evidence of prospectors and engineers warrants high hopes for a large, varied, and widely-distributed production of minerals there. The chief areas are of limestone and greenstone, with dikes of andesite and porphyry that are yet to be carefully examined. The entire geological area is varied, and the fact that it is now accessible not only to prospectors, but as well to tourists, must give it speedy and wide-spread confidence.

Apart from its importance as a prospective mining territory, the Chitina basin is of interest as containing untried agricultural resources; also for its majestic beauty and favorable summer climate. It is well wooded and watered. The present gateway is the new town of Chitina, situated at the junction of the Chitina and Copper rivers, which place the railway has lately reached over a steel bridge across the Copper River.

Exploration in the Chitina Valley.—*Exploration in the Chitina River valley was begun in 1885, when Lieutenant (now Major) Henry T. Allen, in the course of a remarkable journey from Prince William Sound to St. Michael, during which he traversed portions of the valleys of Copper, Tanana, Koyukuk, and Yukon rivers, ascended Chitina River on the ice from Taral to Nikolai house near the mouth of Dan Creek. Lieutenant Allen made a reconnaissance route map of the region through which he went and in his report mentioned the occurrence of copper in the vicinity of Chitistone River, or Nizina River, as it is now called.

In 1891 Lieutenant Frederick Schwatka, U. S. A., and C. Willard Hayes, of the Geological Survey, entered Chitina River valley by way of Skolai Pass. They descended Nizina River nearly to Dan Creek on foot, and after building a canvas boat continued their journey down Nizina, Chitina, and Copper Rivers to the coast. They also made a reconnaissance route map of their traverse. In 1889 a party in charge of Oscar Rohn explored the region south and east of Mount Wrangell. This party was a detachment from the military exploration in charge of Captain W. R. Abercrombie.

In 1900 a geologic and topographic reconnaissance of the Chitina and Hanagita valleys and of the lower Copper River was made under the direction of the Geological Survey. A topographic map was made and geologic investigations were carried on. This work, although hastily done, owing to the difficulties of travel and the necessity of covering the greatest possible area in the time available, has nevertheless been of very great value to prospectors of the region.

In 1902, Walter C. Mendenhall, geologist, investigated the geology and mineral resources of the Central Copper River region, and visited the copper prospects of Kotsina River and Elliott Creek, its tributary.

A list of the publications resulting from the work of these expeditions is here given:

Mendenhall, Walter C., and Schrader, Frank C. The Mineral Resources of the Mount Wrangell District, Alaska: Professional Paper United States Geological Survey, No. 15, 1903.

Mendendall, Walter C. Geology of the Central Copper River Region, Alaska: Professional Paper United States Geological Survey, No. 41, 1905.

Rivers and Mountains of District.—Copper River is joined about 100 miles from its mouth by its large eastern branch, Chitina River. From there its general course is nearly west-

* Bulletin 374, United States Geological Survey.

northwest. The two branches of Copper River, the Chitina and the upper Copper, nearly surround the Wrangell Mountains. The area included between these two streams and the heads of White, Chisana (or Shusana), and Nabesna Rivers is generally referred to as the Copper River region. It is divided into a northern and a southern district by the Wrangell and Skolai Mountains, the ice-covered ridges of which form an almost impassable barrier between them. United States Geological Survey Bulletin 374, from which this information has been taken, deals with the southern district only.

The Wrangell Mountains are a somewhat detached or partly isolated mass, bounded on the north, west, and south by valleys, the trend of which is west-northwest and east-southeast. To the southeast they merge into the Skolai Mountains, and these in turn unite with the St. Elias range. Their summits rise to altitudes ranging from 8,000 to more than 16,000 feet, and reach their greatest elevation in such peaks as Regal Mountain, 13,400 feet; Mount Blackburn, 16,140 feet; and Mount Wrangell, 14,005 feet; all of which are visible from Chitina Valley. Mount Drum, 12,000 feet, and Mount Sanford, 16,200 feet, are conspicuous in upper Copper River valley, but are hidden on the south by the other peaks mentioned.

The lofty summits of these mountains and the ridges that join them are the gathering places for snows that feed the numerous glaciers creeping down their sides and out to the valleys at their feet. These snow fields and glaciers are the sources of nearly all the large tributaries of Chitina River which are, from the north, Nizina, Lakina, Gilahina, and Kuskulana rivers and from the south, Tana, Chakina, and Tebay rivers, draining Hanagita valley.

Fig. 2. Kennicott, Alaska

The Chitina valley floor is a broad, gravel-covered, lake-dotted, flat land expanse with a maximum width of at least 10 miles, with the surface broken here and there by low, round-topped hills, and deep cañons of streams which cross it. Chitina River, in the lower 50 or 60 miles of its course, has cut a deep, broad channel in the valley floor, and for the most part of that distance it flows close to the foot of the mountain slopes on the south. The flood plain in places, particularly along the river's lower course reaches a width of 1 mile, and is bounded on one side or on both sides by banks—in some places of gravel, in others hard rock—which gradually decrease in height down stream, but which have an average height of between 100 and 200 feet. Over this gravel flood plain the river flows in numerous branching subchannels, the positions of which are constantly changing, and are particularly unstable at the time of spring floods, so that those who follow them one year may find them entirely different the next. The current is swift, rarely less than 6 or 7 miles per hour.

About 45 miles above its mouth Chitina River forks, the southern branch retaining the name Chitina, and the northern being known as Nizina River. The latter is almost as large as the former and drains nearly half the copper-bearing region.

Occurrences of Mineral.—General information, and in some instances particulars, relative to occurrences of mineral on various streams and in several basins tributary to the Chitina valley may be found in Bulletin 374, pages 71-100. Space restrictions prevent the reprinting here of even a condensed account of the chief claims and the development work done on them. Those dealt with in the bulletin are situated, respectively, on the following rivers or their tributary creeks: Kuskulana River, with its tributary Nugget and Strelna creeks; Lakina River; Kennicott River, into which flow Hidden, Glacier, Fourth of July, Bonanza, Jumbo, McCarthy, and Nikolai creeks; and Chitistono (upper Nizina River, with Glacier, Dan, and Chititu creeks). The greater part of this information relates to copper claims; the Nizina gold placers, however, are also described, and an account is given of placer mining on Chititu and Dan creeks; mention is made, as well, of the occurrence of realgar (sulphide of arsenic) and coal.

The Bonanza Mine, shown on the hill to the left in Fig. 1, is described as being on the most valuable known copper deposit of Chitina Valley. It is situated at the head of Bonanza Creek, about 1½ miles east of Kennicott glacier and 7 miles north of the southern extremity of that glacier. No other property in the Chitina valley region gives similar promise of ore production in the near future. Bonanza Creek is about 3 miles long and heads on the west side of the high mountain ridge running north and south between Kennicott glacier and McCarthy Creek. Its general course is southwest. The main camp and office of the company owning the mine are, however, situated at Kennicott, shown in Fig. 2, the mouth of National Creek, nearly 4 miles by trail from the mine. Fig. 2 shows wire tram terminal on hill; post office in center; shops and mess house below.

South of National Creek the high north-south ridge between the glacier and McCarthy Creek is made up of Triassic shales and limestones, intruded by large masses of light-gray quartz porphyry. These Triassic rocks are separated by a great fault from the greenstone and overlying Chitistone limestone on the north. The strike of the limestone is northwest and southeast, and its dip averages between 25 and 35 degrees northeast. It therefore cuts diagonally across the main ridge and appears at the eastern edge of the glacier, nearly 9 miles north of the head of Kennicott River. The limestone here has a thickness of more than 1,000 feet. Still farther northeast the shales conformably overlying the limestone reappear, but they do not occur within the area of the copper-bearing rocks. Bonanza Creek and the other creeks where copper claims have been located lie wholly within the greenstone-limestone area.

The Bonanza Mine is situated on the west side of Bonanza Creek, on a spur running down to the southwest from the main ridge. The spur divides Bonanza Creek from a small southwestward flowing tributary heading just west of the mine, and is crossed by the greenstone-limestone boundary about ½ mile southwest of the main ridge. On the axis of the ridge this boundary has an elevation of approximately 6,000 feet above sea level, or 3,800 feet above the mouth of National Creek, where the ore bins are built. To the southwest the spur is greenstone; to the northeast it is limestone, rising to an elevation of more than 1,000 feet greater than that of the contact.

The copper ores are chalcocite* and azurite. The chalcocite is in masses of solid ore up to 5 or 6 feet in thickness, in large irregularly shaped bodies, and in stockworks in the limestone. Two principal veins of chalcocite are seen on the surface. They stand almost perpendicularly, 12 to 15 feet

* Copper sulphide, Cu_2S, 79 per cent. copper.

apart, and strike north 41 degrees east, forming the comb of the sharp ridge, but crossing it at a slight angle, as the ridge at this place has a more nearly north-south direction than the veins. The veins do not extend down into the impure lower part of the limestone, but end abruptly and flatten out on reaching it. In places the precipitous northwest face of the ridge is plastered over with masses of solid chalcocite for a distance of 50 or 60 feet vertically below the top.

Azurite* appears on the surface of the chalcocite and also as a lining of small vugs, but it is present chiefly as thin veins that form a network in the limestone and probably are due to the alteration of original chalcocite veins, for some of the azurite has an inner core of chalcocite. Azurite is more conspicuous than chalcocite in the northern 150 feet of the ore body, but chalcocite forms the great mass of the remainder. The ore bodies formed along the northeast-southwest faults of the northern part of the deposit are not the direct continuation of the large chalcocite veins at the south, but lie in nearly parallel veins which cut the ridge at a regular angle, their strike being about north 60 to 70 degrees east. The very rich ore can be traced on the surface for a distance of about 250 feet. It ends abruptly on the south in a nearly vertical limestone wall, but on the north gives place to the lower grade ores, consisting of small veins of azurite and chalcocite, with scattered masses of chalcocite, some of them weighing several tons. This lower-grade ore shows on the surface for a distance of at least 150 feet northeast from the high-grade ores, and small scattered azurite veins extend still farther in that direction. The ore, as it shows on the surface, therefore, extends northeast and southwest along the strike for a distance of 400 feet. The thickness, however, is more indefinite, but the very rich ore, with its included limestone, as seen at the surface, has a width of approximately 25 feet, although the thickness of ore sufficiently rich to be mined may be greater.

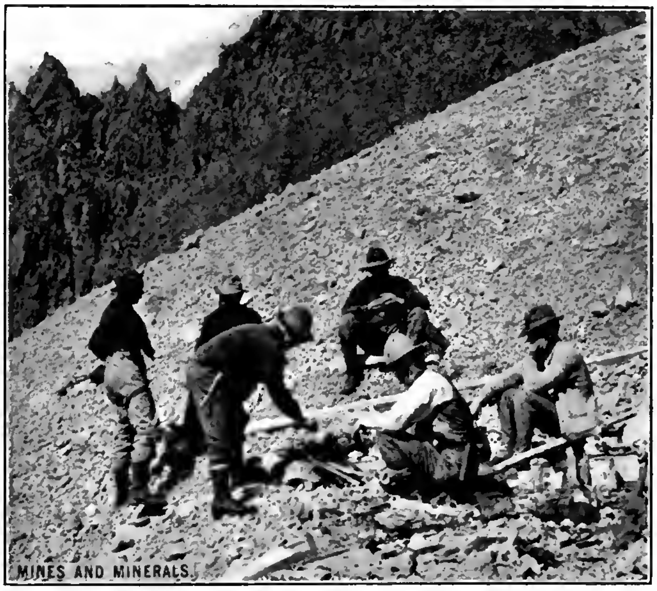

Fig. 3. Geologists on Trail Half a Mile Above Kennicott

A little chalcocite and less bornite is found in some of the shearing planes in the greenstone, but it does not extend far into the greenstone. The quantity is small and inconspicuous and might readily pass unobserved. A small amount of epidote is associated with it in places. The main shear zone in the greenstone cuts an older set of quartz-epidote veins, whose direction is about north-northwest. These quartz-epidote veins do not intersect the limestone. They reach a maximum thickness of 1 foot and carry small amounts of chalcocite, bornite, and native copper.

Two cross-cuts have been driven in the ore body in a direction north 33 degrees west. They are not, therefore, exactly perpendicular to it. The longer of these cross-cuts starts on the east side of the ridge and 75 feet below its top. It is 180 feet in length and extends through to the west side of the ridge. The richest ore, consisting of large masses of chalcocite with some included limestone, is encountered at a distance of 90 feet from the mouth of the tunnel and continues for 21 feet 6 inches, as measured in the roof. There are smaller bodies of chalcocite, however, for a distance of 10 or 15 feet on either side of the main ore body. About 150 feet from the entrance to the tunnel a winze was sunk 33 feet in the ore, and from the bottom a drift zigzags northward approximately 100 feet.

* Blue copper carbonate

About 120 feet southwest of this tunnel is a parallel tunnel driven from the west side of the ridge and 50 feet lower than the little saddle above it on the north. This tunnel starts in a face of solid chalcocite and extends S 33° E for 50 feet. The ore, which is chalcocite, with a small amount of azurite, is exposed for 34 feet along the tunnel, but is interrupted by horses of limestone. The remainder of the tunnel shows limestone cut by small azurite veins and in places containing a small amount of chalcocite

The two main parallel surface veins afford only an imperfect idea of the deposit. Those two veins represent a total replacement of limestone along minor zones where shearing was most intense. The two tunnels show that not only is the limestone replaced along the main shear zone, but that mineralized waters followed minor fracture planes also and thus yielded the low-lying ore bodies and great irregular masses seen underground. Between and around the large masses of chalcocite the limestone was shattered and filled with many small veins of ore, forming a stockwork that is most noticeable in the winze tunnel and on the surface northeast of the main ore body. As a rule the brittle chalcocite is very little fractured. The limestone, on the other hand, is greatly shattered and is filled with thin veins of calcite, which are older than the ore deposition. Open cavities in the fractured limestone have been filled with ice, and both the country rock and the talus on either side of this ridge are frozen all summer except for a few feet at the surface. The talus slopes below the ore body contain a large quantity of chalcocite resulting from weathering of the veins above, and are a valuable source of copper.

It is a suggestive fact that, although the main shear zone of the Bonanza Mine extends from the limestone through the thin shale bed into the greenstone below, the large chalcocite bodies, so far as can be determined on the surface, end abruptly at the top of the impure shaly beds forming the lower 50 or 60 feet of the limestone. Copper minerals are associated with the shear zone in the greenstone, but only in small amount. Apparently the impure thin-bedded part of the limestone was a less favorable place for deposition than the purer massive beds above. This fact has a practical bearing on the quantity of ore present, for it is evident that if the same condition continues underground it limits the downward extension of chalcocite in the limestone. The continuation of the ore body to the northeast will probably be limited chiefly by the continuation of the shear zone in that direction. The exact conditions which determined the deposition of the Bonanza ore body are not known; possibly it was the presence of a shear zone favorable to circulation, but the occurrence of such a zone, together with that of the Jumbo and Erie chalcocite bodies to the northwest indicates that favorable conditions for deposition have been established in more than one place and offers encouragement for seeking other chalcocite bodies at the base of the Chitistone formation.

From the description that has been given it will be seen that there is little on the surface or in the tunnels by which to determine that the ore body has a greater extension from southwest to northeast than about 400 or, at most, 450 feet, or that it extends down into the basal beds of the Chitistone limestone.

It is evident, however, that the Bonanza is an exceedingly rich and unusual body of copper ore.*

The reason usually given for the comparatively small amount of underground development work yet done in the Bonanza Mine is the high cost of getting in supplies. However, as progress is made toward the completion of the railway the cost of transportation is lessened accordingly. There is one feature of the situation that is probably unique; namely, that notwithstanding there is much coal in Alaska within 50 miles of the railway, none of it is at present available for use in the locomotives, so that foreign coal has to be taken by sea to Cordova, costing, it is stated, $12 per ton delivered there. There seems, therefore, to be force in the contention that existing conditions, which do not permit the development and utilization of coal in Alaska, are retarding the full development of that territory.

Estimates have been published of the quantity of ore available at the Bonanza Mine. These are, necessarily, roughly approximate. They place the quantity at 200,000 to 300,000 tons of ore ranging up as high as 50 per cent. copper. A considerable quantity is contained in the talus slope, and this is easily accessible for shipment.

Transportation from the mine to the terminus of the railway will be over a Trenton Iron Works aerial tramway completed last year; this has been constructed in two sections of about 7,000 and 8,000 feet in length, respectively, the upper section being the shorter. The difference in altitude between upper and lower terminals of the tramway is about 4,000 feet.

Pending the opening of coal mines in Alaska, and the subsequent erection of smelting works for the reduction of copper ores, ore from the Bonanza Mine will, it has been announced, be shipped to Tacoma, Puget Sound, Wash. Conditionally that the Copper River & Northwestern Railway shall be completed to Kennicott by the end of the current year, as hoped it will be, production and shipment will be commenced next January. The realization of this expectation will be matter for much congratulation as marking another important advance in the development of the mining industry of Alaska.

* The ore body described is not sufficiently developed to warrant a railroad; and looks to be too rich to be large.

ORE MINING NOTES

The Iowa Tiger Mine, in the Eastern San Juan, Colo., gold belt, was considered a silver-lead milling proposition until it was noticed that by putting more run of mine into the ore the concentrates increased from 1 to 2 ounces in gold. Recently, when prospecting in the hanging wall, minute stringers of what appeared to be pyrite were found to be gold. This ore is known to cover an area of 60 ft. × 50 ft., but as the stope is filled with ore below, and not opened above, the extent is unknown. It seems to be a repetition of the Camp Bird experience, where galena was supposed to be the rich ore, until the late Thomas Walsh found the gold in the hanging wall.

During the two years in which the 300-foot level in the British Mine, at Broken Hill, New South Wales, has been idle, it has been converted into a miniature Jenolan cave. This has been brought about by the percolation of water through the filling in the worked-out stopes becoming charged with sulphate of zinc, which forms stalactites and stalagmites, the former being in some instances 4½ feet long. An analysis shows that for the most part the stalactites are composed of goslarite, which is hydrosulphate of zinc.—*Australian Mining Standard.*

In mining silver-lead ores in the Yellow Pine district, Nev., large quantities of light-colored material were thrown on the dump piles as worthless. This was eventually identified as zinc ore and investigation showed that the mines contained 10 tons of zinc ore to 1 of lead.—*N. B. Gregory.*

At Leadville, Colo., oxidized zinc ores were found in drifts made over 20 years ago. It is presumed that mining engineers did not recognize this material, although the editor is of the opinion that they not only recognized but avoided it to prevent their ores being penalized by the smelters. The Leadville mineral zone is not finished with her surprises and will probably find besides gold, silver, lead, iron, manganese, and zinc, some other metal mineral.

The last fiscal year the Granby Smelting and Refining Co. took over the Cliff and Consolidated St. Elmo mines. It produced 22,750,111 pounds of refined copper at an average cost of 10.34 cents per pound, which was sold at an average price of 12.91 per pound. The tonnage of ore mined and smelted was a little in excess of 1,000,000 tons. The company's holding in the Crows Nest Coal Co. paid 10 per cent. interest. With the smelter running at full capacity it is expected to produce between 25,000,000 and 30,000,000 pounds of copper per year. The company has mined 6,250,000 tons of ore to date and has 6,500,000 tons in sight and expects to develop more tonnage each year than is mined, acquiring new properties if necessary, to this end.

The land law of the Republic of Panama governing the acquisition of public lands (tierras baldias) is of interest. By a recent decision American citizens cannot take up public lands unless they are able to show that foreigners are able to do the same in the respective states of the United States in which the applicants reside, or, in case of a company, in the state in which the company is incorporated. The authorities here have decided to accept as competent proof the certificate of the Secretary of State of the various states of the United States to that effect.

One gold-mining company in the Klondike is building a 6-mile ditch capable of carrying 20,000 miners' inches of water to supply a power house for furnishing electrical power for dredges it intends building in the near future. It also intends furnishing power to other dredging companies. Part of the machinery for this plant has arrived at Dawson and the balance is on the way. The company contemplates increasing the size of the ditch and adding to the power house in a short time. The machinery and supplies for this power house were principally purchased in the United States.

Conservationists are at present interested in the plan of leasing government mineral lands on royalty. As far as coal land is concerned this plan might not be so bad, but there are so many considerations independent of royalty that are sure to creep in, that the plan should not be attempted hastily. Conservation of the lead ores of Missouri was undertaken by the United States Government in 1833 and proved so unsatisfactory it was abandoned.

OBITUARY

Edward F. Payne

On October 17, Edward F. Payne, one of the largest coal operators in the anthracite field, died at his residence in Wilkes-Barre, Pa. He was born in Schuylkill County, Pa., 64 years ago; was educated in New Jersey, and soon after leaving school embarked in the coal business at the East Boston Mine, Luzerne Borough, near Wilkes-Barre. For some time he held the position of outside and inside foreman until finally he was made general superintendent of the colliery. At the time of his death Mr. Payne was director of the Morris Run Coal Co., Blue Creek Coal Co., the West Side Colliery, and also a director in the Miners' Savings Bank, at Wilkes-Barre. He leaves two daughters and one son, Edward Payne, Jr., a senior at Princeton college.

Copper mining in Alaska was less active in 1909, when seven properties were productive, as compared with nine properties in 1908. The output for 1909 was valued at $536,211; that for 1908 at $605,267.

THE RUBY

Written for Mines and Minerals, by Morris R. Ward

Anthrax—"live coal," was the beautiful and appropriate title given by the ancient Greeks to the ruby, which by them, as well as other ancient peoples, was held as the very type of all that was rarest and most valued in the natural world.

Composition, Color, and Characteristics. Methods of Mining. Manufacture of Artificial Rubies.

Mineralogically, the ruby belongs to the corundums, of which the sapphire, topaz, Oriental emerald, and Oriental amethyst are also members. Corundum is a sesquioxide of aluminum, and the various tints are due to the presence of different coloring matter. In the ruby, oxide of chromium in greater or less degree is responsible for the ruddy color so sought after.

A ruby of perfect color is a very rare and beautiful gem, and its value is commensurate with its rarity. Indeed, a flawless, "pigeon's-blood" ruby weighing 5 carats would be worth ten times as much as a first-water diamond of the same weight, while perfect rubies of 6, 8, or more carats are of such unusual occurrence as to bring very high prices. By the term "pigeon's blood" when applied to the color of the ruby, is meant that shade which is by international taste accorded the post of honor, though many of the gems have a darker tint which is quite as beautiful. A drop of blood from a freshly-killed pigeon, when deposited on a sheet of white paper, gives the shade which such a ruby should have.

While rubies, as they increase in size, are almost always filled with serious defects, flawless specimens of large size have been found, though such discoveries are few and far between. A few years ago, a remarkable ruby, perfect in color, was found in Burma by a Shan. This gem weighed 80 carats, was over an inch in length, and in form resembled the celebrated Shah diamond of 86 carats. Taking 20 carats to the ounce, this ruby would weight about 4 ounces, though owing to the wide divergence of a carat in different countries, the ounce weight given is merely approximate. The value of such a stone would be enormous, combining, as it does, perfection in color with size. For the sake of comparison, we may say that a Burma ruby of but one-twentieth the weight of the above (or 4 carats) brought $20,000. And the value of a perfect ruby does not increase directly as its size, but many fold.

Numerous other large rubies of beautiful color are known to exist, most of them probably belonging to imperial courts. In the Russian treasury is said to be the largest ruby in Europe and perhaps the largest perfect one in the world. This stone is described as weighing 100 carats, of a beautiful color, and free from serious flaws. It formed one of the numerous other objects of value which the Chinese brought over to Russia in exchange for pelts.

Another beautiful specimen belongs to the crown jewels of France. This ruby was long in the rough state, owing to a serious imperfection, but an expert diamond cutter turned this flaw to account by forming the ruby to resemble a dragon with outstretched wings. According to *Le Diamant*, of Paris, this is the most beautiful Oriental ruby known.

In 1875, the appearance in Europe of two magnificent rubies from Burma aroused great interest. These stones had been sold by the Burmese Government, owing to certain financial troubles, and extravagant care was taken in conveying them to the ship, a strong military guard being placed about the vehicle in which the rubies were carried. After being recut, they weighed $32\frac{5}{16}$ and $39\frac{9}{16}$ carats, and were sold for $50,000 and $100,000, respectively. Competent judges pronounced these gems the finest of their size ever seen, and of beautiful color.

Besides the above specific instances of large rubies, there are any number of fine stones to be found in private collections, not to speak of the hidden and well-guarded stones of various Oriental monarchs, one of whom (the Shah of Persia), is said to possess a ruby of 175 carats; and stories are told of rubies the size of hen's eggs, and of the immense fortunes represented by the hidden gems of old Indian rulers, who, as "Lords of the Rubies," claimed all stones worth over $50 and inflicted terrible tortures on all who were suspected of holding back desirable stones. We find old travelers like Marco Polo, John Mandeville, and others (aided, we fear, by generous imaginations and credulity) writing of rubies so large as to form pillars in palaces, bowls made of that gem, and specimens which extend beyond the palm of the hand, when so held; and so on. Such tales, while they have their place in literature, are not to be trusted. It is not at all impossible, however, that the deposed king of India, Theebaw, has hidden away great numbers of fine, beautiful rubies, the accumulation of years, which may some day be unearthed.

In the United States are a number of rubies worth over $10,000, and one of $9\frac{3}{8}$ carats is valued at $33,000.

Notwithstanding the many tales of the fortune-making rubies, the mining of these stones is by no means a romantic occupation. The industry has its difficulties and keen disappointments precisely as occur in the search for coal, though the difficulties are intensified because of the great rarity of the gem.

Burma, in India, is conceded to be the principal source of the true pigeon's-blood ruby. There the mining is in the hands of the Burma Ruby Mines, Ltd., an English corporation, which secured the right of working the district soon after Burma became ceded to Great Britain in 1886. Previous to that date the location of the famous mines was unknown, and all attempts to learn about them resulted in failure, for the rulers exercised a most strict surveillance over foreigners, and saw to it that any such were kept in ignorance of the exact location, etc. It is known, however, that the methods used were very crude and tedious; the natives merely dug out the "byon," or ruby-bearing earth, hoisted it by crude derricks to the top of the pit (these "pits" were from 50 to 60 feet deep), and there left it to dry in the sun before searching for gems. Today, essentially the same methods are used by the native miners, in whose hands such labor is still left, and who work under terms much more advantageous to themselves than were permitted under the old regime. In defense of the antiquated methods used it may be said that they bring results, and do away with the necessity of costly machinery.

Besides the true gems, large quantities of spinel and balas rubies are found. These spinels, though often (and quite excusably) mistaken for the genuine stone, are really minerals of very inferior qualities and entirely different composition, being in this latter respect aluminate of magnesium. The spinel is much less rare than the ruby, and not so hard. Besides red, they exhibit a great variety of colors, some being bright cherry; a rare variety is a deep violet, others have a cinnamon shade; and a white spinel comes from Brazil mixed with diamonds. Many of the large historic rubies in royal regalias (including that in the Maltese cross of the English crown), have been pronounced spinels by modern mineralogists, and are, consequently, of little value. The balas ruby is merely a spinel of proper quality, having a rose or deep pink color. The best balas are found principally in Ceylon, though both they and spinels are generally found wherever the ruby occurs.

From Ceylon also comes a true ruby of a rich rose color, but not many of the desired pigeon's-blood shade are found, though in all other respects they are beautiful and attractive stones, suffering, of course, from the flaws which occur in all rubies. The Ceylon stones often belie the name, for in color they run from very light red almost to a pinkish; being otherwise very brilliant.

Similar to the Ceylon stone in many respects is the ruby of Siam. This country, though principally noted for its beautiful sapphires, often produces rubies that rival the best Burma

stones, though their color is more frequently a deep red (often called "ox blood"). It is believed that any really good stones which may be discovered in Siam are sent overland to Burma, and sold as Burma rubies.

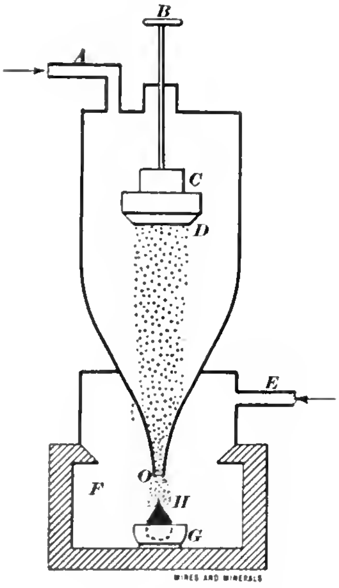
The United States has brought forth rubies as well as sapphires. The principal districts are in North Carolina and Montana. In the former state gems of 3 and 4 carats were found, free from inclusions and of good color; indeed, the quality of these stones often equals the pigeon's-blood rubies of Burma, though their occurrence is rare.

Concerning the discovery of corundum gems in Montana, Mr. E. W. Streeter, a prominent gem expert, has said: "Excepting the South African diamond field, I consider the sapphire and ruby mines of Montana to be the most important (gem) discovery of modern times." Our own expert, however, Mr. George F. Kunz, after a critical examination of these fields, found no true red rubies. So Montana must, for the time being, content itself with producing sapphires of exceptional beauty and purity.

The detection of artificial rubies, as they are made today, is an exceedingly difficult task, for the reason that the best artificial ruby is made of precisely the same materials of which the natural ruby is composed—pure alum, and oxide of chromium or manganese, which latter form the coloring matter.

The furnace used in making these "synthetic rubies" is illustrated in the accompanying diagram. It is a very ingenious application of the principles of the oxyhydrogen blowpipe, and by its means a temperature as high as 2,000° C. (over 3,000° F.) may be obtained. The process of manufacture is as follows:

A certain amount of powdered alum is placed within the box *C*, along with a proportionate measure of oxide of chromium to produce the red color of the ruby. By means of a small hammer operated by an electromagnet, the tapper *B* is touched at various times. This causes the box to vibrate, and the powdered mixture is thus sifted through a fine gauze sieve *D*. Thence it passes down to the orifice *O* within the firebox *F*. At that point the combining of the oxygen gas (admitted through the pipe *A*) with the hydrogen, which enters at *E*, on ignition causes a heat so intense that the powdered alum and oxide of chromium are instantly melted and fused into crystal globules, which fall into the platinum crucible *G*. In this manner a pear-shaped gem *H* (called a "brut") is built up, the size depending upon the amount of material used. Some of these synthetic rubies are 80 carats in weight.



Furnace for Making Rubies

After this "brut" has been allowed to cool (if touched when warm it would fly to pieces owing to the great strain of its molecules), it is sent to the jeweler's, by whom it is cut into one or more gems which in color, refraction, hardness, durability, and general beauty are identical with the natural ruby. Indeed, so absolute is this identity that the pawnbrokers of Paris and other great cities refuse to take rubies on pawn, for they cannot distinguish the artificial from the genuine.

Rubies can be made in this way at an expense of about 40 cents a carat. In the little laboratory of M. Pasquier in Paris (who introduced this method), 100 carats a day may be produced; and 8 to 10 carats an hour is a fair average in all such factories.

Such a discovery as this will have a serious and lasting effect upon the legitimate mining of stone. According to Mr. R. K. Duncan, in his "Chemistry of Commerce": "The ruby mines on their present basis of profitable working, are absolutely doomed." We can only hope that those who control this process will exercise good judgment in regulating the manufacture of their beautiful product, so that the market may not become unstable or overstocked.

Already the use of these synthetic gems is very widespread, and the natural ruby bids fair to become the exception rather than the rule. This fact, however, is not to be greatly deplored, for the artificial product is not an imitation; it is an equal of the genuine, even excelling it at times in beauty of color and crystallization, and in freedom from flaws. If this were not so, the synthetic ruby could never have become the success which it is today.

New Inventions

Complete specifications and drawings for any of the following patents can be obtained from the Commissioner of Patents, Washington, D. C., at the following rates.

Single copies	5 cents each
Copies by subclasses	3 cents each
Copies by classes	2 cents each
At entire set of patents	1 cent each

PATENTS PERTAINING TO MINING ISSUED OCTOBER 4 TO OCTOBER 25, 1910, INCLUSIVE

No. 971,614. Car haul, Paul W. Holstein and George C. Horst, Columbus, Ohio.

No. 971,779. Mine-timbering machine, Joseph C. Pardue, Willowton, W. Va.

No. 972,017. Ore concentrator, Ira F. Monell, Boulder, Colo.

No. 972,109. Magnetic ore separator, Anders Gustaf Holmberg, Langgrufvan, Sweden.

No. 971,638. Air or steam rock drill, John Redington, Cobalt, Ontario, Canada.

No. 972,352. Treatment of coke, Benjamin Ely and Arthur Rollason, Pye Bridge, England.

No. 972,463. Ore concentrator, Eldor H. Moe, Salt Lake City, Utah.

No. 972,149. Method of treating ores, Charles E. Baker, Chicago, Ill.

No. 972,726. Power rock drill, Sterling Stanley Stevenson, Saltillo, Mexico.

No. 972,509. Curve for double-rope tramways, Sebern A. Cooney, Trenton, N. J.

No. 973,234. Miner's safety lamp, Josef Szombathy, St. Louis, Mo.

No. 973,180. Ore-concentrating jig, Melvin Doubledee, Joplin, Mo.

No. 973,281. Ore jigger, Camden E. Knowles, Webb City, Mo.

No. 973,467. Apparatus for separating minerals from their ores, Samuel K. Behrend, Denver, Colo.

No. 974,075. Ore concentrator, William O. King, Mountain Home, Idaho.

No. 973,984. Magnetic ore separator, Charles A. Sellon, Halleck, Cal.

No. 973,732. Process of reduction of ores containing sulphur and iron, Arnold Wiens, Bitterfeld, Germany.

To manufacture air-nitrate fertilizers, the Southern Power Co., near Charlotte, N. C., has acquired the right to use the "Geneva process" of abstracting nitrogen from the air and also rights to use a newer process. The first plant to be built by the Charlotte company will be used to a great extent for experimental purposes, and the second, which will require 24,000 horsepower to operate, will be used for the manufacture of nitrate fertilizers on a large scale.

Mines and Minerals

Vol. XXXI—No. 6. SCRANTON, PA.—JANUARY, 1911—DENVER, COLO. Price, 25 Cents

THE TOOELE SMELTER*

Method of Handling the Ore. Utilization of Waste Heat. Smelting Processes. Power Plant

The Tooele smelter is situated about 4 miles east of Tooele City, Tooele County, Utah, and by rail is 41 miles from Salt Lake City. The smelter, which belongs to the International Smelting Co., is connected by its own railroad called the Tooele Valley Railroad, with the San Pedro, Los Angeles & Salt Lake Railroad, the junction being about 7 miles from the smelter site. The smelter is on a hillside, which makes it possible, to a large extent, for the level of delivery of the product of one building to be on the level of the charge floor of the next succeeding one.

The ore treated comes principally from the mines of the Utah Consolidated Mining Co. in Bingham cañon. These mines are connected with the smelter by an aerial tramway, 4 miles long, having a capacity of 125 tons per hour.† Custom ores from other mines are received over the San Pedro and the Tooele Valley railroads.

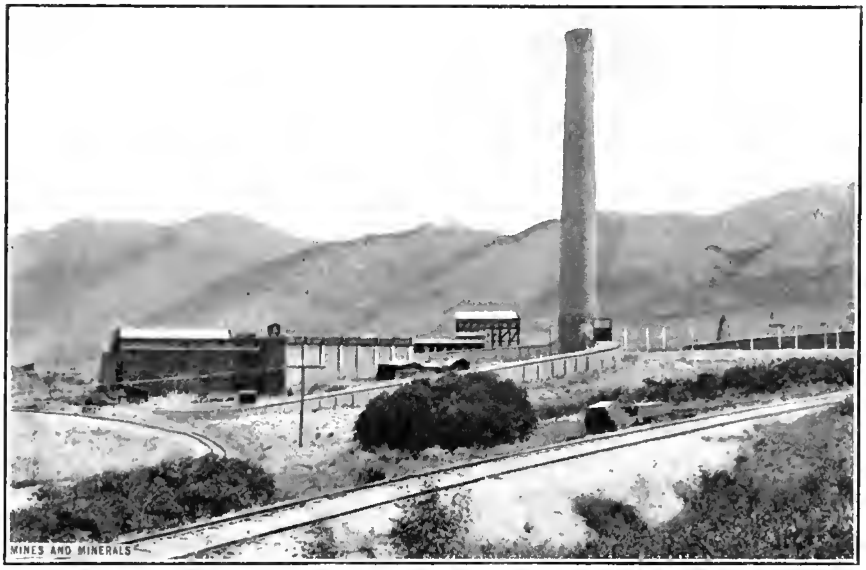


Fig. 1. Tooele Smelter

The ore bins are constructed of steel, are fireproof throughout, and have a capacity for 10,000 tons of ore and coal. The bins are so arranged that they may be served either by the 50-ton electric larry cars, which deliver the ore from the tramway terminal, or by standard railroad cars.

The building in which the crushing and sampling is carried on is of steel and concrete. It is shown in the center of Fig. 3 and is 40 ft. × 84 ft. in plan, and five stories high. The mill is in two sections, and each has a crushing and sampling department. The ore from the receiving bins is automatically fed upon belt conveyers, as shown in Fig. 4, which convey it to shaking grizzlies that discharge the coarse ore into the crushers. The ore from the crushers is lifted to the top of the building in bucket elevators. In the sampling department the ore is cut four times by Brunton automatic samplers, taking one-fifth of the amount each cut and discarding four-fifths, so that from each ton of ore crushed a sample weighing 3.2 pounds is obtained.

Fig. 2. Electric Ore Cars

The sampling department of each section of the mill contains, besides a 12″ × 24″ Blake crusher, which is common to the crushing and sampling department, the following machinery and apparatus: One 0-A sampler, one 20″ × 10″ crusher, one 1-A sampler, one 48″ × 12″ rolls, one 2-A sampler, one 26″ × 15″ rolls, one 4-A sampler.

The discard from the sampling machines drops into the screens of the crushing department, from which it is conveyed to the roaster bins, shown to the right of the sampling building in Fig. 3. The final sample is cut down by a quartering shovel, the sample placed on a steam dryer to expel moisture, then ground to pass through a 100-mesh sieve. The 100-mesh product is put up in three sample packages, one of which goes to the smelter laboratory for analysis, one to the owner of the ore, and one is filed away for use in case of a dispute.

The crushing department of each section of the mill contains one 12″ × 24″ Blake crusher, two 15″ × 9″ crushers, two 48″ × 14″ screens, two 48″ × 12″ rolls.

From the crushing plant the sampled ore is carried by belt conveyers to the McDougall roaster steel receiving bins, which have a capacity of 5,700 tons. If it is desired, the coarse ore after being sampled may be conveyed to the blast-furnace steel receiving bins, shown to the left in Fig. 3, which have a capacity of 3,500 tons.

A blast furnace has not yet been constructed, but provision has been made for it.

From the roaster bins the ore is automatically fed upon a conveyer system which conveys it up to, and discharges it directly into, the McDougall furnace charge hoppers. The ore in transit from the bins to the roaster plant passes over a Blake-Denison automatic and continuous weighing and recording machine, which accurately weighs all the ore delivered to the roaster plant.

*Abstract from paper read by C. H. Redpath and C. M. McGregory, Consulting Engineers.

†Mines and Minerals, October, 1910, page 150.

The roaster plant consists of two buildings, each 64 ft. ×162 ft. Each building contains 16 McDougall calcining furnaces, with six hearths 16 feet in diameter, and 18 feet high. The furnaces have revolving water-cooled shafts and arms, driven by a suitable gearing from the bottom. The rabbles are set to move the material from the circumference to center and vice versa on alternate hearths, until it finally drops into

Blast-Furnace Bins *Sampling and Crushing Plant* *Roasting Ore Bins*

FIG. 3. ORE BINS AND SAMPLER, TOOLE SMELTER

the calcine hoppers, immediately over the tracks of the electric cars shown in Fig. 2, for transportation to the charge floor, shown in Fig. 5, of the reverberatory building. No fuel is used other than the sulphur in the crushed ore, the burning of which furnishes sufficient heat to do the calcining. The gases are taken through flues into the large brick and steel dust chamber, which is 120 ft.×140 ft.×40 ft. high. This dust chamber is so arranged that the bottom forms a series of hoppers. The entire contents of the dust chamber can be drawn into flue-dust cars of the electric tramming system, and conveyed directly to the reverberatory furnaces for smelting. Each of the 32 McDougall furnaces has an approximate capacity of 45 tons in 24 hours.

The reverberatory plant consists of three buildings joined together; the reverberatory charge building, containing the ore and coal hoppers over the furnaces, 66 ft.×280 ft.; the reverberatory furnace building, covering the larger portion of the furnaces, 82 ft.×280 ft., and the boiler house, 36 ft.×326 ft. The latter, at the present time, contains four 746-horsepower waste-heat boilers and three 350-horsepower hand-fired boilers. The boilers are all of the Stirling water-tube type. The furnace plant contains five coal-fired reverberatories, the hearth dimensions of which are 19 feet in width, 102 feet in length, with a grate area of 7 ft.×16 ft. These furnaces have a maximum capacity of 300 tons of roasted ore in 24 hours, on natural draft. The fuel used is Diamondville coal, shipped from the mines in Wyoming, owned by the Washoe Copper Co. The coal is dumped from large railway coal cars, or from cars of the electric tramming system, into hoppers that have five points of discharge, directly over the firebox. The flame after leaving the furnace passes through a 746-horsepower Stirling boiler, which reduces the temperature of the gases going to the main flue to about 600° F. By this means approximately 600 boiler horsepower are obtained from each furnace from the waste heat. The ashes from the furnace firebox fall into the hopper cars of an electric tram system, and are hauled away to the ash dump. The slag is skimmed from the reverberatories twice in 8 hours. It is allowed to accumulate until its depth is from 3 to 4 inches above the skimming plate in the front of the furnaces, then it is skimmed into slag cars having a capacity of 225 cubic feet, and hauled to the slag dump over the electric tramming system. The matte is tapped from the side of the furnace through a copper tap-hole plate and run through cast-iron launders directly into the converter building.

One of the waste-heat boilers has been equipped with a superheater, placed at the rear of the boiler. In case it proves satisfactory the other waste-heat boilers will probably be equipped in the same manner.

The main converter aisle of this plant is 65 ft.×408 ft., and the casting shed is 52 ft.×255 ft. The aisle contains five stands for converters, and the lining department. The converters are of the horizontal-barrel type, shown in Fig. 6, 96 inches in diameter, 150 inches in length, and are electrically operated. The main isle is served by one 60-ton electric traveling crane; and the casting department by a 30-ton electric traveling crane. The end sections of the launders from the reverberatories are pivoted, so that the matte will flow directly into the converter opposite a reverberatory furnace, or the launder may be turned so that the matte will flow into a ladle, and be transferred to any of the other converters in the building. The slag is poured from the converters into unlined cast-steel ladles, and transferred to the reverberatory furnaces by means of overhead cranes. There are two of these cranes of 12½ tons capacity each. The blister copper from the converters is poured into a ladle, lifted by the crane, and transferred by car to the casting department. In the casting department the ladle is lifted by a crane and its contents emptied into anode molds, which completes the operation. The anodes, which are virtually the metal called pig copper, contain 99 per cent. copper and the gold and silver. They are shipped East where they are electrolytically refined and the gold and silver recovered.

The converters are lined in the main building, but the lining material is prepared in a 24 ft.×40 ft. building, adjacent to the ore-crushing plant and receiving bins. The lining material contains a high percentage of silica, also some gold and silver. The material is crushed in the crushing plant and conveyed to a 7-foot dry pan and pug mill in the clay and silica mixing and grinding plant. The product of the pug mill drops directly into a bin over the electric tramming system, from which it is transported to the converter lining plant. The lining plant at the converter contains a 7-foot grinding and mixing pan. From the grinding pan the material is transferred to the converter, where it is tamped around a cast-iron form by a special Ingersoll-

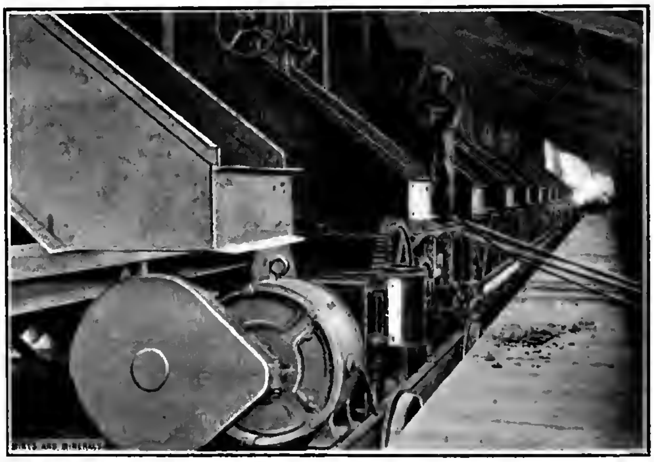

FIG. 4. FEEDERS TO BELT CONVEYER

Sergeant tamping machine, 5-inch diameter by 20-inch stroke. The tamping machine is supported by a revolving jib crane, the vertical motion of which is controlled by an electric hoist. After lining, the converter is removed to its stand, where it is dried.

The smelter power plant building is of brick and steel, the main aisle of which is 52 ft.×240 ft. It has a lean-to 30 ft. ×90 ft. for the steam auxiliaries, and one on the other side

30 ft. × 60 ft. for the switchboard and transformer. The building contains the various power engines, blowing engines, compressors, and auxiliaries and is equipped with an overhead electric traveling crane.

The building contains one 16″ × 32″ × 36″ Corliss engine, direct-connected to a 250-kilowatt, 500-volt, direct-current generator; one 15″×30″×36″ Corliss engine, direct-connected to a 250-kilowatt, 500-volt, direct-current generator; two 18″ × 26″ and 40″ × 24″ vertical triple expansion engines, each direct-connected to one 750 K. V. A., 2,200-volt generator; one 15″ × 30″× 36″ × 42″ blowing engine; one 26″× 52″× 48″ blowing engine; one 13½″ × 26″× 26″× 15″× 36″ steam-driven air compressor; one 26¼″ × 15¼″ × 18″ motor-driven air compressor; one 200-kilowatt, motor-driven, direct-current generator; one 50-kilowatt, motor-driven, exciter generator; one engine-driven, 50-kilowatt, exciter generator; two feed-pumps, having a total capacity of 678 gallons per minute; one fire-pump of 750 gallons per minute.

Besides the machinery listed, the plant contains the necessary condensers, vacuum pumps, feedwater heaters, traps, etc. The steam for these engines is furnished by the waste heat and hand-fired boilers adjacent to the reverberatory building.

The engine-driven generators, in addition to furnishing power for the various motors about the plant, will also furnish power for driving air compressors and for hoisting and pumping purposes at the mines of the Utah Consolidated Mining Co.

A cooling tower of the natural draft type has been constructed for cooling the water from the power plant condensers, and for cooling the cooling water for the McDougall roasting furnaces. The tower is 49 feet high, and at the base is 20 feet wide by 140 feet in length.

The equipment of the electric tramming system consists of three 7½-ton and two 18-ton electric locomotives, also 50 cars of various kinds for handling ore, coal, calcine, flue dust, ashes, and slag. There are about 10 miles of industrial tracks in the plant.

The main flue, shown in Fig. 1, which conveys the gases from the reverberatory furnaces and converters, is 20 feet wide, 18 feet high, and 1,360 feet long. One section of the converter flue is 8 feet wide, 12 feet deep, and 248 feet long; the other section has a cross-sectional area of 132 feet, and is 181 feet long. Both sections are provided with hopper bottoms and chutes for removing the flue dust. The roasting plant flue is

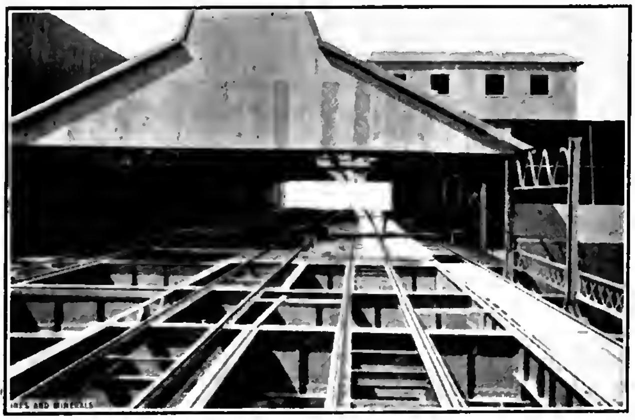

Fig. 5. Reverberatory Charging Tracks

16 ft.×16 ft. and is 255 feet in length. The main and roasting plant flues are rectangular in section, and of brick and I-beam construction, while the converter flues are constructed entirely of steel.

The stack is 25 feet inside diameter at the top by 350 feet in height above the base.

The offices and shops are in steel frame buildings, the outsides of which are covered with corrugated iron. The office rooms are lathed with expanded metal and plastered. The main building is 74 ft. × 348 ft.; at one end are the offices; and at the other the machine, carpenter, and electrical shops, Between the shops and office are the warehouse, change rooms. and laboratory. The blacksmith and boiler shop is 180 feet away from the machine shop. It measures in plan 74 ft.×117 ft. Adjacent to the blacksmith and boiler shop is the locomotive

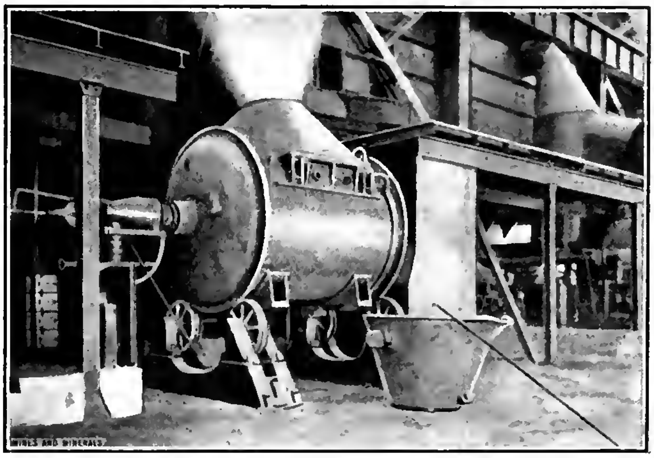

Fig. 6. Converter

shed, which is 42 ft.×89 ft. The locomotive shed shelters the locomotives and spare electric tramming equipment.

The water for various purposes in the smelting plant is obtained from a dam in Pine cañon. The water flows by gravity from the cañon through a 12-inch pipe, approximately 5,000 feet long, to a standpipe of 50,000 gallons capacity at the plant. From the standpipe the water is distributed to the various departments.

Two tanks having a capacity of 43,900 gallons each, are located at an elevation such that ample pressure is afforded for fire purposes at any part of the plant. Water is pumped into these tanks from the general water supply by the fire pump at the power plant.

COST OF CORE BORING

Mr. Moffett, of the Plainfield Mining Co., with pyrite operations at Occoquan, Va., gives the following information which will be of interest to those who drill prospect holes. The tools used were the Terry Core Drill Co.'s 3¾-inch size, which removed a 2⅞-inch core. The men operated the drill 9 hours per day through slate. The advance, which varied from 13 to 36 feet, but averaged 18 feet per day, cost less than $1 per foot, including $4 per day for hauling fuel and water, $7 per day for drill runner and helper working 9 hours daily, and $2 per day for miscellaneous expenses. This record compares favorably with the percussive drill boring of the American oil well rig. The log is as follows:

Date	Material	Total for Day Feet	Total to Date Feet
July 19	Earth 4 feet, slate	23	23
July 20	Slate	36	59
July 21	Slate	15	74
July 22	Slate	13	87
July 23	Slate	13	100
July 25	Slate	24	124
July 26	Slate	15	139
July 27	Slate	22	161
July 28	Slate	14	175
July 29	Slate	18	193
July 30	Slate	15	208
Aug. 1	Slate streaked with pyrites	13	221
Aug. 2	Slate streaked with pyrites	14	235

THE OLD DOMINION PUMPING SYSTEM

Written for Mines and Minerals, by R. L. Herrick.

Having experienced several partial shut-downs of its mine because of sudden flooding in the lower levels, the Old Dominion Co. has recently completed a pumping plant that should easily prevent another such experience, and the capacity of the new plant added to that of the old makes it one of the largest in the country. The new plant is concentrated upon the twelfth level of the A shaft, whereas the old one was distributed over three levels; namely, the tenth, twelfth, and fourteenth, thus entailing as many different sets of pumpmen. The new plant now handles the ordinary flow of the mine, which at this writing amounts to about

Equipment of Pumps. Arrangement of Sump. Methods of Supporting Column Pipes

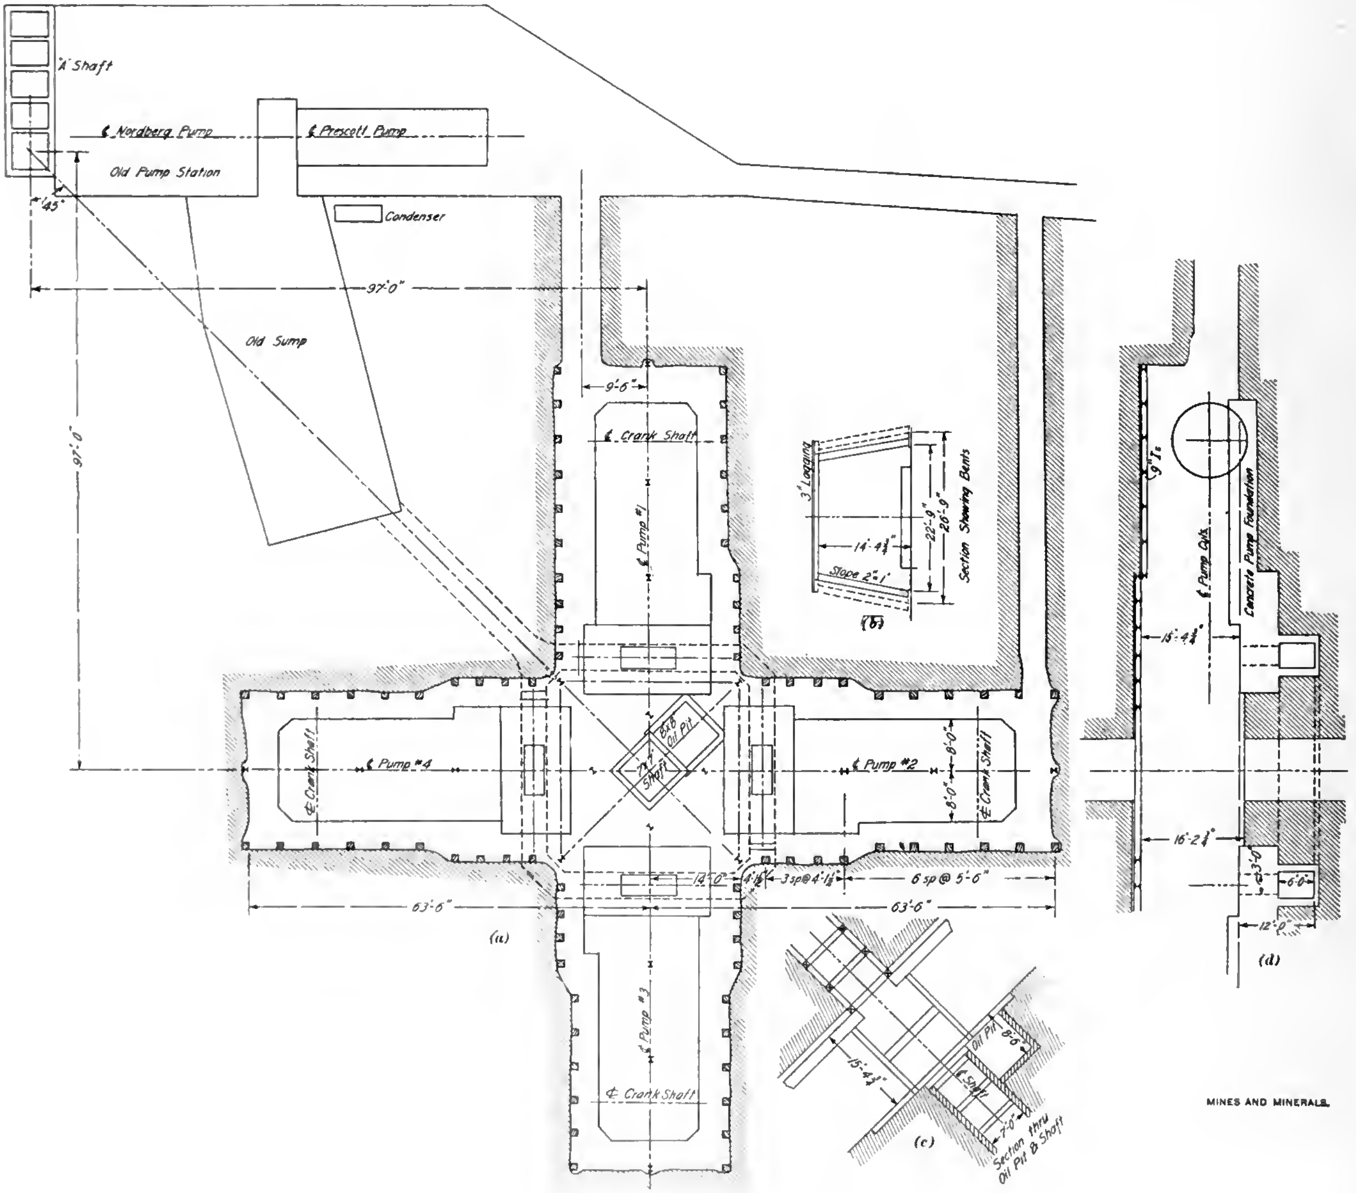

FIG. 1. PLAN OF PUMP STATION, 1,200-FOOT LEVEL "A" SHAFT

2,800,000 gallons daily, while if a sudden flooding is threatened in the future, the old pumps can be started at a few moments' notice, and the combined plants handle nearly 10,000,000 gallons daily, which capacity seems adequate to prevent another flooding.

The total normal drainage capacity of the old plant was therefore 2,750 gallons per minute, or 3,960,000 gallons per day, which by speeding the pumps was at times increased to nearly 5,000,000 gallons per day.

The old pumping plant consisted of the units shown in Table 1.

The pumps on the 1,000-foot level threw to the level of the top shaft landing 30 feet above its collar, from which the water flowed by gravity to supply the concentrator and smelter. The pumps on the 1,200-foot level, however, threw to the level of the drainage tunnel, 205 feet below the collar, where the water discharged into a concrete flume and ultimately into Pinal Creek.

The new system consists of the units shown in Table 2.

From this it is seen that the new plant has a capacity of 4,200 gallons per minute, or more than 6,000,000 gallons per day. This capacity is based upon the normal speed of 50 strokes per minute for the Nordberg pumps and may be increased by speeding them at more than 50 strokes. The combined capacity of the old plant units on the tenth and twelfth levels and the new plant thus easily exceeds 10,000,000 gallons per day.

Of the present flow of 2,800,000 gallons, 1,296,000 gallons are used by the company's concentrator and smelter, and this amount is pumped by one of the smaller pumps to the top shaft landing. The remainder is pumped to the drainage tunnel level

and it is of interest to note, 1,000,000 gallons will be used by the Miami Mining Co.'s concentrator.

The new pump station is located upon the twelfth level of the A shaft, a short distance back of the old station, the arrangement being shown by Fig. 1. The illustration clearly shows the novel cross-shaped plan of the station. The four arms of the cross each have an area 25 ft. × 50 ft. × 15 ft. high outside the timbering, while the central rectangle is 32 ft. × 32 ft. The 7′ × 7′ shaft noted in the center of this rectangle, as best shown by view *C*, comes up from the 1,400-foot level below and was especially driven to carry the pump columns from the electric pumps below, as well as to promote ventilation in the station.

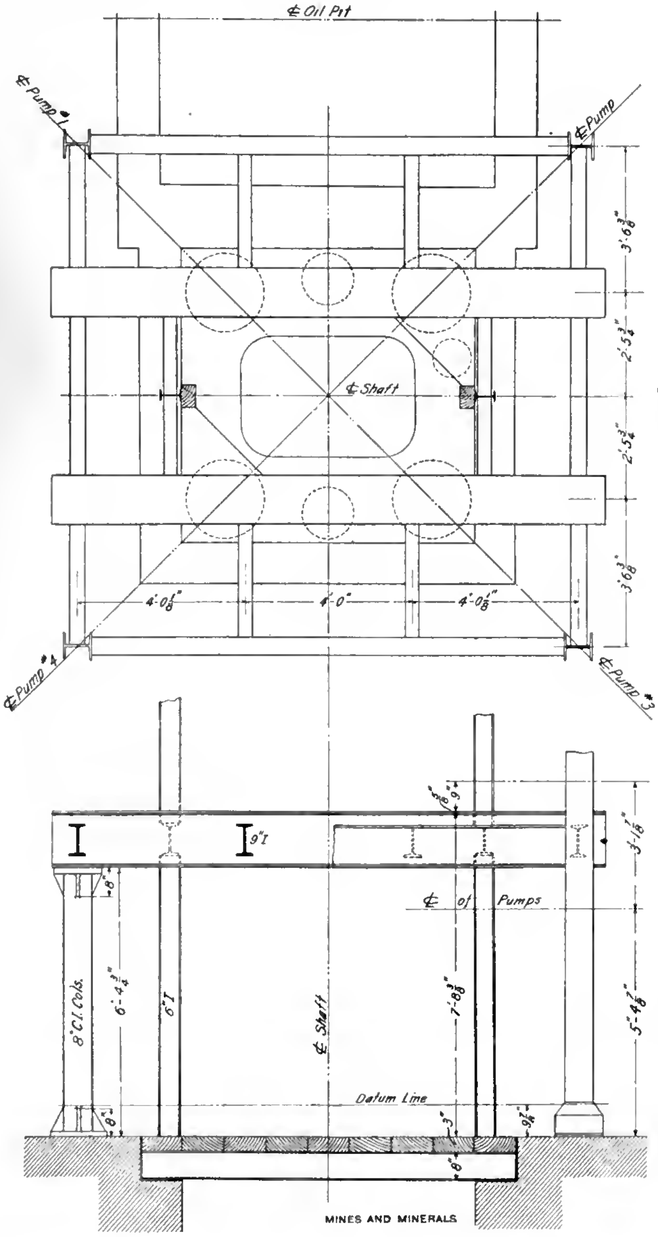

Fig. 2. Pipe Column Support

Above the 1,200 pump station this shaft continues up about 100 feet to where a horizontal cross-cut, 137 feet in length, connects with the pipe compartment of the A shaft. The steam pipes from the plant above come down to this cross-cut and follow thence to the pump station below. The pump water columns are all conducted up the A shaft to the drainage tunnel where they discharge behind a concrete dam into the tunnel flume. As shown in Fig. 3, the columns leading from the two smaller pumps are equipped with valves at the level so that they may deliver either on the surface or into the drainage tunnel. At the present time only one pump delivers at the surface.

Table 1

Level	Depth Below Collar Feet	Pumps	Level to Which Water is Thrown	Capacity Gallons Each Per Minute
1,600	1,229	2 electrically driven triplex Goulds pumps............	1,400	200
1,400	1,028	1 Prescott, steam driven.....	1,200	500
1,200	828	1 Prescott, steam driven.....	205	750
		1 Nordberg.................	205	500
1,000	627	1 Prescott, steam driven.....	Surface	750
		1 Nordberg.................	Surface	750
		Total		2,750

Sump Arrangement.—The large sump, shown in Fig. 1, behind the Nordberg and Prescott units of the old plant is utilized by the new plant, so that in case of emergency both new and old plants will pump from the same sump. Fig. 1, view (*a*), shows a drift 4 feet wide by 6 feet high driven entirely around the central rectangle and connected with the main sump near the A shaft. This sump receives the heaviest flow of the mine which makes on the tenth level and is piped down the shaft to the sump. The bottom end of the rectangular sump shown in view (*d*), is 9 feet below the level of the floor station, and the suction pipes of the four pumps draw from the sump through wells 8 feet long by 3 feet wide.

Station Construction. The station walls are supported by 12″ × 12″ timber posts, set on 5-foot centers and given a batter of 2 inches per foot of height, or 30 inches for the total height of 15 feet. Instead of timber caps, however, whose length would be a minimum of 18 feet, as shown in view *b*, Fig. 1, the posts support 9-inch steel I beams, lagged transversely with 3-inch plank. The massive concrete foundations for the pumps are shown in section in view (*d*) Fig. 1.

Each of the four arms of the Maltese cross contains one of the Nordberg pumps, as described in Table 2. Each pump is of the four-cylinder triple-expansion type equipped with Corliss valves, standard on the low-pressure and intermediate cylinders, but having a full stroke cut-off on the high-pressure cylinder. The two larger pumps having a capacity of 1,200 gallons each per minute, speeded at 50 strokes, have the size 14″ and 26″–26″–26″ × $7\frac{5}{16}$″ × 36″ stroke while the two of 900 gallons capacity each have the size 14″ and 26″–26″–26″ × $6\frac{3}{8}$″ × 36″ stroke.

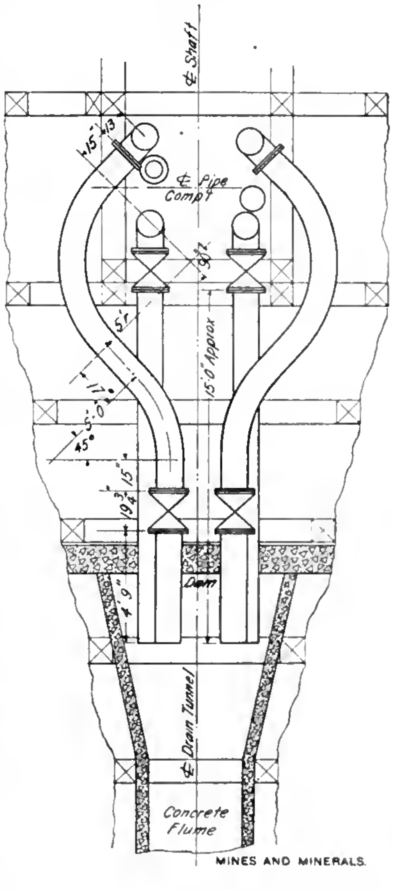

Fig. 3. Plan of Connection of Columns to Drain Tunnel

These pumps work under a pressure of 135 pounds of steam at the throttle. Their flywheels of 12-feet diameter, weighing 9 tons, insure an even running, while the Corliss valves effect a maximum efficiency which results in considerable steam economy. Each pump has two 12-inch diameter suction pipes

drawing from the wells, connecting with the sump, which are situated about the four sides of the central rectangle. The two 8-inch discharge pipes connect with branches of the 12-inch column pipe leading to the surface. Of the four column pipes leading up the shaft, three are of 12-inch diameter and the fourth, which is wood lined, is of 14-inch diameter, the latter being formerly used for pumping the most acid water from the lowest mine levels.

Pipe Arrangements.—It will readily be understood that the support of both the water-column pipes and the steam pipes of such an extensive system requires an arrangement out of the ordinary. View (*c*), Fig. 1, gives a hint of this arrangement, but for details reference must be had to Fig. 2. The sectional view illustrating this support shows that the main weight is borne by four cast-iron cylindrical columns of 6-inch interior diameter and 1 inch of metal thickness. These columns support two heavy 15-inch I-beam girders. Four 9-inch I beams likewise constitute the supporting columns for the four corners of the structure which are further supplemented by two central 6-inch I-beam columns. The rest of the structure consists of 9-inch and 6-inch I-beam girders as shown.

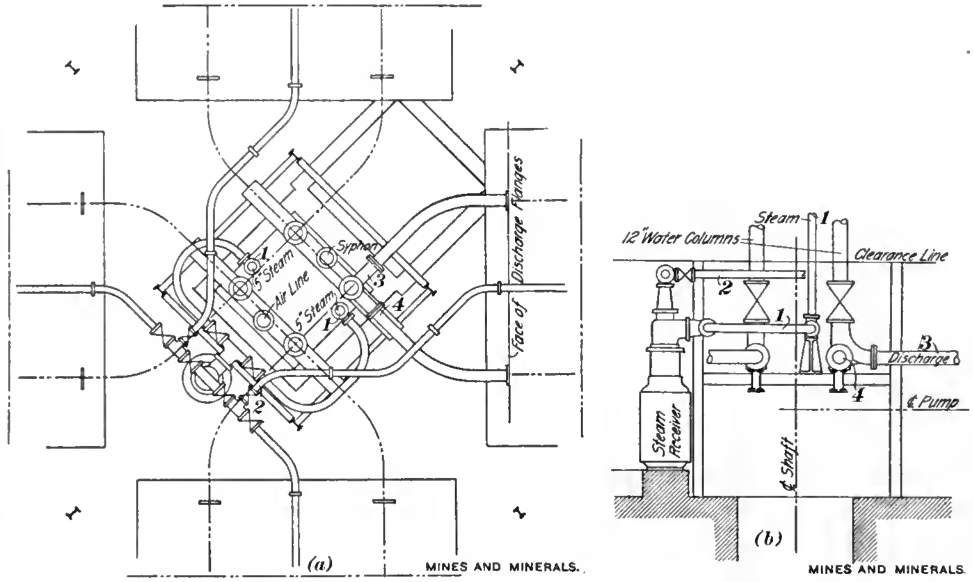

FIG. 4. PLAN OF PIPE ARRANGEMENT, 1200-FOOT LEVEL

This structure is built in the central rectangle of the Maltese-cross-shaped station and supports the weight of both the steam pipes and water columns. By referring to view (*b*), Fig. 4, the method of supporting the pipes from the I-beam girders will now be apparent.

TABLE 2

Level	Depth Below Collar Feet	Pumps	Level to Which Water is Thrown	Capacity in Gallons Per Minute Each
1,600	1,229	2 electrically driven Goulds triplex, size 5½"×7".......	1,400, head 200 feet	250
		1 Goulds triplex, size 10"×16" to be installed in the near future..............	1,400, head 200 feet	500
1,400	1,028	2 electrically driven Goulds triplex, size 12"×16"......	1,200, head 200 feet	750
1,200	828	2 steam driven Nordberg four-cylinder triple-expansion, size 14" and 26"–26"–26" ×7 5/16"×36" stroke........	Drain tunnel 205 feet, head 623 feet	1,200
		2 steam driven Nordberg, same type; size 14" and 26"–26"–26"–26"×6¾"×36" stroke..............	One throw to surface, head 858 feet. Other to drain tunnel, head 623 feet	900

In Fig. 4, view (*a*), it will be noted that two steam lines of 5-inch diameter come down the shaft from the cross-cut and unite in a T leading to the steam-trap receiver, shown in sectional view (*b*). These traps are provided in duplicate and serve to abstract the water from the steam. In the near future the steam will be given 100 degrees of superheat at the boiler plant so that dry steam will probably be delivered at this point. From the receiver the four steam mains radiate to the pumps located in the arms of the cross. The mains from the two 8-inch discharge ends of pump No. 2, numbered 3 and 4 on the illustration, are likewise shown uniting at the 12-inch column pipe that goes up the shaft.

Owing to the arrangement, previously mentioned, of carrying the pipes up 100 feet, thence through the 137-foot cross-cut to the pipe compartment of the A shaft, the column and steam pipes are necessarily given two bends, as shown in Fig. 5 (*a*). By giving these columns a 5-foot radius of bend, however, friction is reduced to a minimum, so that it is said no jarring at the elbow is perceptible. Fig. 5 (*b*) likewise shows how a proper spacing of pipes in the A shaft was effected by giving them ample radii of curvature. Fig. 3 shows the pipe arrangement at the level of the drainage tunnel where the pipes discharge behind the concrete dam into the tunnel flume.

Steam for these pumps is generated at the surface plant, located a short distance from the shaft, which likewise supplies the hoisting engines. This plant consists of five oil-burning water-tube Stirling boilers of 325 nominal horsepower each, and one of 250 horsepower. This plant is modern in every respect, having as additional equipment a Cochran feedwater heater, feedwater pumps in duplicate, as well as a duplicate set of oil pumps.

Summary.—By concentrating the pumping plant which will serve ordinary requirements at the 1,200 level, a considerable steam economy was effected, not to mention the saving in wages of pumpmen. Although the new installation may be assumed to have cost in excess of $100,000, the daily economy as well as provision against flooding has already justified the expense. This daily economy is said to amount to about 25 per cent. of costs.

In conclusion the writer acknowledges his indebtedness to Manager S. H. Dowell and Mechanical Engineer C. H. Weideman for much of the data and the accompanying illustrations of the above article. To Master Mechanic John Langdon, and Mr. Frank Zlatnick, of the Nordberg Co., and to Chief Engineer H L. Norton, thanks are likewise extended for their painstaking assistance.

During 1909 Alaska's auriferous lode mines produced gold valued at $4,107,363, an increase of $749,928 over the product of 1908 and the largest annual lode output yet recorded. The number of producing mines was the same as in 1908, but a score of prospects were in course of development and some of these made small outputs.

JOPLIN DISTRICT ZINC AND LEAD ORES

In excavating for the new union depot at Joplin, Mo., free galena has been encountered and weekly turn-ins are being made by hand-jig operators who pay a royalty to Jenkins & Jennings, the contractors having the excavation work in hand. The ore is found within a few feet of the surface. The site of the new depot is within two blocks of the main business center of the city.

A lower run of ore than any hitherto worked on the tract has been encountered in a drill hole at a depth of 127 to 137 feet by the Waneta Mining Co., operating on the Riseling estate, west of Joplin. A shaft is to be put down to the new formation. On adjoining leases recent drilling has disclosed a still deeper run from 180 to 200 feet. The formations are the typical open-ground variety common in that vicinity.

In the development of the Hackett Mining Co.'s land, west of Joplin, the longwall system of mining is to be tried. This is only one feature of the Hackett development that is radically different from any other mining work in the Joplin district. The company has a large concentrating plant combining features of the western mining plant with those of the prevailing types found in this district. The crushing, the jigging, and the concentrating departments are absolutely independent of each other. Any department may be operated while the other two are shut down. This is effected by means of separate power units and intermediate storage bins. The plant is situated near the center of a 40-acre tract. At regular distances shafts are to be sunk and the ore supply is to be carried to the mill over surface tramways with the exception of the ore that comes from the mill shaft which is hoisted direct to the hopper. The ore occurs in brecciated flint in an 18-foot face beneath a solid cap rock of limestone. It consists of a good quality of zinc blende thinly disseminated through the ground and cemented between the openings in the chert.

Shallow mining operations on the Log Cabin Mining Co.'s tract east of Joplin are resulting in large turn-ins of free galena, while five good prospects hold promise of still further increasing the production from a tract that has been almost unworked for many years and which was looked upon as exhausted. The shallowest ore encountered was at a depth of 25 feet. Other deposits were encountered at 40 to 60 feet. Some of the dirt requires hand jigging.

Each week sees additional mines closed down in the thin sheet-ground districts where operations cannot be conducted at a profit with zinc ore selling for $41 a ton, basis of 60 per cent., and lead ore bringing $49 a ton. The demand for open-ground properties, on the other hand, is increasing. Many mines, similar to those that flourished when zinc ore brought only $18 a ton, are being opened in all parts of the district. The life of these little producers is short as a rule, but the profits are large while the mineral supply holds out. When prices reach

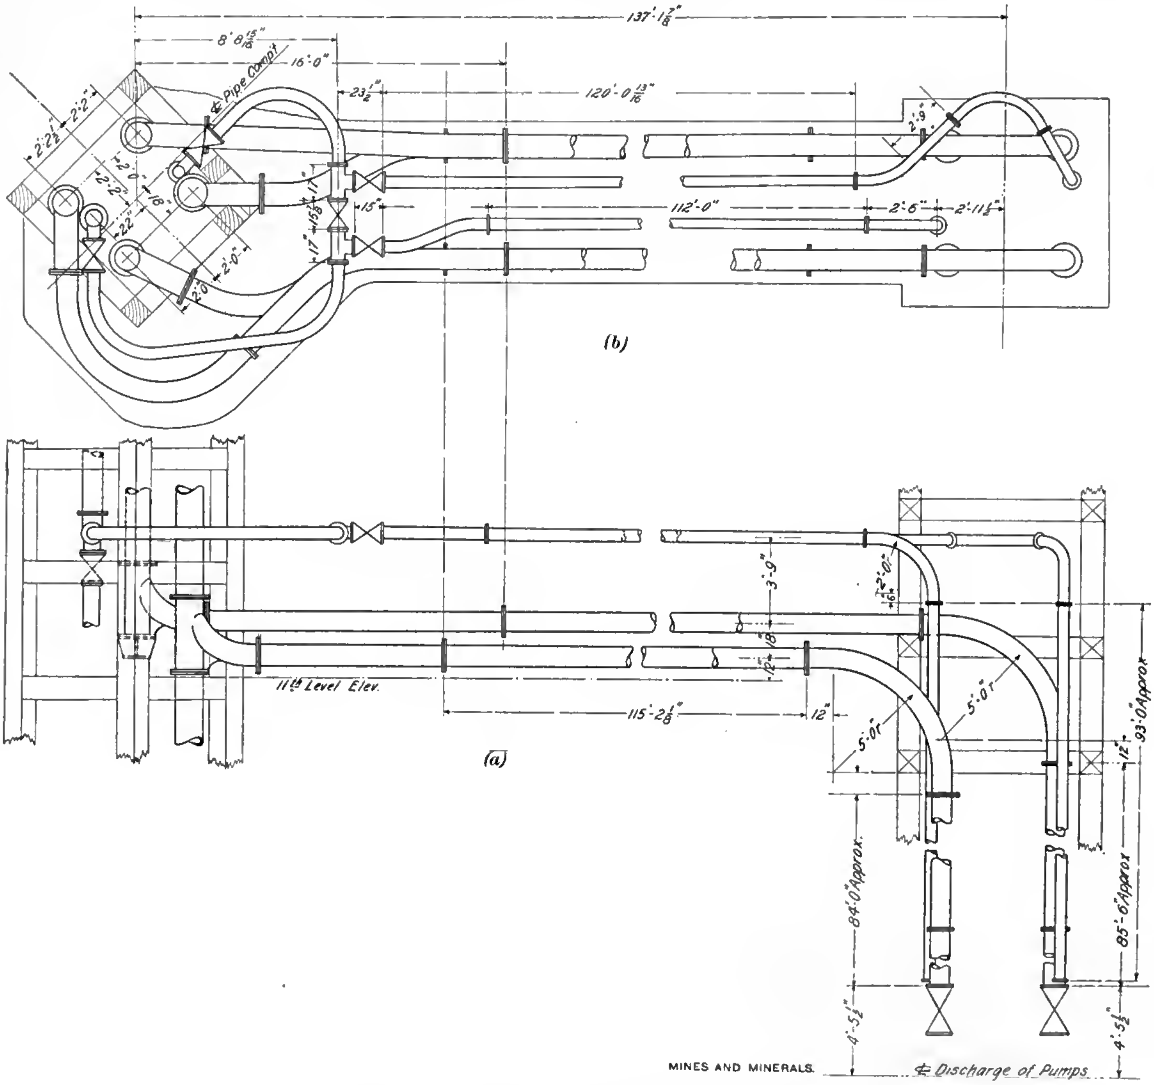

FIG. 5. ARRANGEMENT OF PIPES FOR CONNECTION BETWEEN CROSS-CUT AND SHAFT

a level permitting of profitable operation in the sheet-ground areas, where the deposits supply ore for many years, it seems the operators prefer this costlier mining in preference to the gouge method from which the profits are almost sure, but small.

The heavy weekly turn-ins from the Quick Seven Mining Co., in the Neck City camp, 20 miles north of Joplin, are attracting attention. The mine is a new one, having been discovered by a company of Neck City prospectors, comprising saloon keepers, hardware dealers, bank presidents, and physicians. The tract lies near a small stream and was conspicuous for years as being the only unproductive area in one of the most fertile agricultural regions of the country. Nothing would grow on this property. Drill prospecting was started after several close observers had noted the peculiar tallowness of the clay brought up by crayfish that had burrowed hundreds of holes. This surface indication hinted of mineral lower down. The ore was found below the 100-foot level, and occurs in large pockets both in soft and hard ground. Where it is richest heavy timbering is required. Three big concentrating plants are working on the land and the weekly output of zinc blende is from 200,000 to 600,000 pounds. The ore as a rule runs better than 62 per cent.

Civic improvement leagues in Joplin and Webb City, Mo., have undertaken to improve the landscape of the mining district by planting creeping vines to cover the hundreds of unsightly dump piles and tailing heaps. Superintendents of the public schools of these two cities have distributed seeds to the students with the request that they be planted as soon as possible.

In the Wentworth, Mo., camp, near the site of the famous Gobbler Mine, in which Frank Rockefeller placed so much money in development, the Mocking Bird Mining Co. is reported to be opening a good deposit of calamine. Several small companies in the Wentworth district also report shallow ore strikes.

The "Fellow Servant Law" recently enacted in Missouri has caused the casualty companies, with one exception, operating in this district, to abandon the field. This law makes it possible for employes to secure damages for injuries due to the negligence of their fellow workmen. The original liability insurance rate of 3 per cent. of the pay roll has grown to 4 per cent., and the single remaining company now is contemplating a raise to 4½ per cent.

Workmen risked their lives when they removed the Avondale concentrating plant at Carterville from the brink of an ever-widening cave. The mill was almost swallowed by a sudden fall of earth which left the plant on the edge of a pit 200 feet deep and 100 feet across. It was purchased by a Joplin machinery company and removed to a place of safety.

The 250-ton plant, of the Boston Land and Mining Co. at Galena, has been completed and the work of opening a daylight mine has started. The ground is to be stripped, the ore coming to within a few feet of the surface.

The Newton mill of the Old Dominion Mining Co., at Galena, has just been finished and put in operation. It has a capacity of 200 tons per shift and is to handle ore from a stripped pit, 55 feet deep, 130 feet long, and 65 feet wide.

Pete, Kirke & Co. report drill strikes of zinc ore on the Clark land, 2 miles east of Alba. The formation occurs at a depth of 200 feet and is in virgin territory. A similar strike is said to have been made in several drill holes by Bowman & Ball, prospecting on the Hannum & Shaw land.

The Du Pont Powder Co. has purchased for $75,000 1,000 acres of land from 15 farmers living east of Joplin 8 miles. A dynamite plant, the estimated cost of which is said to be $500,000 is to be established.

It is said that the famous Blue-grass editor, Henry Watterson, requested the proprietor of a poker parlor to let him have $20 worth of chips, stating that he would send Ben around to the office for the money. "You can have the chips, colonel, on this condition: If that lad comes back with the coin your play counts; if he fails to make connections, it don't." "That's all right, Bill," said the silver-penned editor; "pass over the markers." By a singular chance Watterson won from the start and before long had chips representing $500 piled up in front of him. Then Ben came in and Watterson seeing him said: "Hello, Ben, what luck?"

"None, colonel, all the cash was banked; not a centavo in the till." Watterson looked regretfully at his winnings, and then solemnly said: "Ben, beware of cards. I've just lost five hundred hard-earned dollars."

Big Keys, a full-blooded Chickasaw Indian, was in the district recently en route to his home in Oklahoma after a tour of exploration through the Ozark Mountains in Southern Missouri. Numerous other Indians recently have been exploring the Ozarks in search of a cave, which tradition says, is filled with silver, both ore and metal. It is claimed the cave produced silver for many years. Several Joplin miners have sought in vain for the cavern.

More than 50 of the big mills in the sheet-ground districts of Webb City, Duenweg, Prosperity, and Carterville are closed, due to a slump in prices for zinc ore. This shut-down, however, has stimulated operations in the shallow, pockety districts where the cost of production is much less.

Prospects are being opened at Glen Haven, in Grant County, where surface mines were worked fifty years ago. The miners in early days did not stay out among the bluffs, as they soon got below Mississippi level, making pumping expenses too burdensome to bear. There are ranges of crevice ore along the river; some of the crevices being forty and fifty feet high, and half a mile to a mile in length underground.

RIO BLANCO COUNTY, COLO.

The plans of the recently incorporated Grand River, Meeker & Salt Lake Railroad Co. call for the immediate construction of the road from Chapman, a new town between Rifle and Newcastle, on the Denver & Rio Grande and Colorado Midland railroads, to Meeker, in Rio Blanco County, and the ultimate extension of the line down the White River valley through a rich section of Utah into Salt Lake City.

Between Chapman and Meeker, a distance of about 50 miles, the new road will pass through the Grand Hogback and Danforth Hills coal fields. There are 41,720 acres of coal land available for mining in the Grand Hogback field, and 159,700 acres in the Danforth Hills field. The total thickness of the coal at Newcastle, in the Grand Hogback field, is 105 feet; and one seam, the Wheeler, is 45 feet. The total thickness of the seams in the Danforth Hills field is 73 feet. Most of the coal in northwestern Colorado is a high-volatile product. It averages close to 12,000 British thermal units, and is equal in all respects to any of the coals in competitive markets.

Farther down the White River, along the line of the proposed railroad, is the Rangely oil field. The producing wells in the field have been plugged, awaiting the provision of transportation to market. The oil has a paraffin base and is free from asphalt. In color it is a clear light red, with a strong green fluorescence, closely resembling the Pennsylvania oil. Its odor is like that of kerosene, much resembling that of a refined oil. It is apparently free from sulphur. The specific gravity of the crude oil from Requina well No. 1 is .8092 or 44° B. It would, therefore, be described as a very thin light oil.

As the White River approaches its confluence with the Green, it enters a hydrocarbon field the like of which has been found nowhere else in the world except in the Ural Mountains. There are perhaps 20 varieties of these hydrocarbons, among them gilsonite, elaterite, and ozocerite.

The carnotite of the White River valley is an ore of uranium and vanadium, and is highly radioactive. It occurs as impregnations in sandstone along fracture planes. It is cheaply mined, but the recovery and separation of the uranium and vanadium present some difficult problems.

AMERICAN INSTITUTE PANAMA MEETING

Written for Mines and Minerals, by E. W. Parker

An Account of the Trip to Panama. The Conclusions of the Institute in Regard to the Panama Canal

The ninety-ninth meeting of the American Institute of Mining Engineers, held on the Canal Zone of the Isthmus of Panama, will long be remembered by those taking part, as one of the most enjoyable meetings in the history of the organization. Much of the success and enjoyment was due to the unselfish and cheerfully rendered services of Dr. Joseph Struthers, who made all the arrangements, and saw that they were carried out. Doctor Struthers was assisted by A. E. Vaughan, and if Struthers was not happy Vaughan was, and vice versa, with the result that no one but these two had trouble, while the others had the time of their lives.

The party, 120 in number, sailed from New York on Friday, October 21, making the first stop at Havana, on Tuesday, October 25. The sea, which was slightly rough the first two days, was for the rest of the trip as peaceful as could be desired. Three days were allowed the members to get accustomed to ocean travel, but on Sunday morning divine services were led by Dr. R. W. Raymond, LL. D., secretary of the Institute. In the afternoon, Doctor Raymond also talked (to those able to sit up) on Jamaica and its people. The first session of the Institute was held on the steamer, Monday, October 24, and it was devoted to the discussion of mine fires, which was begun by W. A. Lathrop, of Wilkes-Barre, Pa., who, with blackboard illustrations gave an account of the walling off of the fire in the Summit Hill colliery, at Summit Hill, Pa. The discussion was continued by S. D. Warriner, of Wilkes-Barre, Pa., on a fire in No. 8 shaft of the Calumet & Hecla Co., Michigan; R. V. Norris, of Wilkes-Barre, Pa., on the fire of 1901 at the Big Lick slope of the Lykens Valley Coal Co.; W. J. Richards, of Pottsville, Pa., on the prolonged fight of the fire in the Pineknot colliery in the Heckscherville Valley; S. A. Taylor, of Pittsburg, Pa., on the recent fire at the Monarch Mine, near Rock Spring, Wyo.; President Brunton, of Denver, Colo., on the fire in the Anaconda Mine, at Butte, Mont.; C. W. Goodale, of Butte, Mont., on the fire at the Leonard Mine.

Fig. 1. Gamboa Bridge on Panama Railroad Near Canal

The features of the stop in Havana were visits to Cabana Fortress and Morro Castle; a reception by the President of the Republic, drives about the city and the purchase of cigars. Promptly at the hour set, on Wednesday, departure was made for Kingston, Jamaica. On Thursday, October 27, the second session of the Institute was held, the discussion of mine fires being continued as follows: Fire in the Luke Fidler colliery, at Shamokin, Pa., by R. V. Norris. Four fires in the Vulcan iron mine, by Wm. Kelly, of Vulcan, Mich. Recent explosion at Palau No. 4 Mine, near Las Esperanzas, Mexico, by Edward W. Parker, of Washington, D. C. Fire in the De Beers diamond mines, South Africa, by Gov. Gardner F. Williams, Washington, D. C. Only one paper was presented at the session held on Friday afternoon. It was by Prof. Jos. W. Richards, on the electric smelting of pig iron in Sweden. Professor Richards illustrated his lecture with blackboard drawings.

Kingston was reached early Saturday, October 29, and here, after practically sacking the town of light clothing, the party drove to Castleton Garden; took a trip by rail on Sunday to Bog Walk, and then a drive through the cañon of Rio Cobre to Spanish Town and returned to Kingston, whence they set sail for Colon.

Monday, October 31, at the fourth session, W. L. Saunders, of New York, gave a historical account of the conception of the Panama Canal with a description of the isthmus and of the work so far accomplished. He was followed by John M. Sherrerd, of High Bridge, N. J., with an address on the social life of the Canal Zone.

An accident to the ship's machinery caused a delay of 3 hours, and on this account the contemplated stop at Gatun Dam, en route to Panama, was put off until a later day, in order that sufficient time could be given after arrival at Panama for the members of the party to get settled.

The strenuous program for the Canal Zone meeting began on Wednesday at 8 A. M. when the party started on a special train for the Culebra Cut. Here the most profound impression made upon the visitors was by the perfect system of handling the dirt trains. These were kept going with a clock-work regularity, over a bewildering network of tracks in a comparatively narrow ditch, that becomes more narrow as the channel deepens. The system of moving trains so that a minimum of time is lost by the steam shovels, in the switching and hauling to the dumps, and in discharging the loads, impresses the observer. Fig. 2 shows a Lidgerwood unloader en route for the dumps. The plow is on the end of the train and is drawn across the entire length of train by a wire cable. The unloader is similar to a mine hoist. A train of 20 cars can be unloaded in about 25 minutes.

After passing through the cut the special train was taken over a part of the new location of the Panama Railroad, which must abandon most of its present right of way when the water is turned into the canal. In the afternoon the Institute party was given the pleasure of greeting the President of the Republic, Don Pablo Arosemena.

Thursday, November 3, was Independence Day in the Republic of Panama. Those who desired were taken by special train to Culebra for an inspection of working models of the locks at the Pacific end of the canal. In the afternoon the visitors were lookers on at the fiesta, and in the evening were guests of Mr. Saunders at a Spanish presentation of the "Merry Widow" at the opera house.

Starting at 8 A. M. Friday, the party was taken by special train to the locks at Miraflores and Pedro Miguel, these being the steps at the Pacific end from tidewater to the main canal. A visit was made to the pumping station which furnishes water for two "giants" that hydraulic the soft material in the Rio Grande flats and pump the resulting mud out of the canal

channel. In the afternoon a trip by tugs was made to the harbor end of the canal, where interesting subaqueous excavation is in progress. At an evening session, held in the Hotel Tivoli, Colonel Gorgas delivered an address on the sanitary work on the isthmus and the successful fight against dysentery and the yellow fever mosquitos. So completely have the latter been eradicated that there has not been a case of yellow fever on the

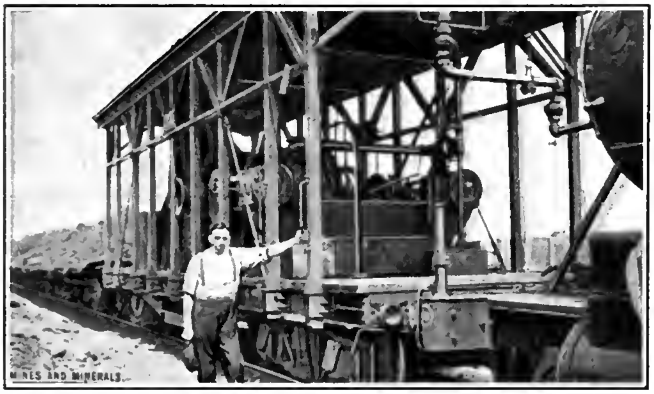

Fig. 2. Lidgerwood Car Unloader

isthmus in 3 years. Colonel Gorgas was followed by Dr. C. W. Hayes, who gave a concise statement of the geologic structure of the isthmus. The session concluded with a lantern-illustrated description of diamond mining at Kimberly, South Africa, and gold mining on the Rand, by Gardner F. Williams, formerly general manager of the De Beers Consolidated Mining Company.

On Saturday the party were tugged to the islands in the harbor and a stop for bathing and luncheon was made at Taboga. Sunday gave an opportunity for a visit to the hospital and a not unwelcome rest. Sunday evening a session of the Institute was held in the hotel. The first paper was by Edward W. Parker, on "Recent Developments in the Undercutting of Coal by Machinery." David B. Rushmon showed some views on the applications of electricity to mining.

The visit to Gatun dam Monday morning was to many the most interesting day of the meeting. The party was taken over the great fill, which will eventually form the dam, and shown through the uppermost of the three locks that will lift and lower the traffic to and from the main stretch of the canal. Tuesday morning the party left Panama for Colon, and at 11 A. M. sailed for New York, stopping en route at Kingston on Thursday for cargo. President Brunton took advantage of this stop to entertain the party at luncheon at the Myrtle Bank hotel. At a session of the Institute held on Wednesday, the Panama Canal was made the subject of discussion. Each speaker was limited to 5 minutes. Absolute unanimity of expression was given to the opinion that the present type of canal is the only one dictated by wisdom and by the conditions existing on the isthmus. High tributes were paid to the men engaged in the construction of the canal and to the sanitation of the isthmus, the feeling being that every man, down to the water carriers, was on "his job." The opinions of the party will be printed in the "Transactions."

On Friday an animated discussion followed a description by C. W. Goodale, of the compressed-air hoisting plant at Butte. This plant is being installed to hoist the ore from 30 mines within a radius of a mile and a half, the power for compressing the air being brought 130 miles from the electric-power plants developed on the Missouri River near Great Falls. The discussion following Mr. Goodale's paper occupied the remainder of the 2-hour session, except for a few minutes allowed D. M. Riordan for reading his sentiments regarding the constructing and constructors of the Panama Canal, which paper was in reality the crystallization of the opinions expressed at the session held on Wednesday. The session on Saturday was given up to a discussion of the draft of a bill which it is proposed to submit to the legislatures of the several metal-mining states in the hope of securing more uniformity in the mining laws and greater safety to mine employes. The bill as submitted was the one prepared by a committee of the American Mining Congress and has the support of that body. W. S. Ayres read a paper on "The Losses Incurred in the Various Methods of Preparing Coal for Market."

Divine services were led by Doctor Raymond on Sunday morning, and in the afternoon the party listened to an interesting address on South America, by Robert P. Porter, of the editorial staff of the *London Times*.

On Monday, November 14, the men in the party signed the following statement:

S. S. Prinz August Wilhelm, at sea,
November 14, 1910

We, the undersigned, members and guests of the American Institute of Mining Engineers, after a visit to the Isthmus of Panama, and an inspection of the work of the United States Isthmian Canal Commission, and after full discussion of our individual impressions, find ourselves in unanimous agreement as to the following conclusions:

1. The present plan of the work is clearly practicable, and the best in our judgment that could be devised under the conditions imposed. It is perhaps a question whether by the choice of a higher level some of the difficulties and uncertainties of excavation in the Culebra Cut might not have been minimized; but a higher level has its disadvantages also; and no one now seriously proposes such a plan. On the other hand, we are convinced that a canal at a lower level, and especially at sea level, is practically out of the question; that no man can estimate its cost, or even guarantee its satisfactory completion and maintenance at any cost. We are satisfied that the sea-level canal, as proposed, if actually completed, would be inferior to the present lock canal, by reason of its necessarily narrow and tortuous channel, its liability to many disturbances from which the lock canal is comparatively free, etc. The experience gained in the Culebra Cut throws additional light upon the sea-level plan, and renders that scheme less worthy of approval by engineers than it was when, with less information, some eminent authorities favored it. In a word, we do not think that any prudent engineer would now recommend the deepening of the Culebra Cut below the level now fixed for it.

Fig. 3. Miraflores Portal of Tunnel on Panama Railroad

The creation of the great Gatun Lake by means of the Gatun dam seems to us to be the best possible way of dealing with the floods of the Chagres and other streams. The location of the Gatun dam, spillway, and locks is singularly favorable for such constructions; and there is, in our judgment, no reason for any anxiety as to their stability.

The one serious remaining problem is presented by the nature of the ground in the Culebra Cut. There have been

extensive slides on the sides of this excavation, and more of them are to be expected; but they involve nothing more than the cost and delay of removing the material which they will force into the cut. They will ultimately end; and we regard as reasonable the calculation of the engineers in charge as to the time and money which they may call for. The results of these calculations are included in the estimates of the Commission as to the cost of the canal and date of its completion.

2. We are unanimous in our praise of the manner in which sanitation, excavation, transportation, and construction are performed with rapidity, skill, and economy. A spirit of loyalty, emulation, industry, and pride seems to animate employes and officers alike. This spirit, so difficult to arouse among workers in tropical climates, is due in this case to two causes: first, the inspiring example of Colonel Goethals and his associates, and, secondly, the splendid work of the sanitation department under Colonel Gorgas. The cities of Panama and Colon, though politically outside of the Canal Zone, have shared in the benefits of the sanitary administration, and reflect an unwonted cleanliness, comfort, and safety.

3. We acknowledge the entire freedom and fullness with which everything we desired to see was shown to us, and everything we desired to know was told us, by the officers of the Commission. There was evidently no wish to withhold or conceal. On the contrary, inquiry and criticism were frankly sought and heartily welcomed.

This is but a meager summary of the points on which we are agreed. The details of individual opinion will appear later in the published report of our discussions. Meanwhile, we unite in this common declaration, which covers our conclusions on all main points. We think the present plan of the canal is good; that the work is in thoroughly capable hands; that it is progressing satisfactorily, and that it will be completed by the date set for it, January 1, 1915, and probably earlier, provided Colonel Goethals and his associates receive the hearty support of the American people, and its representatives in Congress. The canal engineers are the right men in the right place. The great work in which they are engaged is not connected with partisan politics, and citizens of all parties should combine to secure its early triumph and completion. In that consummation every American should take greater pride than in any victory of military or political conflict. (Signatures)

The concluding paper of the session and of the meeting was

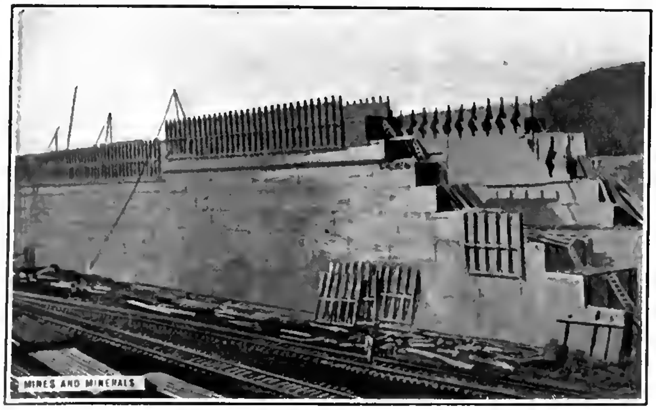

Fig. 4. Section of Pedro Miguel Locks, Pacific Side

on the "Electrical Manufacture of Steel in the United States," by Prof. Jos. W. Richards.

New York was reached Tuesday afternoon, the steamer having been delayed by adverse winds. There had not been a single storm, however, nor had there been one untoward incident during the entire trip. The sea voyages were attended with exceptionally favorable weather, the sessions were all well attended, discussions were full and interesting, and with the week of inspection of the work on the canal, made the ninety-ninth session of the Institute one of the red-letter meetings in its history.

TEPIC TERRITORY, MEXICO

Although the Territory of Tepic, Mexico, has several hundred miles of coast line on the Pacific Ocean, its few ports are

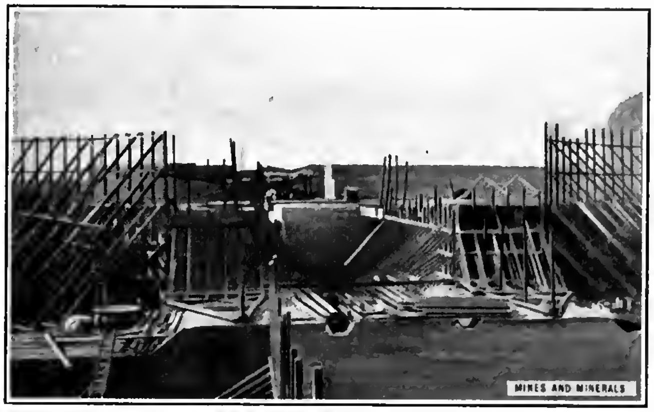

Fig. 5. Lock Construction Work at Gatun

comparatively unknown and cannibals inhabited some of the islands not longer ago than 1900. Immense mountains form its eastern boundary and it is shut off from direct communication with Guadalajara and the south by deep and wide gulches or barrancas.

This isolation has been broken by the Southern Pacific Railway, which has already entered the Territory from the north and proposes to continue building on to Guadalajara across the barrancas, and thus Tepic will have for the first time good communication with the rest of Mexico.

The temperature rarely goes lower than 48° F. in the winter and above 90° F. in the shade in the summer. There are no severe storms and sunstroke is unknown.

Some mines are worked in the Territory, but it is thought that only a beginning has been made, for the mountains which form the eastern boundary of Tepic should be as rich in minerals as those of the same chain in Sonora and Chihuahua.

The plateau lands of Tepic are not as high as those of the tablelands of Central Mexico, of which they form the western boundary, being only about 3,000 feet above the sea. From this plateau there is a gradual rise to the higher lands of Jalisco to the south and east and the natural fall to the Pacific on the west. The soil on this high land is a composite of volcanic ash, and capable of producing good crops, which can be readily marketed in this country when transportation is supplied.

There are few large towns in Tepic. The capital, Tepic, has a population of about 10,000. The chief port is San Blas. Other places of importance are Compostela, Santiago, Ixcuentla, Acaponeta, and Ahauchitlan.

The Southern Pacific Railway connects its Mexican system with its system in the United States at Nogales, Ariz. Plans are being considered for crossing the great barranca north of Tequila, Jalisco, and then entering Guadalajara on the lines of the National Railways of Mexico, which will be met at Orendain, Jalisco, a little northwest of Guadalajara.

The main shaft of the Temiskaming Mine, Cobalt, will soon be the deepest in the district. It is now down more than 460 feet, and is being rapidly sunk to the 500-foot level. At this level the sixth station will be cut. At each 100 feet there is a level. There is also one at 350 feet. Below 425 feet there is no ore in the shaft itself. From the 500-foot station crosscuts will be driven to explore for all the main veins.

A GRAPHICAL NOTEBOOK

Written for Mines and Minerals, by F. W. Gray

Graphic Method of Recording Different Data in Connection with Mining Work

The modern industrial organization is arranged in departments, all interdependent and reporting to one central head. It is manifestly impossible that one man can assimilate all the details of many departments, and the chief must rely upon his departmental heads to take care of these details, wherein, needless to state, is the reason of the departmental system. This has been said many times before, but nevertheless the force thereof is not always appreciated, and many a chief executive dissipates his energies on chasing details, or in doing work which he should require of his subordinates. There are times, however, when the chief finds it is

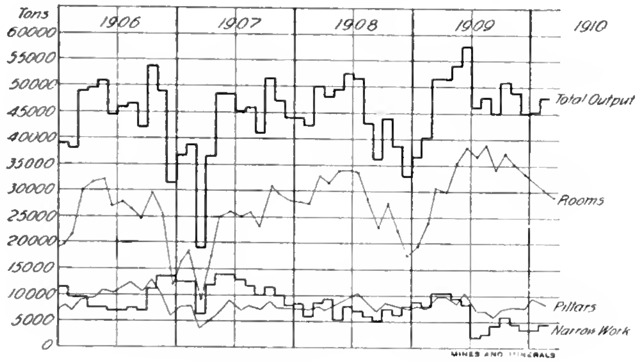

Fig. 1. Dissection of Output of Colliery

very necessary that he should delve into details, and the utility of all the reports and statements which find their final resting place in the office of the general manager is to indicate to him just in what direction he should direct his energies so that they may accomplish the most. The work of the staff immediately surrounding the general manager consists in large part in condensing these reports into such compass, and putting the information contained therein into such shape as will enable him most easily to grasp the essential points, and to judge where personal investigation is most likely to result in improvement. The more complex the operations of a corporation the greater is the necessity of conserving the energy of the head by relieving him of detail, and of so presenting operating results as to utilize to the fullest extent the time of the man who holds the highest

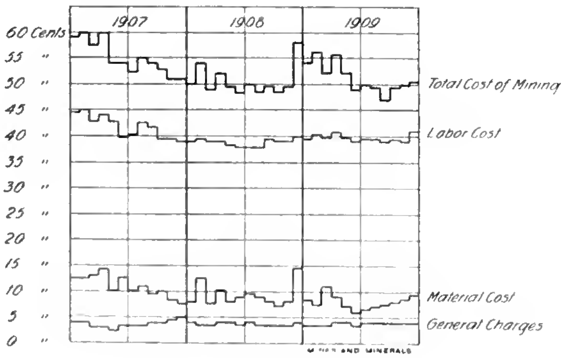

Fig. 2. Cost of Mining Coal

place and is paid the largest salary in the corporation. Therefore it follows that one of the most important parts of the equipment of the chief executive is his notebooks and reference data. These divide themselves into two; namely, compilations of accurate data, more or less bulky, which are usually kept in the private office and deposited for safekeeping in the vault at night, and pocket notebooks which the chief carries about with him in his journeyings around the mines and works under his charge. The graphical notebook affords a means of condensing a large amount of information in a remarkably small compass, and to the general manager whose training has been that of an engineer rather than that of an accountant, the facts are presented in a far more convincing and direct manner than is possible in any other way.

The graphical notebook can be taken out and studied in odd moments of leisure. It also affords a useful reference when discussing the operations of a department with the man in charge, and it can be instantly referred to in corroboration of a statement made or to refresh the memory. The plotted lines in a graphic record show the general trend of affairs, and often-

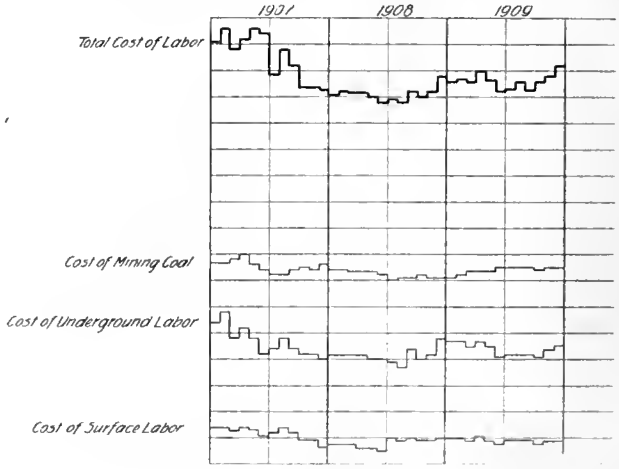

Fig. 3. Cost of Mining. Dissection of Labor Charges

times by the study of the relation of these lines to each other the mind receives illumination that it would fail to get from the study of a mass of figures.

The coal company with which the writer is best acquainted operates about a dozen collieries and is also a transportation company, owning and operating a railway, an electric tram line, numerous loading and discharging plants and a fleet of coal-

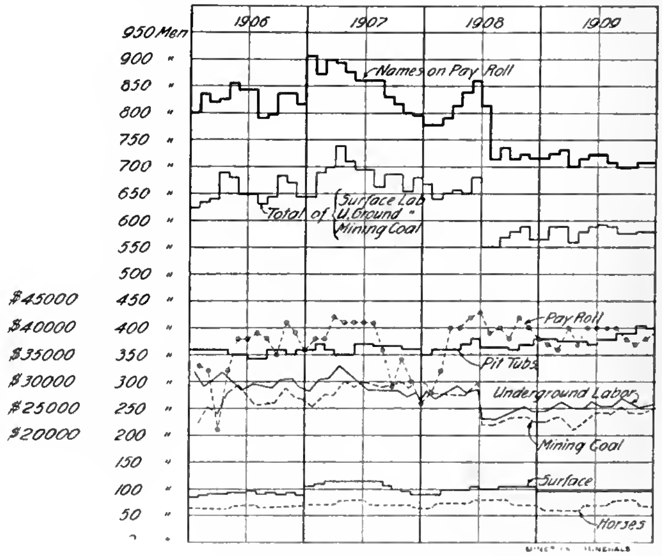

Fig. 4. Organization. Dissection of Mine Force

freighting ocean steamers. The subsidiary operations include a coal washery, retail stores, machine and car shops, foundry, etc. A record which shall contain the essential data of a concern of this nature affords extensive scope for a graphical notebook and for varied methods of plotting. In practice, the labor required in connection with the graphical record is mostly in the initial arrangement of the book. The actual entering up of the record month by month entails small labor compared

with the blocking out of the sections, the arrangement of the graphic scales and in deciding just what is necessary and what is not.

The illustrations accompanying this article are merely intended to be representative. In the actual compilation of a graphical notebook, great use can be made of different colored inks, and some of the records shown cannot be properly appreciated when reproduced in black and white lines.

Figs. 1, 2, 3, and 4 show typical graphs for a colliery, dealing with four of the most important features; namely, output, cost of production, pay rolls, and the distribution of the force employed.

Fig. 1 shows the dissection of the output in a mine worked on the room-and-pillar method, showing how each stage of coal extraction has contributed to the output. An important feature in a mine worked on this method is that the "narrow work," or development work, should be kept well ahead and, also, that the pillars should be extracted systematically to avoid loss by crushes due to allowing them to stand too long. From the diagram shown, the chief could deduce that in the latter months something had gone wrong, as the line denoting "narrow work" has dipped down.

Fig. 2 shows the total cost of production and the relative proportions of its components; namely, labor cost, material cost,

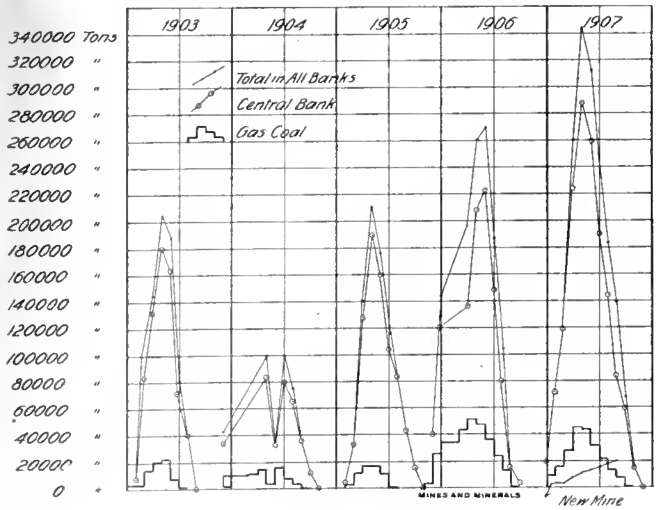

FIG. 5. COAL STORAGE BANKS

and general charges. It will be noticed that there is an increase in the cost during the first four months of each year. During this period it is usual to repair the mines and put them in good order for production of a large output during the summer season.

Fig. 3 shows how the cost of labor is again subdivided into the cost of surface labor, underground labor occupied in the transportation of coal and other auxiliary operations, and the cost of the labor actually engaged in cutting coal at the face. The last-named class are all paid on contract tonnage rates, and the cost line remains very constant. The high cost of underground labor in the first year is noticeable, due to special repair work in the slack time in the spring. While the actual number of men employed on the surface did not greatly vary, owing to the low output during this same period a proportionate increase is noticeable in the cost of surface labor.

Fig. 4 (Dissection of Mine Force) shows the relation existing between the number of men whose names appear on the pay roll and the number of men-days actually worked, these men-days being computed as follows:

$$\frac{\text{Total shifts paid for}}{\text{The number of days mine worked}}$$

The difference between these figures affords a rough indication of how the men are attending their work. The total number of men-days is subdivided, like the cost, into surface men, underground laborers and men mining coal. The relation of the two last-named lines is of peculiar significance, being an indication of the proportion borne by the non-producers or auxiliary workmen underground, to the men cutting coal at the face or the producers. By an adaptation of the scale, the amount of the pay roll can be plotted, as shown, and its relationship to the number of men employed can be followed. If it does not complicate the sheet too much, the number of pit tubs and the number of horses employed in the mine can also be shown, and the one graph will then include the main features of the mine organization and will afford a very interesting record as the years go on. This graph would, of course, show to very much better advantage if lines were plotted in different colors. For example, in the book used by the writer, the lines representing the number of men employed as underground laborers and on cutting coal are plotted in red and blue ink, and their relation one to the other is an unfailing indication of what may be expected in the way of mine costs. Where there are a number of collieries it is usual to keep an "All Collieries" sheet for each separate record, and this sheet can be amplified in the graphical record to suit the larger figures.

Where several seams of different quality contribute to the general output they can be shown graphically as components of the total production and as percentages. In cases where the more valuable seams have been extensively worked for long periods and are becoming exhausted, it is necessary sometimes

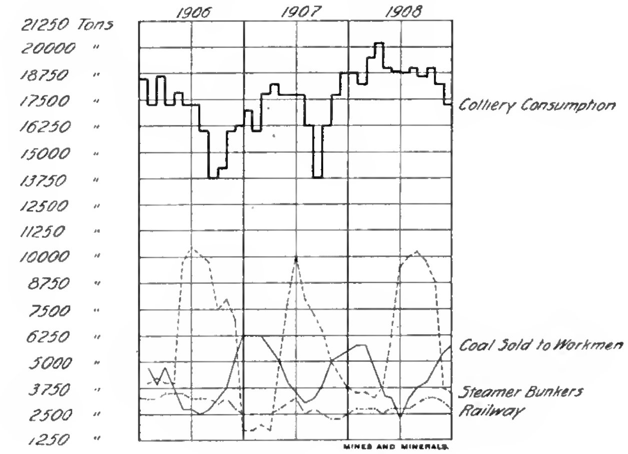

FIG. 6. COMPANY'S COAL CONSUMPTION

to have a correct idea of the proportion of new seams being opened up and their effect on the general output.

The growth of coal-storage banks in the stocking season and their diminution in the shipping season can be well shown. Fig. 5 is an example showing two separate banks at different points. In the last year a third bank is plotted, which accumulated at a new mine before the railroad was put through. The graph shows an increase in the amount of coal stored in bank each year, the gross total being indicated by the peak of the graph, which, it will be noticed, is generally reached in the month of April, at which time the shipping season usually commences. One of the main endeavors of the company, whose stock piles are represented by this diagram, has been to avoid the marked disproportion between the summer and winter work necessitated by climatic and trade conditions. This inequality has, naturally, a bad effect on the organization. The graph shows that the efforts of the company in this direction have been fairly successful.

Fig. 6 illustrates the amount of coal used in "Company's Consumption," showing colliery engine coal, coal used in the bunkers of freighting steamers, locomotive coal used on the railway, and coal supplied to the workmen. The effect of the winter season is seen in the lessened amount of coal supplied for bunkers and the increase in the amount of coal used by the

workmen. Among some of the records that are peculiarly adapted for graphical record are shipments to sales agencies and large consumers, the cost of freighting coal, railway costs, cost of shipping coal, cost of horse keep and many other records which will occur to those who are acquainted with colliery data.

This article has concerned itself more particularly with the notebook of a chief executive, but it does not exhaust the field of the usefulness of the graphical records in colliery work. A colliery engineer will find it useful in keeping a record of his boiler repairs, tube renewals, performance of wire ropes, performance of pumps, etc.

In keeping a graphical record it will be found necessary to give the work to some person having some little knowledge of engineering and draftsmanship, and it will be found necessary to have the plotting done carefully and neatly. It is also well to avoid crowding too many lines into one graph, or carrying the method to an excess and wasting valuable time by arranging and plotting data that is not essential nor useful.

VANADIUM STEEL

Written for Mines and Minerals

To meet the special engineering conditions of recent years, it has become necessary to develop and introduce alloy steels. This has led to the production of a new class of material known as vanadium steel, which may contain, in addition to the usual ingredients, vanadium alone, vanadium and chrome or nickel, and vanadium, chrome, and nickel, and probably some other ingredients as well.

The increasing demand for vanadium steel is due to the high ratio of its elastic limit to its ultimate tensile strength, its great resistance to failure under dynamic stress repeatedly applied, and its great strength and toughness. All of these qualities are necessary requirements in the design of locomotives, automobiles, bridges, and those parts of moving machinery requiring increased resistance to failure through repeated progressive applications of dynamic stresses.

Of the many metals used as alloys in steel for enhancing its good qualities, vanadium occupies the premier position on account of its universal range of applicability in comparison with that possessed by any other steelmakers' alloy. The element vanadium seems to act in several different and well-defined directions, and its incorporation in steel is accompanied by preliminary chemical reactions of the utmost value. It has been noted and confirmed that the increase of strength due to the addition of some method of forming alloy with steel, even if it does not detract from the ductility of the steel to which it is added, or if it enhances the static ductility of that steel, generally renders the metal greatly inferior in its powers of resisting continued repetition of stress, and therefore negatives the improved service value of the material.

Chrome vanadium steels are noted for their great superiority to the maximum resistance which they offer to the breaking-down action of repeated alternations of stress. It is now conceded that the usual tensile-test figures alone do not give any indication regarding the service properties of a metal, and it has been shown that two steels giving the same physical tests for strength and ductility will give widely varying results when placed in use and subjected to moving loads of greater or less magnitude.

The reason for the superiority of vanadium steel is due to at least two causes, namely, the inherent excellence of texture of such steel, and its almost complete freedom from oxides and nitrides, which tend to promote disintegration and gradual rupture under repeated stresses.

Vanadium indirectly toughens steel by sending oxides and nitrides in a fluid form to the slag. Hence any steel containing vanadium is generally free from the occluded gases. Under good normal conditions of operation .7 per cent. of metallic vanadium is sufficient to do this work. Again, under normal conditions vanadium will pass into solid solution in the ferrite or carbonless portion of the iron, which it will directly toughen to a high degree. An alloy containing free vanadium or vanadium combined with another element which will also go into solution in ferrite, such as silicon, must be used, or otherwise direct toughening action will not be obtained. The early experimenters used electrically made ferro-vanadium alloy, but the contradictory results terminated in its abandonment. The high melting point and low degree of solubility of such alloy also added to the difficulties of the steelmaker and contributed to its suppression. It is thoroughly demonstrated by microscopic investigation that ferrites which contain vanadium in solid solution retard segregation of carbides through them to a marked degree. Vanadium steels therefore are susceptible to the improvements conferred by what is generally known as "heat treatment," a term which really comprises the proper annealing and tempering of steel.

The strengthening effect of vanadium on steel is due to the fact that it enters into the formation of carbides of a complex nature, but the strength will largely depend upon the nature of those carbides and the amount of them present for the vanadium to work upon.

Vanadium steel is capable of greater physical improvement by heat treatment than any other class of steel, but this susceptibility to heat changes carries with it the need of performing the heating and cooling with great accuracy. The Carnegie Steel Co. has issued a book on vanadium steel in which is given the minimum physical properties of different types of vanadium steel after heat treatment.

It is stated that to obtain satisfactory results in heat treating vanadium steel, there are three essential features: determination of the correct temperature; an accurate pyrometer for measuring temperatures; and careful heating of the piece to be treated so that the temperature obtained by the pyrometer at any given point is uniform throughout the piece. This means that the element of time must be considered in heating the piece. Most failures in heat-treated steels are caused by not heating uniformly during the treatment. The Carnegie Steel Co. makes suitable grades of vanadium steel to meet the various requirements of the trade. The types are designated alphabetically and the modifications termed "Mild," "Regular," and "Full," are due to variations in carbon content only, the balance of the composition remaining unchanged.

Taking a Type A "Mild," the approximate heat treatment is given as follows: After raising the steel to 1,650° F. it is quenched in water unless the pieces are of a size and shape liable to crack with water treatment when they are quenched in oil, the drawing temperature, however, being lowered about 212° F. After this, the steel is reheated to 930° F. and cooled in air. The physical properties of vanadium steel Type A "Mild" after heat treatment are said to be as follows:

Elastic limit, pounds per square inch, 70,000; tensile strength, pounds per square inch, 90,000; elongation in 2 inches, 22 per cent.; reduction of area, 50 per cent.

Taking again the same brand of steel, raise its temperature to 1,650° F. and quench in water as before. Reheat this steel to 1,290° F. and cool in air. The material after treatment will give, elastic limit, pounds per square inch, 40,000; tensile strength, pounds per square inch, 60,000; elongation in 2 inches, 35 per cent.; reduction of area, 65 per cent. This 30,000 pounds difference between the tensile strength of the same kind of steel is due entirely to heat treatment. From this it will be seen that it is impossible to give a universal strength figure for vanadium steel, and since it may be alloyed with all grades of steel, from the mildest boiler plate to the hardest tool steel, it is safe to say that the strength imparted by vanadium is equal to that of any other alloy, besides it possesses toughness to a greater extent.

GOLD DEPOSITS OF SAN JUAN, COLO.

*Written for Mines and Minerals, by Warren C. Prosser**

Geology of the Country With a Description of Some of the Veins and Mines

The first company to mine in what is now San Juan County, Colorado, was the Little Giant Mining Co., organized in Chicago in 1872. The Little Giant was a gold property and the $150-per-ton ore was treated in arrastras from which the gulch in which they were located was called Arrastra Gulch.

Subsequent developments were mainly on sulphide ores, principally argentiferous tetrahedrite and galena, and Silverton was named as the result of an extensive production of these ores. Lixiviation and smelting works were erected in many places in the county at an early date and several sampling works were operated. Ores were readily marketable and the production increased with the decrease in freight and treatment charges.

Up to 1893 very little gold was paid for in the ores, by the sampling works. A few mines were able to mine gold quartz, in which the native gold was plainly visible, such as the Sunnyside, Sunnyside Extension, and Gold King, but the practical exploitation of gold has been left until today.

San Juan County covers the crossing of the San Juan range with the Rocky Mountains and has for a portion of its eastern border the Continental Divide.

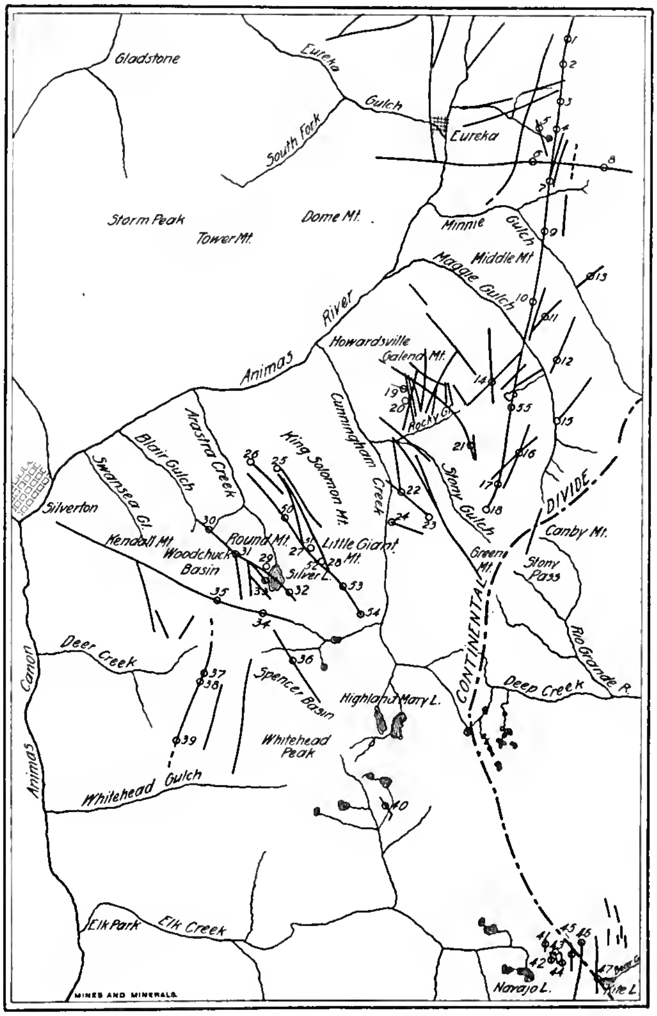
The fissuring attending the formation of the several ranges is complex and greatly diversified.

The directions in which the fissures predominate are northeast to southwest; northwest to southeast, and north to south. The northeast to southwest and the northwest to southeast fissures are attributed to compressive stress, acting along the range of which they are a part in a nearly north and south direction. In the Silver Lake and Galena Mountain districts, the northwest and southeast fissures contain ores of galena, sphalerite, chalcopyrite, pyrite, and tetrahedrite, associated with considerable silver and free gold, usually in the oxidized areas near the surface.

Toward the northern part of the section, the north and south fissures, which are large and well mineralized, are evidently the oldest, as they are faulted by the others.

Besides the stresses in an east and west direction which produced the north to south fissures, and those in a north and south direction which produced the other two sets, minor stresses produced smaller fissures in great numbers.

In the section extending from Hunchback Mountain and the Vallecito River, on the south, to Woods Mountain on the north, silver and gold ores occur. This area is extensive, and, aside from the mines of Silver Lake Basin, Galena, and King Solomon mountains, has been hardly prospected.



MAP OF SAN JUAN REGION, COLO.

The rocks of Bear Creek and Kite Lake sections are Algonkian quartzites and slates in contact with Archæan schists and gneisses, and partly covered with Tertiary andesites and rhyolites.

The fault contact to the north between the quartzite and schists is marked by a long narrow dike-like block of quartzite. The white quartz veins cut through the slates and quartzites at nearly right angles to the folds and faults. They are more clearly defined in the quartzites than in the slates.

The Gold Bug Mine is located on the northwestern shore of Kite Lake. The main tunnel is driven over 900 feet to the Repeal vein, on which a raise has been driven to the surface. The Gold Bug vein was cut at 600 feet in this tunnel, and has been partly developed by shaft from the surface. Sylvanite comprises the principal part of the ore and occurs in pockets of 6 inches thickness or less. Several levels started above the cross-cut, which have all encountered ore, show the existence of ore shoots in the veins at several places. At the Kankakee Mine, to the southeast of Kite Lake, considerable sylvanite and calaverite ore was found while drifting on a vein. The vein is of brecciated quartzite, with the interstices filled with secondary quartz and the telluride minerals disseminated through it. The ore increases in value and quantity as the drift approaches a contact with schist.

In the Hercules property, close to Beartown, the same kind of ore has been found in a porphyry-rhyolite contact.

Other properties in this district are the Sylvanite, Good Hope and Wonder, Robinson, Camp Bird, Golden Shear, Summit, and Little May.

The Gold Mines and Power Co. property is located at Navajo Lakes, across the range, and to the west of Kite Lake. Here a power site is located and the equipment is on the ground to supply this district with electrical energy. The development of this district has been slow, mainly on account of its inaccessibility and the necessity of hand work in hard rock.

The following assays show the proportions of gold and silver in the ore:

	Gold Ounces	Silver Ounces
Gold Bug Mine	158.5	282.5
Kankakee	5.0	1,160.0
Kankakee	20.0	56.0
Hercules	34.0	1,176.0

To the north for several miles are mountains of gneiss and schist, covered at the high altitudes by andesites and rhyolites. The northern contact of this schist is at Mountaineer Creek,

* Mining Engineer, Silverton, Colo.

where there are a set of fissures, one of which traverses the country for many miles across the length of King Solomon Mountain, and has been mined extensively, producing considerable tetrahedrite carrying from 20 to 800 ounces in silver.

Mountaineer Creek heads in Spencer Basin, where considerable free gold in panning quantities has been found on the Gold Lake claims. The gold occurs in quartz veins and stringers in an iron-stained rhyolite. Here wires, nuggets, and flakes of gold are in the quartz and scattered through the spaces between the interlocked crystals.

To the west of Spencer Basin, in Deer Park, considerable free gold has been found in pockets in quartz on the Mabel, Little Ray, and Titusville veins.

In Silver Lake Basin, beside many intersecting fissures, one main fissure crosses the lake, and trending northwest passes through Woodchuck Basin and into the head of Blair Gulch. On this fissure are located the Royal Tiger, Silver Lake, Whale, and Nevada mines, all of which have produced considerable gold. Some of the ore in the Tiger Mine gave returns of 34 and 62 ounces in gold per ton. It was found in the hanging wall to which the sulphide vein had been clinging.

On the northwestern slope of Hazelton Mountain, by assiduous prospecting gold was found in the summer of 1909, on the Big Bull vein, bordering the Aspen Mine, which has been working since 1872. Here the valuable minerals are in quartz veins in porphry dikes.

The Little Giant and Big Giant mines produced gold during the 70's and 80's. Both the veins were apparently minor fissures, branches of the Mayflower, Shenandoah, and Highland Mary fissures. It is singular that these large fissures should have contained gold, while the main fissures produced principally silver.

Galena Mountain, a peak of andesite, surmounting a deposit of Eureka rhyolite, contains many large fissures of varying width, several of which are distinctly visible from Silverton, 5 miles to the southwest. The Old Hundred Mine includes a number of these important fissures, which were developed in 1905–7. From the upper levels $30,000 to $40,000 in gold was caught on the plates of a 40-stamp mill in 30-day intervals.

The dump of No. 2 level of the old Green Mountain Mine shows free gold, which had been overlooked by those who operated the mine in the past. It occurs in the upper oxidized part of the vein, above the sulphides in the lower part of the mine.

In Stony Gulch several important strikes show gold and silver in considerable quantities.

View in San Juan Co., Colo

In the Summit Mine, at the head of the gulch and on the crest of the Continental Divide, ore has been found carrying 4 to 5 ounces in gold and 400 ounces silver.

The Stony Pass Mining Co., just to the northwest of this place, when operating a large quartz vein cut into some gold and silver ore in sinking a shaft, and being forced to abandon the shaft on account of water, a tunnel was driven down the hill to come under the shaft. Where the vein was met in this cross-cut good ore was found, and on driving across the vein 12 feet a concentration of the minerals on the foot-wall was found.

In Stony Gulch the ore is different from the deposits of Bear Creek, or in the properties surrounding Kendall and King Solomon mountains. It consists mainly of finely disseminated argentite and tetrahedrite carrying gold and silver. Some of the mineral taken from the Stony Pass property is sectile and under the blowpipe yields metallic silver readily.

In the Buffalo Boy Mine, in the same gulch and near this property, 5 feet of argentite, profusely sprinkled with proustite, forms an ore worth from $400 to $500 per ton. This was met while drifting on a quartz vein from 6 to 12 feet in width.

To the north of the Buffalo Boy, the Golden Egg group has a deposit of argentite that contains 2 ounces in gold and from 30 to 700 ounces in silver per ton. The quartz in this vicinity is white and the minerals are in bluish streaks and narrow bands which look very little like ore.

The continuation of this vein is judged to be the Gold Nugget vein on the northeast slope of Maggie Gulch on Middle Mountain. Here the values are in argentite, although some free gold occurs in iron rust spots, scattered through the vein matter. Ten thousand dollars was taken from one pocket on the surface of this property.

On the Maggie Gulch slope of Middle Mountain, four prominent veins showing outcrops traverse the side of the gulch diagonally. These are the Gold Nugget, Dewey, Little Maud, and Victor Hugo veins. These fissures are roughly parallel and the vein matter and argentite in them is similar in appearance. They will average from 10 to 12 feet in width.

The Ridgeway vein, which outcrops on the ridge above Crystal Lake, has been developed beyond the prospect stage. It has produced many thousands of dollars, mainly to leasers, operating $40 to $50 ore, streaks of which run 5 ounces in gold and 158 ounces in silver. The ore is chiefly argentite with free gold scattered throughout the quartz gangue in bluish and black streaks in which the ore minerals are scarcely visible to the naked eye.

At the head of Maggie Gulch where it begins to rise abruptly to the foot of Canby Mountain, the Intersection Mine is located on three intersecting veins. A long tunnel has been driven on the Maggie Creek vein and a shaft sunk near the intersection of the Maggie Creek and Iron Mask veins to a depth of 160 feet. The vein is drifted on both ways from this shaft and some stoping has been done above this level. The ore is finely divided argentite disseminated through the quartz gangue, giving it a dark bluish appearance. It is associated with pyrite. The veins are from 3 to 6 feet wide. The property has a five-stamp mill and operates a vanner and concentrating table, which produces a heavy pyrite concentrate, besides amalgam on the plates.

Farther down Maggie Gulch is the Victor Hugo Mine. The vein at this mine is white and yellow quartz from 3 to 12 feet wide, and outcrops on the slope of Maggie Gulch and over on the other side of Middle Mountain in Minnie Gulch. It has been opened on three levels from which considerable $40-per-ton ore was extracted by stoping to surface from the third level. The ore is argentite, associated with iron oxide, pyrite, and free gold. The lower tunnel, in over 900 feet, shows white quartz for over 800 feet, when the formation changes abruptly from a rhyolite tuff to a hard pyroxene andesite. The ore is said to be better and more stable after it passes into the andesite. A mud streak almost at right angles to the vein shows the fault line between the two formations.

Between the Victor Hugo and the Gold Nugget veins is the Little Maud Mine, located on a large quartz vein roughly parallel with them. This mine, opened by a long tunnel, has been developed mainly by leasers, who have worked some rich argentite ore containing more or less gold.

In Minnie Gulch the extension of the Gold Nugget vein is

probably the All O. K. which outcrops in the cliffs on Crown Mountain. At the point where it is first exposed near the base of the cliffs an ore shoot was found that gave assays of 22 ounces in gold and 127 ounces in silver per ton. Several tons taken from this place returned $86 per ton from the smelter. About 600 feet farther up the hill ore has recently been found assaying 2.65 ounces gold and 400 ounces silver per ton. On this property the vein is from 5 to 20 feet wide and is held in andesite walls. It is faulted by several east and west veins and veins of the other two general sets, showing it to be a member of the oldest family of fissures. To the east of this vein is the Parallel vein, which is 25 feet wide, of solid quartz. Its course is slightly divergent from the O. K. vein, and as they pass over the crest of Crown Mountain and down into Niagara Gulch the Parallel vein is several hundred feet to the east. On the northern slope of Crown Mountain, the O. K. vein outcrops down the mountain side where it is hardly accessible. It continues over Niagara Mountain and through the Golden Hammer and Grand Potentate veins. On Jones Mountain it is prominent, and on the ridge is nearly 50 feet wide, showing about half and half white quartz and calcite. It descends into Burns Gulch on the Broadgauge vein, where considerable sulphide ore was found with free gold. It has been traced up over the succeeding mountains through Grouse Gulch and Cinnamon Pass into the faulted area of Woods Mountain.

It is noticeable that the east and west veins, crossing the north and south fissures are heavily laden with sulphides as a general rule. In Silver Lake Basin and on King Solomon Mountain this may be observed in the Silver Lake-Tiger vein and on the North Star-Shenandoah vein. On Galena Mountain the northwest to southeast veins contain sulphides, as do also the Pride of the West and the old Green Mountain veins. In Maggie Gulch, near its mouth, the Hamlet vein, one of this set, is strongly mineralized. It has been explored 1,400 feet in vertical depth and 1,800 feet into the hill, disclosing heavy copper and zinc sulphides.

In Minnie Gulch the Tantallon-Joyce vein of the Peerless, San Juan, and Kittemac mines shows abundant lead, copper, and zinc sulphides, and in Niagara and Burns gulches are more of the same kind.

Two periods of dynamic action are represented by the most important veins of this section. The north and south set were probably formed by the upheaval of the San Juan Range and the second set by the rearrangement that followed. That a third disturbance followed is evidenced by the veins on King Solomon Mountain, Galena Mountain, and other places along this section, which fault both the other sets of fissures, but which lend little to the mineralization of the section.

Cyanide tests made on the ores of the Bear Creek region, from the Buffalo Boy, Ridgeway, Intersection, Gold Nugget, and Esmeralda mines indicate over 90 per cent. recovery. There appears to be no difficult metallurgical problem involved in the cyanidation of the gold ores of this section, as none of the undesirable factors are present in amounts that would seriously interfere with the process.

Below are several assays from the mines of the Bear Creek section, which shows the relation of the gold to the silver, but not the average gold and silver content:

	Gold Ounces	Silver Ounces
Summit Mine	5.00	400.0
Buffalo Boy	3.80	200-3,400
Golden Egg	4.68	67.6
Intersection	25.00	
Victor Hugo	4.00	1,160.0
Little Maud	80.90	1,160.0
Little Maud	11.50	80.0
Gold Nugget	28.00	1,333.0
All O. K.	22.00	127.0
Ridgeway	5.50	158.0

This paper does not cover all the mines and good prospects of this section, but includes some of the most important to show the existence of an area mineralized with the gold and silver. The interest displayed in San Juan County is bringing out almost daily important features which shed more and more light upon the ore occurrence.

METAL MINE VENTILATION

Good ventilation is not merely a legally recognized necessity for the preservation of health, but has an important economic aspect in its effect on the industrial efficiency of the workman and the cost of mineral production.

The Final Report of South Africa Mining Regulation Commission

The necessity for ventilation in metalliferous mines arises mainly from the injury to health caused by the presence in the mine air of fine dust, of the poisonous gases produced in blasting, and of human emanations, respiratory and other.

The ventilation of mines may be (*a*) natural, and (*b*) artificial or mechanical; natural ventilation depends upon (1) the difference in temperature and humidity, and consequently in weight, between the air in and out of the mine; (2) the absolute humidity of the outside air; and (3) the difference of level between the mouths of the connected shafts; natural ventilation has the advantage of being inexpensive, but is subject to the following drawbacks; viz., (1) the amount of air supplied depends upon conditions beyond control, and independent of the varying mine requirements and hygienic necessities; (2) as the temperature and humidity of the outside air approximate to that of the mine air, the ventilating current diminishes and may completely disappear; (3) the direction of the air-current is variable.

Natural ventilation is supplemented on the Witwatersrand by the exhaust air from machine drills; this supply is of great local importance as it is delivered at the working place, but the amount only constitutes a fraction of what is required for the proper ventilation of a mine, and its beneficial effects do not extend for more than 100 feet from the face; some miners are prejudiced against compressor air, though there is no evidence that it is injurious to health; it stirs up from the sides and floor of the working place the dust which is the principal cause of miners' phthisis, and occasionally contains some of the poisonous gas *CO* derived from the accidental combustion of the oil used for lubrication.

Judged by the relative frequency of gassing accidents, natural ventilation is on the whole not so effective on the Witwatersrand as on some other fields, this inefficiency being probably due to (1) the very slow rise of the rock temperature as depth increases; (2) the high temperature and humidity of the outside air at certain seasons; (3) the great extent of the underground workings and large number of men at work; and (4) the large consumption of explosives in blasting, and consequent production of great quantities of poisonous gases.

Artificial or mechanical ventilation is effected by means of either (*a*) the extractive force of a furnace at the bottom of the upcast shaft; or (*b*) fans—usually exhaust fans—at the top of the upcast shaft; at the East Rand Proprietary and Cinderella Deep Mines the total running cost of an extremely effective installation is under 1d. per ton milled.

The degree of ventilation in a mine may be measured either by (*a*) a quantity standard, that is, the quantity of pure air entering the mine per minute; or by (*b*) a quality standard, this being a determination of the amount of impurity present; the existing Transvaal law provides for a quantity standard of 70 cubic feet per man per minute, and also for the splitting of the current and distribution of the air over the working faces; the application of this standard is open to very serious practical difficulties; the provision as to distribution is not enforced,

probably because attempts to direct natural air-currents usually merely retard them, and the quality standard is better adapted as a general indication to mine inspectors than as a basis for legislation.

The object of a quality standard is to fix the permissible amount of air vitiation, and for this purpose the quantity of carbon dioxide present is accepted as bearing a roughly constant proportion to the amount of impurity present.

Our knowledge of the exact nature of such impurity is incomplete; there is no reliable evidence to support the former belief that during respiration the lungs exhale a volatile organic poison; the immediate ill-effects, headache, general discomfort, etc., of bad ventilation are probably the results of the oppressive smell which arises from the breath, bodies, and clothes of those present, and is caused by very minute quantities of volatile substances present in the air.

According to Pettenkoffer (1858), Dr. J. S. Haldane, F. R. S., and other modern observers, this smell becomes distinctly perceptible when the carbon dioxide CO_2 in the air exceeds 10 volumes per 10,000; but in 1875, De Chaumont recognized it in barrack rooms when the CO_2 reached 6 volumes per 10,000.

Continued subjection to bad ventilation means increased liability to disease, and especially to infection produced by organisms present in the mouth and air passages, and conveyed directly through the air from person to person.

Doctor Haldane, F. R. S., who has closely investigated the subject and is the foremost British authority thereon, considers that the worst consequences of a defective air supply are "the evil effects produced by inhaling poisonous or infective dust"; he doubts that "constant exposure to volatile respiratory impurities has by itself a very great influence on health," and agrees that carbon dioxide is "the best objective criterion of the sufficiency of ventilation."

In mines, the highly poisonous gases, carbon monoxide CO and nitric oxide NO_2 are also present, the result of the detonation or of the burning of explosives; in dead ends, and immediately after blasting, the ratio of CO_2 to CO in the gases produced by explosives in local use averages 1 to 12, and therefore CO_2 serves in some degree as an index of this danger (presence of CO).

Carbon dioxide, unaccompanied by any injurious substances, is in itself innocuous in quantities under 1 per cent. Of this nature are the normal atmospheric CO_2, amounting to 4 volumes in 10,000 of air, the CO_2 produced by open lights and by the action of acids on carbonates.

The difficulty in fixing a quality standard lies in the impossibility of distinguishing between the noxious and innocuous CO_2 when both are present together.

On the Witwatersrand the only innocuous CO_2 known to exist in appreciable quantities is the normal atmospheric CO_2, and that produced by open lights.

Exhaustive inquiries made by the Mines Department show that a considerable body of carbonates which could give rise to CO_2 by the action of acid water, is present in the workings of one mine only, the remainder having either no carbonates at all, or only inappreciable quantities in the shape of flakes in fault planes, or as an occasional stringer adjoining a dike; in view of the minute percentage of acid in mine water, there would generally be in these places a sufficient excess of water to hold in solution the CO_2 generated, and as mine air is nearly saturated with moisture, it is improbable that any dissolved CO_2 would subsequently be released by evaporation.

In the Lydenburg and other districts, and in base metal mines, masses of carbonates occasionally exist in proximity to very pyritic reefs, and a considerable amount of innocuous CO_2 may be locally produced.

It was suggested to us that additional quantities of CO_2 might be produced from the following sources; viz., (1) "ground" gas contained in rock cavities, or occluded in quartz pebbles in the banket and in the grains of quartzite; (2) from the oxidation of food and timber, evaporation of stagnant water, and decomposition of animal waste.

We find that cavities containing CO_2 are practically unknown in the Witwatersrand metalliferous mines; that the occluded gases would not be liberated under the conditions of underground work, and are in any case noxious, containing a large percentage of the poisonous CO; that the oxidation of timber and food would produce quantities of CO_2 too small to affect any standard of vitiation, and that the gases from stagnant water and animal waste are inappreciable and offensive or noxious in character.

Careful experiment was made at the Langlaagte Deep Mine, under the supervision of the Mines Department, to ascertain whether any production of "ground" CO_2 could be inferred from the difference between the estimated amounts of CO_2 entering and leaving the mine; the possibilities of error in the assumptions upon which the estimates were based appear so considerable, and the results calculated on different assumptions so widely discordant, that we regard the various Langlaagte Deep results as inconclusive, and in this view we are supported by the Government Mining Engineer.

In the absence of any theoretical source of any appreciable quantity of "ground" CO_2 in the Witwatersrand metalliferous mines, we consider that practically the whole of the noxious CO_2 is due to respiration and explosives, including fuse, etc., and that the innocuous CO_2 is derived from the atmosphere and open lights only.

The limits for noxious CO_2 previously recommended or embodied in legislation are as follows:

(*a*) Five volumes per 10,000, by the Roscoe Committee (1896) on the Ventilation of Humidified Factories. This was legalized under the Cotton Cloth Factory Act, and also in the Factory and Workshops Act, 1901.

(*b*) Eight volumes per 10,000, by Haldane's Committee (1902) on Ventilation of Factories and Workshops. This standard now regulates all factories, including humidified, in the United Kingdom.

(*c*) Eight volumes per 10,000, by West Australian Mines Regulations Act.

(*d*) Six volumes per 10,000, by New South Wales Mines Act.

(*e*) Eight volumes per 10,000, by Victoria Mines Act, 1907.

Because we cannot definitely state that there is no material quantity of "ground" CO_2 in the mines of the Rand, though we believe that the actual amount, if any, is small, we propose that a working allowance of 5 parts in 10,000 be made for it, and for CO_2 from other uncertain possible sources, with the sole object of fixing a standard which is practicable from the administrative point of view, and which will enlist the voluntary cooperation of the mines in its enforcement; and, in view of our recommendation (see below) as to a CO limit, and as to sectional and local ventilation, the prevention of dust and fumes, the total limit of 20 parts of CO_2 per 10,000 is well within the limits of safety, is reasonable and easily obtainable, and should be enforced.

We therefore recommend as follows (see Draft Regulations 56–63):

GENERAL VENTILATION

(*a*) That the legal maximum for noxious CO_2 permissible in mines in the Transvaal be fixed at 8 parts by volume in 10,000 of air.

(*b*) That an amount of 4 parts of CO_2 by volume in 10,000 of air shall be allowed in addition to the aforesaid maximum as representing innocuous CO_2 normally present in the atmosphere.

(*c*) That where candles or similar illuminants are in use, a further addition of 3 parts of CO_2 by volume in 10,000 of air shall be allowed as representing innocuous CO_2 resulting from the combustion of such illuminants.

(*d*) That in order to meet, from the point of view of practical administration, difficulties in regard to possible innocuous

CO_2 from "country rock" and other uncertain sources in the mines of the Rand, a further allowance of 5 parts per 10,000 be made, making a total limit of 20 parts of CO_2 per 10,000 of air.

(*e*) That in the Lydenburg and other districts where there is geologically strong presumptive evidence of a production of ground CO_2, early investigation be undertaken by the government, and that a proper and reasonable allowance be made therefor, the total amount in the mine air not to exceed 1 per cent. by volume.

(*f*) That all samples for testing purposes under these provisions be taken not less than one hour after blasting.

(*g*) That each mine be informed of the results of any official analyses of the air therefrom, and notified that the ventilation is defective when the above proportions have been exceeded, and at the same time supplied, so far as practicable, with information as to the nature of any defect noticed; and that legal proceedings be not taken against a mine unless, after a reasonable interval following such notice, the stated proportion is found on examination of one or more samples to be again exceeded, and the mine is unable to show that steps have been taken reasonably calculated, in the opinion of the Government Mining Engineer, to secure the requisite ventilation.

(*h*) That any analysis on which a prosecution immediately depends shall be made by a specially qualified person.

(*i*) That arrangements be made for inspectors of mines to have the use when desired of a properly tested portable apparatus for estimating on the spot the proportion of CO_2 in the air.

With regard to the very interesting question as to the necessity for correcting the proposed CO_2 limit for the altitude of the Rand, the evidence is somewhat conflicting, and many samples will be taken at considerable depths, and therefore we do not recommend any addition on this account to the proposed standard.

In view of the extremely poisonous effects of CO and NO_2 on the human system, and the frequency of gassing fatalities on the Rand, we also recommend that the maximum permissible amount of CO in any part of a mine shall not exceed .01 per cent., and no practically determinable amount of NO_2 shall be permitted in any part of a mine.

SLIME SETTLER OR DEWATERER

*By Rollo E. Huntley**

The settler here described has been in use at the Brownhill Consols Gold Mine, Kalgoorlie, W. A. for the past 18 months, handling the product of a public crushing mill, varying from exceedingly light oxidized, to dense sulphide, ores, and has always given satisfaction. The points to be noted in its favor are: (*a*) Cheapness; (*b*) efficiency; (*c*) simplicity of erection; and (*d*) very little attention necessary.

The settler consists of a circular vat with central inflow of the pulp, and peripheral overflow of the clear water. The thickened slime is discharged by means of a centrifugal pump drawing from the center of the bottom.

The vat is made of 22-gauge corrugated galvanized iron, 20 feet in diameter, by 5 feet deep, with plain galvanized-iron bottom.

It is also provided with a false bottom in the shape of an inverted cone made of 1-inch jarrah†, with a fall of one in nine to the center. This false bottom is made of 6″×1″ jarrah, in 9′ 2″ lengths, sawed diagonally from ½-inch wide at one end to 5½ inches at the other. The large end is placed in the corrugation in the side of the vat, 12 inches above the real bottom, and the small end is butted up against a 2-foot diameter ring of 1-inch square iron, bolted in the center of the bottom.

These jarrah sectors are spaced about ⅛ inch apart, and allowed to slime up underneath, thus forming a solid conical bottom.

The overflow from the sand collecting vats is run to the middle of the settler, where it is received in an "inflow bucket" consisting of a 9-inch diameter funnel, which leads the pulp 6 inches below the surface of the settler when full. The funnel is surrounded by a 15-inch diameter bucket, the overflow of which is 3 inches below the surface.

This "inflow bucket" is most essential, as it secures a quiet and evenly distributed flow of the pulp into the settler, thus preventing any disturbance of the already settled slime.

The clear water flows over the entire rim into an annular launder made as part of the vat. To insure an even overflow, 6″×½″ pine matchboard is bolted round the periphery and leveled with a plane as desired.

When full of thick slime to within a few inches of the top, the inflowing pulp is sent to another similar vat. After settling for half an hour, any clean water is siphoned off, and the sludge transferred to the agitation vats, by a 4-inch centrifugal pump, driven by an 8-horsepower motor, with power from the Kalgoorlie Electric Power and Lighting Corporation.

The pump has a 4-inch suction and two 3-inch deliveries. It draws from the apex of the inverted cone bottom, and delivers part of the sludge to the filter-press agitation vats, and part back into the settler to dislodge and mix the densely settled slime. The amount sent to either place can be regulated by means of a valve on each delivery.

While the settler is being emptied, a jet of cyanide solution is run in to thin down the slime.

Instead of using a valve, the suction is opened and closed by means of a wooden plug at the end of an iron rod, which passes through a guide near the bottom of the vat and projects above the surface near the inflow.

When milling with fresh water, such a settler will give a clear overflow from five stamps on oxidized, and eight to ten stamps on sulphide or clean quartz ores. The use of lime nearly doubles the capacity for settling, but the resulting slime holds more moisture.

Running on average Kalgoorlie oxidized ores, the overflow from the sand collectors contains from 4 to 8 per cent. of solids, and is thickened in the settler to from 50 to 70 per cent. of solids.

The sludge is always thinned down with cyanide solution during the process of emptying the settler.

The time required to empty one vat containing from 30 to 40 tons dry slime is 1½ hours, and the cost when handling 900 tons per month is 2½d. per ton from mill to press.

The only attention necessary is that of one man for 1½ hours when emptying.

From a metallurgical point of view it is a success, the agitation through the centrifugal pump and the aeration caused by pumping some of the sludge back into the settler both tending to improve the extraction.

The cost of emptying could be considerably reduced by placing the settlers over the agitation vats, and discharging by gravitation, but it is doubtful if such saving would not be at the expense of the extraction in places where only mechanical agitation is used.

Vats of greater depth and diameter could be economically used, but would probably need larger pumps, and would either have to be made of steel, or corrugated iron buttressed with sand, as these vats in larger sizes than 20 feet tend to go out of shape when full.

*Australian Mining Standard.

†An Australian tree which is not attacked by any of the usual organisms of and or water that produce decay in wood.

TOTAL GOLD PRODUCTION OF ALASKA

The total gold production of Alaska at the close of 1909 was $162,686,455, of which $118,219,757 came from placers and $44,466,698 from lodes. The record of production begins with 1880.

ZINC MINING AT YELLOW PINE, NEV.

Written for Mines and Minerals, by Newman B. Gregory, B. S.

In Clark County, Southern Nevada, about 45 miles south and west of Las Vegas, is the Yellow Pine mining district, an area which, owing to the character of its ore deposits, presents a new feature in the western mining industry.

The Discovery and Development of Large Deposits of Zinc Carbonate

Ever since the Mormons discovered the Potosi Mine, in about 1860, mining of lead-silver ores has been carried on in a fitful manner. Until the advent of the Salt Lake Railroad in recent years, the remoteness of the district from railway and smelting facilities precluded the shipment of any but the best of these ores.

The discovery of oxidized zinc ores at Leadville 4 months ago in drifts which had been cut for over 20 years, and the oxidized ores plainly disclosed, but unrecognized by mining engineers, geologists, and mineralogists, illustrates the limitations of ordinary human discernment; and the discovery of zinc ores in the Yellow Pine district is only another example of such limitations. Deposits of zinc carbonate and silicate ores equaling any known deposits of their kind in the world occur in the Yellow Pine area, and it was not until 4 years ago that the true character of these deposits was accidentally discovered.

FIG. 1. YELLOW PINE MINE, YELLOW PINE, NEV.

In mining the lead-silver ores the miners found dikes of a brittle, light-colored material which they took for granted was nothing but vein matter, and carelessly threw it on the dump piles. This "vein matter" was eventually identified as zinc ore, which, on being assayed, showed a high percentage of zinc. An investigation was started, innumerable samples assayed, and it was discovered to the astonishment of every one in the district that the mines contained 10 tons of zinc ore to 1 of lead.

Outside of Goodsprings, the town nearest the mines, and the few neighboring camps, this discovery created almost no excitement, because, with the nearest zinc smelter some 2,000 miles distant, and the nearest railroad a dozen miles away, these ore bodies seemed to be valueless.

In the face of these discouraging conditions a few of the operators decided to determine the possibilities of the newly-discovered ore bodies, believing that with the opening up of a large quantity of an ore which is very much in demand, reduction works would necessarily be erected, thus making of these oxidized ores a commercial product.

Continued development work attracted the attention of the zinc smelters in the United States, and in 1906 the first carload of zinc ore, consigned to Kansas points, was shipped out of the district. Since that time probably 400 or 500 cars have been shipped to the Kansas zinc smelters, and the general average of these shipments has assayed in the neighborhood of 40 per cent. zinc. When it is considered that this production has been made in the face of high wages, almost without the use of machinery, a long and expensive wagon haul to Jean and other shipping points on the Salt Lake Railroad, and a freight rate of $8 per ton, results and achievements of the miners of Yellow Pine district show conclusively the richness of these newly-discovered zinc deposits.

A large tonnage of clean zinc ores has been developed in several of the mines, but an even larger tonnage of mixed zinc-lead-silver ores has been found, these ores assaying on an average 30 per cent. zinc, 15 to 20 per cent. lead, and 12 to 15 ounces of silver to the ton Owing to the difficulties attendant upon an effective separation of these metals, it was not until 1909 that a market for these mixed ores was established.

The smelting companies engaged in the business of manufacturing oxide found this ore to be an especially desirable raw product for making a high-grade zinc-lead pigment, and since 1909 a large quantity of such ores have been shipped at a fair margin of profit to the miner.

Goodsprings operators now find a ready market for all kinds of ore which they produce. In contrast with expensive methods of milling low-grade zinc ores, the ores of this district require merely breaking down, hoisting, hand sorting, and shipment.

Ore occurs practically from the surface to the greatest depth attained by any of the mines (600 feet), and will very probably continue downward to water level and beyond. Not a drop of water has been encountered in any of the mines, and the depth of ground water level has never yet been determined.

The country rock is a Carboniferous limestone and is traversed in every direction by porphyry dikes. The ore deposits are the result of replacement and oxidation in limestone, and are in all cases closely associated with the porphyry.

The Yellow Pine, the Potosi, Monte Cristo, Prairie Flower, Hoodoo, and a number of other mining properties, have been producing these zinc and zinc-lead-silver ores, and are now engaged in the development of an increased tonnage.

Closely associated with the zinc deposits, but occurring practically free from zinc ore, are found deposits of galena and cerrusite ($PbCO_3$), averaging about 60 per cent. metallic lead and carrying silver.

In addition to the production of oxidized zinc ores, the mixed zinc-lead-silver ores, and lead-silver ores, the Yellow Pine district has produced copper and gold ores.

Copper ores carrying some gold and silver are found generally throughout the district, and about 2,000 tons of the higher grade ore has been shipped to the smelters. Copper occurs principally as a carbonate, but when found in porphyry dikes, is in the form of a sulphide.

Previous to the building of the San Pedro, Los Angeles & Salt Lake Railroad, the production of gold from the Keystone and two or three other mines, was the chief resource of the district. The metal is found in irregular masses of iron oxide or mineralized porphyry and requires a close study of the ore formations, due to the extensive faulting to which the region has been subjected, in order to avoid losing the ore chutes. As an example, the Keystone Mine has been repeatedly closed down, the miners thinking the ore was exhausted. Intelligent cross-cutting by some more venturesome operator has disclosed a large body of ore. This mine was discovered 17 years ago, has produced over $1,000,000, and today has sufficient low-grade ore developed to keep a large mill running for a number of years.

The Spring Mountain range, about 25 miles in length and 8 miles in width, is included in the Yellow Pine area, and it is in this range that nearly all the mines are located. Practically every square mile of the entire area has mineral croppings of some kind.

The discovery of zinc ores has naturally overshadowed all other resources. Recently strong financial interests have entered the district, taking over 14 of the better properties and starting construction work on a standard-gauge railroad from Jean, the shipping point on the Salt Lake Railroad, to the Yellow Pine Mine, a distance of 12 miles. Switches will undoubtedly be run as needed from this new spur to everything on the east side of Spring Mountain range. In order to eliminate the heavy cost of freight to Kansas smelters and Wisconsin oxide plants, these same interests are putting in an oxide plant at San Pedro.

Fig. 1 shows the derrick and hopper at Yellow Pine Mine with sorting table near the foot of the hopper. The ore is trammed from the sorting table to loading bins shown at the right, and from there is loaded into wagons to be hauled to the railroad at Jean.

The acquisition of 14 properties practically guarantees to the new company a plentiful supply of ore; the construction of a standard-gauge railroad will almost eliminate the cost of hauling by wagon, effecting at once a saving of nearly $3 per ton of ore; and the erection of their own oxide plant at San Pedro effects a saving in freight charges of about $6 per ton. In addition to this the profit derived from the manufacture and sale of oxide must be considered.

In the event that this pigment finds a ready market in the western states, the saving effected by these improvements will certainly exceed $10 per ton. Should it become necessary to send the oxide to the central or eastern states to find a market, the cost of the freight on the finished product must be deducted from this saving.

Such conditions cannot fail to directly benefit every miner and to result in a markedly increased activity throughout the Yellow Pine area.

LAKE SUPERIOR COPPER ORE

The Lake Superior copper producers are spending millions of dollars in efforts to reduce the cost of manufacturing copper and they have been successful to the extent that all of the money spent toward this end, and probably much more, has been returned during the last three years.

Costly regrinding machinery, new and the latest improved slime tables, tubular mills and other machinery for the big stamp mills have been purchased. Large buildings constructed entirely of steel, and covering acres of ground, have been erected at Lake Linden, by the Calumet & Hecla Co. in an effort to cut down the cost of manufacturing copper.

The Copper Range Consolidated, Wolverine, Mohawk, Quincy, Franklin, Hancock. Osceola, and other companies are following closely in the footsteps of the Calumet & Hecla in this regard. The Wolverine probably manufactures copper at less cost per pound than any other company in the district, and yet this company is making efforts to further reduce costs. The Calumet & Hecla is installing at some shafts more powerful and improved hoisting apparatus, rock crushers, and other machinery. The Hancock is erecting steel head-frames and rock houses, as the steel buildings will last indefinitely. The Quincy is replacing wooden with steel structures. High-salaried mining engineers, metallurgists, and millmen, are employed to figure out places where producing expense may be cut down.

The Calumet & Hecla Co. is striving to so reduce costs that 10 pounds of copper will pay for the milling, mining, etc., of the rock and the marketing of the copper from 1 ton. The company's rock probably average 20 to 23 pounds of copper to the ton. Figuring that the average is 20 pounds to the ton, the company will make as much from its tonnage, when it reaches its goal in the reduction of costs, as it expends on this tonnage. The Calumet & Hecla has made more profits for its stockholders than any other copper mining company in the world.

It is feared that No. 7 shaft of the Quincy Mine, which has sent out into the industrial world the finest copper ever mined, and probably more of it than any other one shaft, is nearing the limit of its depth. As the shaft goes down the runs of stoping ground are rapidly growing shorter. This does not mean, however, that the ground developed will play out in the near future, for the higher runs of stoping ground will furnish an enormous tonnage for many years to come. Quincy is earning more than $1.25 per share per quarter, or $5 per year, and has been paying dividends longer than any mine in this district, about a half century.

There are no leaks in the Quincy system, the power plants, mills, and underground workings being kept in the best of condition. The company's underground motive power is electricity, the trains in the drifts at every level practically being hauled by trolley locomotives. It is probable that electricity will be substituted for steam, within the next two or three years, to haul the rock to the mills.

The Isle Royale, which was a losing proposition for many years until the last year, and which is now under Calumet & Hecla management, is beginning to make a fine record. The property is being developed at a rate that will turn out 9,000,000 pounds of copper per annum and it is only beginning to produce.

The Algoma lode took so sharp a change in dip that the shaft ran over the ore at approximately 100 feet. At 104 feet sinking was stopped and a cross-cut driven in the foot-wall with the result that within 10 feet ore was found and drifting commenced at this depth although the intention was to commence at the 200-foot level.

Calumet & Hecla, the largest planet in the copper firmament, scintillates with increased brilliancy as the decades of its existence are extended. This inspiration comes not from Kentucky, nor yet from lake moonbeams; on the contrary from Beanville where tightwads are paying $600 per ticket.

The Tamarack is said to be recovering from 2½ to 3 pounds copper more than formerly from each ton of ore stamped. Assuming this to be true and that as much ore was stamped in 1910 as in 1909 the additional yield for 1910 would be 1,722,747 pounds copper.

After a long time prospecting at the Seneca Mine, the Kearsage formation was found at the 920-foot level, and in the drifting so far as advanced the mineralization is satisfactory.

The advantages to be derived from persistent and intelligent prospecting are nowhere so apparent as in the Lake Superior copper region. As an illustration, take the Ojibway, which a few months ago offered little encouragement, but which for several weeks past has been drifting in ore on the 500-, 650- and 800-foot levels. The La Salle Co. has a large acreage, which is traversed by all the paying formations in the district yet its Tecumseh shaft is producing only a lean ore carrying .6 per cent. of copper per ton. Judging from the history of the field the La Salle problem is one of sufficient money for continued and intelligent prospecting and the company has probably the former for the latter.

The Michigan company has a territory covering 5,000 acres, traversed by most if not all the lodes in the Lake Superior copper district. Drifting at the adit level exposed bunches of copper and drifting on a level 180 feet below gave better indications. The rock contains wire and shot copper. Diamond drill sections are being made for a distance of 9,000 feet to obtain a complete cross-section of the land from the Butler lode to the eastern sandstone. From a geological standpoint these should be extremely interesting. In the drilling so far conducted, the lode of greatest promise is the Ogima, from which three cores have been taken, all of which carry copper. The lode is a chocolate-colored amygdaloid with quartz and analcite gangue from 12 to 15 feet wide at all three places, with copper uniformly distributed.

DE WILDE PRECIPITATION PROCESS

*By G. Witteveen**

In 1895 P. de Wilde, Honorary Professor of the University of Brussels, published a process for the extraction of gold from the solutions obtained in cyanide practice. Shortly, this process consists in acidulating the solutions by means of sulphuric acid with the addition of cuprous chloride (Cu_2Cl_2). The yellowish precipitate which is immediately formed, consists of an intimate mixture of aurous cyanide ($AuCN$) and cuprous cyanide ($(Cu_2CN)_2$). Professor de Wilde patented his process in the Transvaal, and about 10 years later, in February, 1908, extended his claim to the extraction of silver. The writer made some experiments as to the practical utility of this latter method. According to the Belgian patent the process is carried out in the following manner:

Precipitating Gold and Silver From Cyanide Solutions Either Alone or Both Together

First Operation.—The solutions contain the gold and silver, as soluble salts of alkaline cyanides, moreover an excess of alkaline cyanide, and often caustic soda, carbonates, lime, etc. A strong acid, such as sulphuric acid, diluted to about 20 per cent., containing in solution an alkaline chloride such as chloride of sodium, is added while agitating until blue litmus paper shows an acid reaction. The salt may be dissolved first, and the acid added afterwards.

The acid neutralizes the alkaline matter, as well as the free and combined cyanides and liberates the hydrocyanic acid which remains in solution, while the cyanides of gold and silver are set free. The sulphuric acid also decomposes the metallic chloride, liberating hydrochloric acid, which acts on the cyanide of silver and transforms this into insoluble chloride of silver and hydrocyanic acid. The amount of chloride required is calculated from the amount of silver cyanide to be decomposed, and to make sure a small excess of salt is used. The precipitate is filter pressed and gives a pure bullion.

Second Operation, Precipitation of the Gold.—The liquid coming from the filter press contains free cyanhydric acid and gold cyanide. The gold is now precipitated by adding a copper salt, by preference cuprous chloride (Cu_2Cl_2) dissolved in the solution of chloride of sodium. Only a very small quantity of cuprous chloride is necessary to obtain a complete precipitation of the gold. The cuprous chloride forms with the cyanhydric acid copper cyanide ($(Cu_2CN)_2$), which combines by molecular attraction with the gold cyanide. This precipitate settles easily after some agitation, and can be separated after decantation or filtration. To have a complete precipitation of the gold, there must be about seven times as much copper cyanide as there is gold cyanide. Treating the gold-copper precipitate with chlorhydric acid, or a mixture of diluted sulphuric acid and chloride of sodium, the copper cyanide is dissolved without being decomposed and the gold cyanide is left behind. This is collected and smelted. The chlorhydric solution of the copper cyanide can be used again.

Third Operation, Regeneration of the Cyanide.—After the separation of the gold-copper precipitate the liquids contain all the cyanide as free cyanhydric acid, less the small quantity combined in the gold-copper precipitate, and the very small quantity carried away by the volatilized cyanhydric acid. It is then only necessary to neutralize the solution by an alkali to regenerate the cyanide.

First and Second Operation Combined, Simultaneous Precipitation of the Gold and Silver.—The first two operations may be executed at the same time. After precipitation of the silver and without removing this, the gold can be precipitated by the solution of cuprous chloride in chloride of sodium, or by the chlorhydric solution of the copper cyanide. Thus, the copper cyanide can be used over and over again.

* Paper read before the Institute of Mines and Metallurgy, Mexico.

In the treatment of the gold-silver cyanide solutions, Professor de Wilde claims as his invention: First, the complete precipitation of the silver as a chloride by the action of chlorhydric acid, or by a mixture of sulphuric acid or some other strong acid, with a metallic chloride (first operation). Second, the complete precipitation of gold cyanide by a copper salt and its fixation by molecular attraction on small quantities of copper cyanide, which nevertheless are sufficient to get a precipitate formed by a mixture of the two cyanides (second operation). Third, the combination of the two operations, so as to get in the same liquid a mixed precipitate, containing all the values as a cyanide of gold and copper and as a chloride of silver. Fourth, the repeated and indefinite utilization of the copper cyanide. This is about the process as it is described in the Belgian patent. The reactions upon which the process is based are doubtless correct. Taking the case of silver, this is present as the potassium silver cyanide salt $[KAg(CN)]_2$. By adding sulphuric acid, the silver cyanhydric acid is set free, thus, $2KAg(CN)_2+H_2SO_4=2HAg(CN)_2+K_2SO_4$. The silver cyanhydric acid, however, is such an unstable compound that it immediately is decomposed to cyanhydric acid and silver cyanide $HAg(CN)_2=HCN+AgCN$. In the same way the insoluble aurous cyanide is set free, but its quantity in the liquid is so small that it has to be carried down by another insoluble compound. That is the reason that for the precipitation of the gold a copper salt is added. Since there is a great molecular attraction between the aurous cyanide and copper cyanide, copper salts answer very well for this purpose. The weak point in the process, especially for silver ores, where generally strong solutions are used, is the escape of a considerable quantity of cyanide as cyanhydric acid after acidifying the solutions.

In the description of his process, Professor de Wilde says in the third operation: "The solution contains all the cyanogen, less the small amount combined in the gold-copper precipitate and the very small quantity volatilized as cyanhydric acid." This is true for very weak solutions, such as are generally used in cyaniding gold ores, but with strong solutions it is not the case, since cyanhydric acid is only slightly soluble in water.

The following tests will show this:

250 cubic centimeters of cyanide solutions of .05 per cent., .1 per cent., .15 per cent., 4 per cent. KCN, were acidified with diluted sulphuric acid; .4 cubic centimeter being sufficient for every .05 per cent. KCN to give an acid reaction on blue litmus paper.

After stirring, the solutions were left for 2 hours, and then a 6-per-cent. caustic soda solution was added to make them alkaline. For every .4 cubic centimeter of sulphuric acid, 2.5 cubic centimeters of caustic soda was sufficient to give a plain alkaline reaction on red litmus paper. The solutions were titrated again, and the results tabulated after correction for dilution. The following table is the average of two sets of tests:

KCN Per Cent. Before Treatment	KCN Per Cent. After Treatment	KCN Per Cent. Loss
.05	.0450	.0050
.10	.0900	.0100
.15	.1375	.0125
.20	.1800	.0200
.25	.2250	.0250
.30	.2650	.0350
.35	.3175	.0325
.40	.3625	.0375

It will be seen that, per ton of solution treated in the case of a solution of .05 per cent. KCN, the loss in cyanide is 50 grams per ton, and in the case of a solution of .4 per cent. KCN the loss amounts to 375 grams per ton. So the loss in cyanide, which is not regenerated by the alkaline matter, increases almost at the same rate as the strength of the original solution.

Much better results were obtained in the next tests, where the alkali was added immediately after the solutions were made

acid. The same quantities of solution, acid, and alkali were used as in the foregoing tests, but now the loss in cyanide was practically nil with the solution of .05 per cent. and .1 per cent. *KCN*, and amounted to only 100 grams with solutions of .3 and .4 per cent. *KCN*.

These tests show that the amount of cyanide escaped depends largely on the time the acid solution is left unprotected by alkali.

In practice, where the solutions have to be stirred thoroughly to coagulate the precipitate, where they afterwards have to be decanted or filtered, there is any amount of opportunity for the cyandhyric acid to evaporate, since evaporation depends as well on the surface exposed to the air. Both time and surface will exceed in practice the conditions of my tests.

Now I decided to make an experiment with a silver-bearing solution, and for that purpose imitated the solution of the San Rafael mill in Pachuca, as it enters the zinc boxes. The data were taken from an article by Mr. E. Girault, published in the December number of the *Informes y Memorias* of the Institute of Mines and Metallurgy, of Mexico.

This solution has the strength of .25 per cent. *KCN*, contains 275 grams of silver per ton solution, and .1 per cent. of lime.

Two liters of solution were made up with: 1,730 cubic centimeters lime water; 66.3 cubic centimeters standard $AgNO_3$ solution (13.05 grams per liter); 203.7 cubic centimeters water. A total of 2,000 cubic centimeters.

This gave a solution containing 275 milligrams silver per liter and 1 gram of lime.

Now, 5 grams of pure potassium cyanide were added and the solution titrated, which showed .22 per cent. The loss of .03 per cent. being the amount of cyanide combined with the silver, the theoretical loss would be .003 per cent. more.

Now two bottles were taken, each with half a liter of the solution. To each, 150 milligrams of cyanide were added to make the solution up to .25 per cent. and 100 grams of chloride of sodium. Then 5 cubic centimeters of 20-per-cent. sulphuric acid were run in, the contents of the bottles stirred, after which the precipitate was easily filtered. Two hundred and fifty cubic centimeters of the filtrate were taken and 25 cubic centimeters of a 6-per-cent. caustic soda added. The liquids were titrated and showed in both tests .23 per cent. *KCN*, or with allowance for dilution, .255 per cent. *KCN*.

If there had been no escape of cyanhydric acid the solution would have titrated .28 per cent., so the amount of cyanide not recovered is 250 grams to the ton of solution treated.

Although the liquid was acid after adding the 5 cubic centimeters sulphuric acid, all silver had not precipitated. The filtrate treated with some more sulphuric acid still gave a precipitate of $AgCl$. This shows that an excess of acid is necessary to obtain a complete precipitation of the silver. The tests were therefore repeated with two quantities of 250 cubic centimeters of the original solution. After making up the solution to .25 per cent. and adding 50 milligrams of salt, it was found that 3 cubic centimeters gave a permanent precipitate, but left some silver in solution, and that 4 cubic centimeters caused a perfect precipitation. To compare lime and caustic soda as a regenerator, one bottle was filtered through lime and the other one through clean paper, and afterwards made alkaline by caustic soda. The one filtered through lime showed .245 per cent., and the other one, after making the correction for dilution, exactly the same. The solution passed through lime titrated .122 per cent. of oxide of calcium, thus being practically saturated with lime and containing only a little more than the original solution.

In this test the amount of cyanide not recovered was 350 grams to the ton of solution treated, or 100 grams more than in the foregoing tests, this probably due to he fact that in the last test a small excess of acid was used, which is necessary to get a complete precipitation.

Where such an inconstant factor comes into play, as the volatilization of the cyandhyric acid, it would be difficult to base upon these experiments executed on a very small scale anything like a correct estimation of the cost of the process on a working scale. In the *Mining and Scientific Press* of December 18, 1909, R. P. Wheelock publishes the results of some experiments made on almost the same subject; viz., the regeneration of cyanide in copper-bearing cyanide solutions. Mr. Wheelock, who also made his experiments on a larger scale, found that the discrepancy in that case was more than in his laboratory tests.

In my experiments the original strength of the solutions was .25 per cent., and after precipitation of the silver and making the solutions alkaline again the strength was in the first tests .005 per cent. more, in the last tests .005 per cent. less. We thus may assume that practically the strength of the solutions has remained the same, the amount of cyanide volatilized after acidifying being the same as the amount combined with the silver in solution. So the expenses of cyanide are not lowered.

Now for 250 cubic centimeters solution in the second test 4 cubic centimeters of a 20-per-cent. sulphuric acid was consumed. This means 16 liters diluted acid per ton of solution, or 5.75 kilograms strong acid (66° B.). Putting the price of sulphuric acid at 9 centavos per kilo, this means 52 cents (Mexican) per ton of solution. In the San Rafael mill the amount of solution sent to the zinc boxes is about twice the amount of the ore treated. So the precipitation costs would be on consumption of sulphuric acid alone $1.04 (Mexican) per ton on ore, not counting the lime necessary to neutralize the solution and the salt to precipitate the silver. This is an excessively high cost, the precipitation and melting in the San Rafael mill under present conditions costing only 44 cents (Mexican).

Of course the great consumption of sulphuric acid is largely due to the excess of lime the San Rafael mill is using. According to the formula,

$$CaO + H_2SO_4 = CaSO_4 + H_2O.$$

One kilogram of CaO consumes about 1.75 kilograms pure sulphuric acid, or about 2 kilograms of 66° B., meaning 4 kilograms per ton of ore treated, or 36 cents (Mexican).

PERSONALS

Walter Brinton, Superintendent of the Manganese Steel Department of the Taylor Iron and Steel Co.'s plant at High Bridge, N. J., since 1895, has resigned, and has accepted a position as consulting engineer for the Edgar Allen American Manganese Steel Co., who are manufacturing manganese steel at Chicago Heights, Ill., and at New Castle, Del. Mr. Brinton's headquarters will be in the New Castle plant.

Charles Watson will go to Porcupine, Ontario, to be manager of the Armstrong McGibbon properties in North Tisdale. Mr. Watson has been superintendent of Nipissing; manager of the Chambers-Ferland, and of the Cobalt Townsite mines.

A. C. Bailey, manager of the Casey Cobalt, will assume management of the Cobalt Townsite Mine.

John Shaw, who has been connected with the Trethewey, King Edward, and Cochrane Cobalt properties, has been appointed manager of the Cobalt Casey.

Thomas English, of Streator, Ill., has been appointed superintendent of the La Salle mine rescue station in Illinois. This is one of the three stations in Illinois mentioned in the November issue of MINES AND MINERALS.

Allerton L. Cushman, Henry A. Gardner and Dr. N. Monroe Hopkins, specialists in their respective lines, have combined in order to open an Institute of Industrial Research at Washington, D. C. The combination is a strong one, and there is no reason why success should not go with them.

GRADING ANALYSES

*By H. Stadler**

The universal tendency of modern metallurgical practice toward fine grinding made the desirability of introducing and adopting a uniform system of series of standard screens for comparative purposes strongly felt, and after laborious and careful investigation a standard table of laboratory screens has been established and adopted by the Institution of Mining and Metallurgy.

Discussion Relative to Mines Trials Committee Standard Grades and Screens

Although fully appreciating the merits of the work achieved and the considerations and principles which have guided the Institution of Mining and Metallurgy in establishing and adopting the present table of standard laboratory screens, I have found it necessary to establish a slightly different ratio, and to extend the classification, in order to more exactly secure a grading which is equivalent to a successive reduction by one half of the volume (or weight) of the particles, or, if only the alternate grades are taken, of a reduction by 1 : 4. As, however, the sizes of this grading scale are in agreement with, or very close to, certain of the Institution of Mining and Metallurgy standards, I have shown in the attached Table A the nearest corresponding standards of laboratory mesh.

The following notes will show how the varying proportions of certain standard sizes of particles may be valued in units of energy (E. U.), which will allow of an exact expression of the efficiency of the crushing operation for purposes of useful comparison.

GRADING ANALYSES

1. *Mines Trials Committee* (*M. T. C.*) *Grades.*—The most rational and logical system of classification into grades, is undoubtedly to base it on the reduction of the volume (or weight) of the particles, especially for mining purposes, as the assay values are given with reference to this unit.

2. By reducing the cube of the unit successively by one-half of its volume and assuming these fractures to be again of cubical shape, each size of this series of theoretical cubes obtained represents a grade of a reduction scale of the ratio of 2.

3. If to each of these grades an ordinal number be given, beginning with 0 as representing the unit of 1-inch cube, the formulas in Table B determine the values of the data for the series of theoretical cubes.

4. By taking the sides of this series of cubes, as clear mesh apertures of a set of screens, it is admissable to assume that the functions of the irregularly-shaped average particles, determined by two consecutive screens, vary in the same ratio as the grades of the theoretical cubes.

For the sake of completeness the relations existing between the factors determining wire-woven screens are given in Table C.

5. The absolute values of the true average sizes are smaller than the theoretical cubes, in a proportion which varies with the physical nature of the ore, method of crushing, shape of mesh hole, etc. As far as relative values only are concerned we have not, however, to trouble about their exact relative place in the scale, and we may take the cubes of the respective grade as representatives.

6. Over nine grades, from 1-inch mesh down to 30 mesh (.0166-inch aperture), the true average weight of the particles of each grade has been ascertained, and the ratio of decrease in weight of these particles proved to correspond remarkably well with the correct reduction scale of the theoretical cubes, especially in consideration of the fact that the measurements had to be executed with the product coming from an ore breaker, containing consequently many splinters and flat-shaped pieces, not amenable to perfect classifying by size. The relation of the true average size of the particles to the corresponding theoretical cubes representing the mean grade between the grades of the screens, varied in the nine tests between 58.3 per cent. and 66.9 per cent., and the average of 61.4 per cent. can therefore be considered as fairly representative for the Rand ore and for a product coming from ore breakers.

7. With this factor, the values (as E. U., etc.) of the larger pieces remaining on the 1-inch screen, which would offer difficulties to classifying by screening, can easily be determined, by using the formulas of Table B, from the average weight of pieces of approximately equal size, of divers groups, into which the material to be examined is first assorted by hand.

8. The average value of screen products determined by two consecutive—possibly far distant—screens, are those of the grade having a number which is the arithmetical mean of the ordinal or E. U. numbers of the two screens, and therefore corresponding to those obtained by the application of E. J. Laschinger's formulas ($_9$).

9. The product passing the finest screen used for grading may by practical experience be assumed to be represented by the following values:

Average Product Passing	Ordinal or E. U. Number	Corresponding Mesh Aperture Inch
200 m. (.00246 inch) screen............	28	.00155
90 m. (.00620 inch) screen............	27	.00125

For the estimation of the average grade of the remainder on the coarsest screen, the battery screen used gives, in most cases, valuable information concerning the size of the coarsest particles, allowing to take the mean as above. The amount of the percentages may also be used as a guide in this direction, as a large percentage indicates evidently a coarser average grade than a small percentage, as in the case of final pulps, where the average grade is bound to be very near to that of the coarsest screen used.

10. The number of grades obtained by this scale at the crushing ratio 1 : 2, being too great for general use, each alternate grade only has been retained, and this restricted set determines therefore a reduction scale at the ratio 1 : 4.

11. The present scheme, as will be noted, standardizes not the screens, as such, but establishes an unerring standard for the sizing and classifying of the screen products into grades. It is consequently valid for all screens of any description, and completely independent of purely practical and commercial considerations, which have to guide mill men and manufacturers for meeting the varying requirements in practice.

12. The standard grades apply to screens in practical use as well as to laboratory screens, and the only difference to be made is, that for the latter, as instruments of measurement, a high degree of accuracy must be required. In this regard commendable efforts have been made by the Institute of Mining and Metallurgy, resulting in the creation of a specially made set of standard laboratory screens, which individually are most accurate with regard to mesh aperture and uniformity of discharge area, but, in part do not fill the requirements of the system of classification which I advocate, for reasons given below.

13. Summarizing the advantages of my system of standardization of grades, they are:

(*a*) No really new departure from standard practice.

(*b*) Equality of steps with regard to reduction in volume.

(*c*) A sufficient number of grades.

(*d*) Independence of wire gauge, and therefore, immediate applicability to screens of any description, with round or square holes.

(*e*) The standard grades are exactly the same for screens in practical use in metallurgical operations as for laboratory

* A paper submitted for joint discussion to the Institute of Mining and Metallurgy, read at the meeting of May 19, 1910, in London, and to the Chemical, Metallurgical and Mining Society of South Africa, read at the meeting of May 21, 1910, in Johannesburg.

purposes, whilst the screens may vary in accordance with the gauge of wire used, with degree of accuracy in their manufacture, etc.

(*f*) No limit to extension in either direction or by interpolation.

(*g*) The variations of all other functions of the particles, besides the diameter, can be expressed by equations, or plotted out in regular curves.

(*h*) Any odd screen of which the clear aperture is known can readily be inserted in the scale by the use of the formulas given in Table B.

(*i*) The ordinal numbers represent at the same time the relative value of the energy required to produce the respective grade from the unit.

(*j*) The average values of screen products determined by possibly far distant screens are readily obtained.

(*k*) Any projected standardization of battery screens can easily be made to fall in with the present scale.

(*l*) The so-called 60- and 90-mesh screens (aperture .01-inch and .006-inch, respectively), are already in general use on the Rand.

14. *Accuracy.*—The measurement of the size of particles by grading with screens can never claim to be scientifically exact, as too many factors of inaccuracy have to be reckoned with, as, for instance, the limits of accuracy in the manufacturing of the screens, the alterations in their apertures by wear, and the fact that the actual maximum size of the particles passing through any given screen varies with different ores, different grinding systems, and different methods of conducting the grading analyses, etc.

15. Even if it were possible to bring the measurement by screening to a high degree of perfection, it would be futile to pretend to excessive refinements, as the working conditions of milling plants, are in practice, subject to unavoidable fluctuations, and the samples subjected to grading are only more or less representative averages of mill products, varying within wide limits.

10·0	5	·10	·10	25·0

The M.T.C. grades are based on the assumption of a successive reduction in volume (or weight) of the screen products by one-half from grade to grade.

16. For scientific and accurate work the full set of Mines Trials Committee grades should be used but for the daily control of operations, on the mines, the 60 and 90 Mines

Trials Committee grade (50- and 80-mesh Institute of Mining and Metallurgy screen) are quite sufficient.

17. Considering the above-mentioned factors of inaccuracy, it is unnecessary to work closer than to the first place of decimals in the percentage ratios.

18. *Methods of Conducting Grading Analyses.*—Although the wet method may give more accurate results, the dry method is for practical reasons almost exclusively in use on the Rand. If a sufficient number of screens be taken, a displacement of washed product freed from the finest grade is dried in the same screen frame, and the grading is then continued and finished on the redried sand.

20. The following advantages are claimed for this mixed method:

(*a*) Greater accuracy.

(*b*) Saving in time in spite of the double drying, as with washed sands, in a comparatively short time a clearly-defined end of the operation of screening is reached.

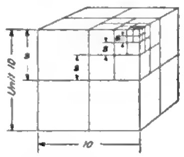

TABLE B. RELATIONS BETWEEN VALUES OF THE DATA FOR SERIES OF THEORETICAL CUBES OBTAINED BY SUCCESSIVE REDUCTION OF CUBE OF UNIT

	Number of Pieces P	Sides of Cubes S	Volume of Cubes V	Area of Fracture F	Ordinal or Energy Number N
Number of pieces produced from unit P=		$\frac{1}{S^3}$	$\frac{1}{V}$	$\frac{F^3}{27}$	2^N
V. & S. ratio values in regard to unit: Sides of cubes (mesh apertures) S=	$\frac{1}{\sqrt[3]{P}}$		$\sqrt[3]{V}$	$\frac{3}{F}$	$\frac{1}{\sqrt[3]{2^N}}$
V. & S. ratio values in regard to unit: Volume of cubes (or weight) V=	$\frac{1}{P}$	S^3		$\frac{27}{F^3}$	$\frac{1}{2^N}$
Area of fracture with reference to unit F=	$3\sqrt[3]{P}$	$\frac{3}{S}$	$\frac{3}{\sqrt[3]{V}}$		$3\sqrt[3]{2^N}$
Ordinal or energy number of grades N=	$\frac{\log P}{\log 2}$	$\frac{\log \frac{1}{S^3}}{\log 2}$ $= -10 \log S$	$\frac{\log \frac{1}{V}}{\log 2}$	$\frac{\log F - \log 27}{\log 2}$ $= \frac{N}{10} + .477$	

N. B.—The surfaces exposed are double of the area of fracture (F).

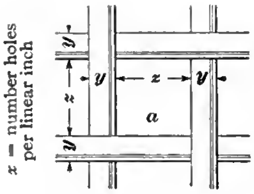

TABLE C. WIRE SCREENING. RELATIONS BETWEEN DIAMETER OF APERTURE, DIAMETER OF WIRE, SCREEN AREA AND NUMBER OF HOLES PER LINEAR INCH IN ANY SCREEN HAVING THE SAME NUMBER OF HOLES EACH WAY AND MANUFACTURED WITH ONE GAUGE OF WIRE ONLY

	Disch. Area a Diam. Wire y	Disch. Area a Apertures z	Disch. Area a No. of Holes x	Diam. Wire y Apertures z	Diam. Wire y No. of Holes x	Apertures z No. of Holes x
Per cent. of discharge of area: a=				$\left(\frac{10z}{y+z}\right)^2$	$100\,(1-xy)^2$	$100\,z^2x^2$
Diameter of wire: decimals of an inch y=		$\frac{10z}{\sqrt{a}} - z$	$\frac{10-\sqrt{a}}{10x}$			$\frac{1-xz}{x}$
Diameter of mesh aperture: in decimals of an inch z= .	$\frac{y\sqrt{a}}{10-\sqrt{a}}$		$\frac{\sqrt{a}}{10x}$		$\frac{1-xy}{x}$	
Number of holes per linear inch x=	$\frac{10-\sqrt{a}}{10y}$	$\frac{\sqrt{a}}{10z}$		$\frac{1}{z+y}$		

The diameter, in decimals of an inch, of a steel wire is approximately: $y = .00315\sqrt{w}$, where w = the weight in milligrams per linear inch of the wire.

even a few percentages from one grade to the next adjacent one, will not appreciably affect the result. More care must be taken with regard to the slime, which adheres to the coarser particles, and if the operation of screening be not prolonged over a very long time, a displacement of about 2 per cent. takes place from the very finest to the coarser particles. This inconvenience can, in practice, be overcome very satisfactorily by adopting the mixed method.

19. A convenient weight of the sample is dried and then the sands are washed in a suitable circular metal frame having the finest screen it is proposed to use fitted into its bottom. The

(*c*) No dusting.

21. For the drying of the sand, steam or water baths should be used, as too great a heat in drying the sand causes the bursting of about 2 per cent. of the coarse particles, the splinters going to increase the +120 grade especially.

22. The practical limits of manufacturing are reached with the 200 mesh (.0025-inch aperture) screen, and for further classification the metallurgist will have to resort to the elutriation method by which the particles are, in a current of water of varying velocity, classified on the basis of their hydraulic value. In consequence of the influence of the varying shape and specific

gravity of the particles, this method gives, with regard to the volume of particles, no clearly defined grades, but on the other hand, the gradings are more in accordance with practical working conditions The portion to be examined by elutriation must be separated from the wet sands before they are dried in order to avoid any alteration, due to heat, of the particular physical properties of the slimes.

APPLICATION OF GRADING ANALYSES

23. *Theory.*—The area of fracture over which the cohesion of the molecules has to be destroyed, multiplied by a coefficient determining the resistance which the molecules oppose to their separation by the exercise of any stress (crushing, tensile, shearing, etc.) represents the force required to cause the fracture.

24. In order to perform mechanical work this force has to run through a distance represented by the deformation which the body can stand before reaching the breaking point. It is in this connection immaterial that this distance of deformation within the limits of elasticity and plasticity is, for not perfectly homogeneous bodies, subject to variations, which for highly elastic and unplastic bodies as quartz, glass, etc., are too insignificant to be considered, and in addition they are by the nature of our crushing appliances averaged to such an extent that these averages are as good as exactly defined figures. Dealing with relative values only, we have not even to care about the exact extent of this deformation, and all that we need is to be satisfied that this factor is a constant function of the diameter of the particles to be crushed.

25. The mechanical work done is represented by the product of the force by the distance, but as in a regular scale of reduction by volume the diameters of the particles decrease at the same ratio as the area of fracture increases, the product, or the mechanical work required for reducing tbe volume (or weight) of the unit from one grade to the next following, is a constant for each grade, called the crushing or energy unit (E. U.)

26. The same conclusion is also arrived at by the application of Kick's Law, which reads:

"The energy required for producing analogous changes of configuration of geometrically similar bodies of equal technological state varies as the volumes or weights of these bodies."

The volumes of the particles decrease from grade to grade at the same ratio as the number of the particles, constituting in their total the volume of the unity, increases, and the product of the volumes into the number of the particles of that grade is, therefore, constant for each grade. As in conformity to the above law the amount of energy absorbed is proportional to the volume of the body to be crushed, it follows again also that the total energy required for reducing the weight of the unit is constant for each grade.

27. The ordinal numbers of any arithmetical progression given to these grades represent consequently the relative values of the energy which has to be spent upon producing this respective grade from the initial unit, or the mechanical value of the grade.

28. For obtaining the mechanical value of mixed sands we need only to multiply the percentages of the gradings by the number of the energy units of the respective grade and add the products. This possibility of having the grading of pulps condensed and expressed in one representative figure proves to be of great value.

29. The useful work done per unit by any crushing machine is determined by the difference between the mechanical values of the samples taken at the inlet and the discharge of the machine, and for obtaining the total work done this difference has to be multiplied by the tonnage dealt with.

30. The relative mechanical efficiency is the value obtained by dividing the total work done by the unit of energy (for instance, horsepower):

$$\text{Relative mechanical efficiency} = \frac{\text{Tonnage} \times \text{work done per unit in E. U.}}{\text{Unit of energy (H.-P.)}}$$

31. *Examples of Efficiency Calculations* (*Rand Ore*).

(*a*) *Stamp:*

Battery screen, 64 mesh, .097-inch aperture.

Running weight, 1,150 pounds (energy 1,174 pounds foot-seconds).

Power consumption, 2.6 horsepower.

Duty, 9 tons per 24 hours.

Mines Trials Committee Standard Grades			Feed	Discharge Pulp		
Denomination of Screen	Aperture	Mechanical Value of Mean Grade		Grading Analyses		Mechanical Value of Discharge
Number	Inch	E. U.		Per Cent.		E. U.
+ 12	.03937	13	Subject to variations, but by practical experience it has been ascertained that the 0 grade (1-inch screen) represents a fair average size.	19.9	+60	2.59
+ 20	.02480	15		12.1	53.2	1.82
+ 30	.01562	17		9.7	+90	1.65
+ 50	.00984	19		11.5	11.5	2.19
+ 80	.00620	21		10.9	−90	2.29

+200	.00246	25		4.2		1.05
−200 including washed slimes	.00246	28		29.1		8.15
				100%		20.34
				Less Mech. value of feed		0.0
				Work done by stamp per unit (say 1 ton)		20.34
Total work done per stamp in 24 bours = 9 tons × 20.34 E. U. =						183.06 E. U.

$$\text{Relative mechanical efficiency per H. P.} = \frac{9 \text{ tons} \times 20.34 \text{ E. U.}}{2.6 \text{ H. P.}} = 70.40$$

(*b*) *Tube Mill:*

Dimensions, 22 ft. × 5 ft. 6 in diameter.

Banket ore feed, 6.75 tons per 24 hours.

Speed, 30 revolutions per minute.

Power consumption, say, 100 horsepower.

Duty, 290 tons per 24 hours.

Mines Trial Committee Standard Grades			Intake			Discharge		
Denomination of Screen	Aperture	Mechanical Value of Mean Grade	Grading Analyses		Mechanical Value of Intake	Grading Analyses		Mechanical Value of Discharge
No.	Inch	E. U.	Per Cent.		E. U.	Per Cent.		E. U.
12	.03937	13	27.6	+60	3.59	–	+60	–
20	.02480	15	15.7	76.9	2.36	–	29.9	–
30	.01562	17	13.7		2.33	7.4		1.26
50	.00984	19	19.9	+90	3.78	22.5	99.0	4.28
80	.00620	21	15.5	15.5	3.26	29.0	29.0	6.09
120	.00391	23	2.0		.46	6.0		1.38
200	.00246	25	1.6	−90	.40	7.7	−90	1.93
200 including washed slimes	.00246	28	4.0	7.6	1.12	27.4	41.1	7.67
			100%		17.30	100%		22.61
			Less mechanical value of intake					17.30
			Work done per unit, say 1 ton					5.31

Total Work Done by Tube Mill in 24 Hours	*E. U.*
Reduction of pulp feed = 290 tons × 5.31 E. U. = ...	1,539.2
Reduction of banket ore = 6.75 tons × 30 E. U. = ...	202.5
Total work done in 24 hours..........................	1,742.4

$$\text{Relative mechanical efficiency per H. P.} = \frac{1,742.4 \text{ E. U.}}{100 \text{ H. P.}} = 17.42$$

32. Under the conditions of the above examples taken from practical work, the efficiency per horsepower of tube mills (17.42) is only about one-fourth that of the stamps (70.40).

33. For general guidance some instructive figures of mechanical values might be of interest:

Battery pulps varying with the increase of the fineness of the screening from 17 E. U. to 24.5 E U.

Tube mill intake depending upon more or less perfect removal of the finest particles by the classifiers two to three E. U. less.

Tube mill discharge, varying with working conditions, especially coarseness of feed, from 21 E. U. to 24.5 E. U.

Final (cyanide) pulp varying between the following extreme limits:

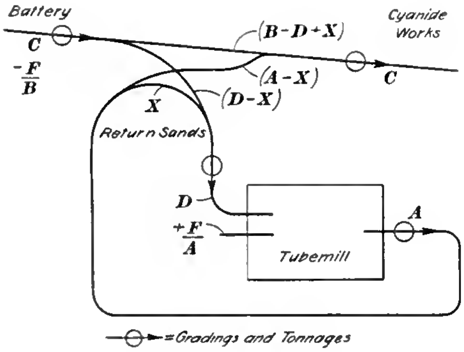
	+60	+90	−90
Coarse pulp................	15%	20%	65% = 24.45 E. U.
Fine pulp..................	3%	10%	87% = 26.13 E. U.

34. The difference between the mechanical value of the final (cyanide) pulp and the battery pulp represents the work done per unit (say, 1 ton), by the secondary crushing appliances, and their total work done, *i. e.*, the sum of the products:

Tonnage × (mechanical value discharge minus mechanical value inlet) of the single units must therefore be equal to battery tonnage × (mechanical value final pulp minus mechanical value battery pulp).

From this fact the correctness of the measurements can readily be checked, or inversely the efficiency of the secondary grinding machines can be controlled by the difference of the mechanical values of the final and the battery pulps, of which reliable average samples are taken in any case for assay purposes.

35. The great advantage connected with my method of expressing the values of the gradings in one representative figure is that it allows of the solution of many interesting problems, for instance, the redistribution of the battery and tube-mill discharge pulps, which in the spitzkasten become mixed up, can by calculation be exactly analyzed into the amounts delivered to the cyanide works or returned to the tube mill for regrinding.



X = tons per 24 hours tube-mill return sands;
A = tons per 24 hours total sand and banket feed;
B = tons per 24 hours total net battery duty;
C = tons per 24 hours total ore milled;
D = tons per 24 hours tube-mill sand feed only;
F = tons per 24 hours banket feed only;
c = difference mechanical values of cyanide and battery pulps;
e = difference mechanical values of tube-mill intake and cyanide pulp;
h = difference mechanical values of tube-mill intake and discharge pulps;
g = mechanical value represented by reduction of banket pieces to size of cyanide pulp;
i = mechanical value represented by reduction of banket pieces to size of tube-mill discharge pulp.

The mechanical work done in tube mills being determined (1) By difference of work done represented in intake and discharge pulps $= D\,h + F\,i$. (2) By difference of work done represented in the portion of the tube-mill discharge delivered to the cyanide works and the tube-mill inlet pulp $= (A - X)\dfrac{D\,e + F\,g}{A}$. (3) By difference of work done represented in cyanide and battery pulp $= B\,c + F\,g$, we obtain by equalizing the above values for instance for the amount of the return sands:

$$X = A - \frac{(D\,h + F\,i)\,A}{D\,e + F\,g}, \text{ or, } X = A - \frac{(B\,c + F\,g)\,A}{D\,e + F\,g}$$

By neglecting the banket ore feed the formula would become reduced to:

$$X = A - \frac{D\,h}{e}, \text{ or, } X = A - \frac{Cc}{e}$$

36. The energy absorbed in the reduction of the banket ore feed to the size of the final pulp can as an average be estimated at 30 E. U. (26 E. U. being the mechanical value of the final pulp with reference to the initial unit, plus 4 E. U. representing the energy absorbed for the reduction of 4-inch pieces to the size of the initial unit or 0 grade.) For 22-foot tube mills, as in general use on the Rand, the work done in reducing the banket ore represents, depending upon the working conditions, 5 to 25 per cent. of the total work done.

37. The mechanical values of the pulps may in many cases, where a great accuracy is not required, be calculated from the gradings of the three grades only, determined by the usual screens, Nos. 60 and 90. This simplified calculation compares for instance for above tube-mill example, as follows:

Grade	Intake			Discharge		
	Weights	Mechanical Value of Mean Grade	Mechanical Value of Intake	Weights	Mechanical Value of Mean Grade	Mechanical Value of Discharge
	Per Cent.	E. U.	E. U.	Per Cent.	E. U.	E. U.
+60	76.9	15.5	11.92	29.9	18	5.38
+90	15.5	21.0	3.26	29.0	21	6.09
−90	7.6	27.0	2.05	41.1	27	11.10
	100.0		17.23	100.0		22.57

CONCLUSION

38. All through the experimental work, executed on behalf of the M. T. C., it could be ascertained that this method of efficiency calculation is for fine as well as for coarse crushing, correct and reliable, and in perfect accordance with the results of practical experience. Based on these facts it can be stated that we are now in a position to determine, with a comparatively high degree of accuracy, the relative merits of different crushing appliances, or the mechanical efficiency of one and the same machine working under varying conditions.

39. In the author's reply to the discussion on his paper on "Heavy Gravitation Stamps," Doctor Caldecott comes forward with a method of his own for computing efficiency, in tacit opposition to mine, the merits or otherwise of which, as an active and interested member of the Mines Trials Committee, he has had under close observation for more than a year. The discussion on his paper being closed, I may be allowed, under these circumstances, to take the controversy up in the present paper. In order to stimulate Doctor Caldecott to redouble his efforts to discover flaws in the correctness and reliability of my methods I begin by saying squarely and in plain terms that his method is not only unscientific, but also inaccurate. All the figures obtained by, and the conclusions drawn from it, are incorrect, misleading, and therefore worthless.

Doctor Caldecott first finds it very convenient to introduce a new "nominal crushing unit." This he defines as a stamp of an arbitrary description as regards weight, drop, and number of drops per minute. With no reasons given, it is difficult to see the desirability or necessity of introducing a new unit for the measurement of the energy used by different stamps when such units as foot-pounds, seconds, or horsepower are already available and easily understood. This device is so much the more needless as the value in normal crushing units of any other stamp of different weight or working conditions is to be determined by the ratio of the foot-pound, second, or horsepower of the particular stamp to that established as the normal crushing unit. There is, therefore, no reason why the usual units should not be taken as a standard. It is then

further arbitrarily assumed that a tube mill of assumed dimensions, with an assumed power consumption, is equal to 30 such nominal crushing units. The admission that this ratio "varies somewhat according to the conditions of operating" is appropriate, provided that the limit of elasticity of the term "somewhat" be made wide enough to stand the enormous strain of the very great effect of these operating conditions on the efficiency of the tube mills of equal cubical capacity inside shell.

I do not lay too much stress on the above points, which are only "somewhat" inaccurate; but a very serious error is made by taking the production of the −90 grade as a standard of the work done in crushing. By the use of his theory, which Doctor Caldecott bases on his finding that "the more tons of this material that can be obtained per stamp, or per tube mill, or per horsepower, the better," undue credit is given to the "finishing" work performed by tube mills on an already very fine feed; whilst the hard work done by other crushing appliances in reducing the coarse particles to the size of this feed is completely ignored. By similar reasoning Doctor Caldecott might have said that the ultimate object sought is the reduction of the +60 grade, and in this case he would have come to just the opposite conclusion, namely, that practically all the work done in crushing is performed by the preliminary crushers and very little is left for the tube mill to do. The fact that the figures obtained by his method do not show any advantage in favor of coarse crushing will perhaps shake his confidence in his method more than any possible criticism. Indeed, according to his figures, the production of the −90 grade is, for the same stamp weights, about the same for any coarseness of battery screens, whilst by my method, which never fails to accord perfectly with practical experience, the greater efficiency claimed for coarse crushing stamps is clearly shown by the figures obtained. They are for a stamp of 1,250 pounds running weight, as follows (see table):

Mesh and Aperture of Battery Screen		Duty Per 24 Hours Tons	Mechanical Value of Pulp E. U.	Relative Mechanical Efficiency Per H. P.
Mesh	Inch			
9	.272	13.0	18.0	234.0
200	.053	7.5	21.5	161.3
600	.028	6.5	23.2	150.8
1,200	.017	5.2	24.3	126.4

40. In conclusion, I wish to record my appreciation of the courtesy of the Mines Trials Committee in granting permission to use data obtained in the course of my investigations whilst in their employ, but I am personally responsible for the mathematical reasoning and considerations derived therefrom, together with the opinions expressed.

Besides many minor articles and contributions scattered in technical publications—too numerous to be quoted—especially the following literatore has been consulted on the subject:

LIMIT OF PROPORTIONALITY

Written for Mines and Minerals

When one body is acted on by another tending to change its dimensions it is said to be subjected to *stress*. The force producing the stress is considered as acting across a certain area and at right angles to a section of the body. When the stress has a tendency to increase the length of the body it is termed *tension*, and when it acts so as to decrease its length the stress is termed *pressure*. Tensile strength is the resistance of the particles of a body to separation. It is proportional to their number in a given transverse section or area of the body and in metals it varies with the temperature.

If a body is rigidly suspended, the load it will sustain without actual rupture or separation of its particles is its *tensile strength*.

Just before rupture occurs the load producing stress is termed the *ultimate load*, and is usually measured by machines constructed for this purpose; at the same time the area and elongation of the body are measured.

If a body be subjected to stress of a definite amount so as to alter its form, the deformation resulting is termed a *strain*. Strain is measured by the ratio of the change in dimension of a body to its unstrained value. *Elasticity* is the property by virtue of which a body subjected to strain returns to its original dimensions and form.

If the body is permanently deformed it has passed its elastic limit, but just before the alteration takes place the body is said to have reached its *limit of elasticity*. The strength of a body is the value of the stress when the body breaks or its particles give way altogether.

It is a well-known fact that rupture may be produced by numerous applications of a load below the elastic limit of the metal; and such an occurrence in the case of shafts and axles is vaguely ascribed to the "fatigue of metals" in service. This term conveys a larger scientific truth than is generally appreciated; and in some testing works it is customary to measure, more or less empirically, the endurance of metals with regard to what may be termed molecular fatigue. If steel were a homogeneous metal, every applied load, less than the elastic limit, should produce a deformation proportionate to the load; and upon the removal of the load the test piece should regain its original dimensions. If, for example, on a steel rod under tension, a load of 1,000 pounds produces a stretch of $\frac{1}{1000}$ of an inch, then 2,000 pounds should produce double this stretch; and 4,000 pounds should cause four times the deformation produced by 1,000. If by successive increments of 1,000-pound loads there is obtained regularly increasing stretch, proportioned to the load, up to 10,000 pounds, but a load of 11,000 pounds produces $\frac{12}{1000}$ of an inch stretch, it is evident that, at 10,000 pounds load, the ratio between strain and stretch changes. This point is called by the French and German investigators the "limit of proportionality." It is far below the elastic limit of the test piece. In the case outlined, the load might be increased to 20,000 pounds before a permanent set would be produced; but it is very evident that the elastic strength of a metal is more accurately measured by the limit of proportionality, where a molecular fatigue begins, than by the commonly known "elastic limit," where an actual molecular distortion takes place.

GEOLOGY OF KOLAR GOLD FIELD

Written for Mines and Minerals, by C. S. Durand, Mysore Province, India

A Description of the Rock Formations, The Mines and General Conditions in Mysore

Practically the whole of the province of Mysore consists of a plateau of about 3,000 feet above sea level. It is quite undulating on the whole, but with the exception of the granite or gneiss peaks scattered about, the country is not hilly. With the exception of the region mineralized with gold-bearing quartz, the whole country is of a foliated granitoid rock which the geologists insist upon calling gneiss. It is uniformly gray in color, varying in crystallization from coarse to fine, and from light to dark in tint. The most striking feature of the landscape is the gneiss hills, which are scattered about without any regularity whatever in their arrangement. In size these vary from a few boulders in elevated places to single haystack-like cones more than a thousand feet high, some forming miniature mountain ranges 10 miles long and 1,500 feet above the surrounding country at the highest points. Much of this gneiss disintegrates rather rapidly, leaving a lot of sandy, barren soil. This rock furnishes the building stone of this whole region, being readily obtained in pieces from 4 inches to 1 foot thick and of any length and width that can be handled, making an ideal stone for steps, copings, and the like.

The laterite drift is one of the most puzzling phenomena presented in all this region, its very obscurity adding interest to it.

The whole surface of the country, with the exception of the gneiss hills and "Goldfield Ridge," is covered with laterite. Indeed, so nearly universal is it that the theory of its covering the entire surface up to certain altitudes at the time it was laid down seems quite correct. How far to the north the laterite extends beyond the sea north of Madras the writer does not know, but between Kolar and Madras it covers many thousand square miles. Near Madras the laterite is used for buildings, railway stations, and bridge piers, but that about Kolar is quite unfit for building purposes. Where found in large masses it is quite amygdaloidal in structure, the cells in it being from the size of beans to that of small marbles. The laterite occurs massive on the top of certain hills, which are uniformly flat, and on one hill 15 miles from Kolar, it is about 20 feet thick; whereas, all over the country—scattered everywhere—is the fragmentary laterite, nearly decomposed, giving the peculiar iron color, dark red or maroon, to the soil to a depth of from 2 to 4 feet, the portions remaining being little shot-like balls, either round or kidney shaped.

The state geologists have not discovered the origin of laterite, nor a place where it is found to great depth; so the theory is that it was spread over the country under water at some very remote period, coming from "parts unknown."

The hornblende schist formation extends roughly for 30 miles north and south, and varies in width from 1 to 4 miles. The Kolar gold field is approximately at the south end of the formation. The rock has a greenish color and its ability to withstand the weather varies everywhere, with the result that ridges of the rock are seen protruding above the surface in some places, while in others it has been completely decomposed into a clayey soil running through all gradations and combinations of color from light green and light yellow to nearly white—and this to a depth of from 6 to 12 feet. It is common in digging to pass through the iron stain from the laterite at the surface for a depth of 2 or 3 feet, and then come to the unstained clay of the decomposed country rock.

In this schist, running nearly north and south, are many quartz veins of various widths from a few inches to 10 feet and even more. These quartz veins carry free and almost pure gold; for example, at the Balaghat mines gold is about 97 per cent. pure as it comes from the mill. Many of the quartz veins are barren, although the quartz to all appearances is the same in one vein as another. The quartz is either white or gray, both carrying some or no gold as the case may be.

The quartz veins which showed gold at the surface were worked out by the natives a long time ago. There are no records extant of these old workings, but tradition indicates that the work ceased with the invasion of the Mohammedans under Arumgzeeb in the latter part of the seventeenth century. Be that as it may, in several places, both at Kolar and in other fields of South India, the natives did work out all the surface quartz down to depths varying from 60 to 300 feet. The present gold mines are working on the same veins at much greater depths.

The natives seem to have prospected this field thoroughly in the old days, for, although there are many quartz outcrops, none of them carry any gold, from which it is quite clear that whatever gold was at the surface was found and removed. So great is the confidence of the present-day mining engineers in the thoroughness of the work of the ancients, that there has been no systematic prospecting of these fields, except at or near old workings. No doubt some day in places where there are barren quartz outcrops with placer gold in the ground all about, there will be serious effort made to find out what exists at depth. There are many such places.

The Goldfield Ridge is one long and nearly straight upheaval bounding this last formation on the west. It is the most interesting feature to the student of geology of anything in this region. The combinations are mostly iron and quartzite, but, for variety in lamination, crumpling, and folding, as well as variety in colors and texture, it would be difficult to duplicate. It seems certain that the "ridge" is a comparatively recent upheaval. There is no laterite on it, although but half a mile from it is a hill 50 feet higher whose top is covered with laterite, from which it may be concluded that if the ridge had been in existence at the time of the laterite drift it would also have been covered with laterite.

Where the rocks of the ridge are in place the stratification is practically vertical, but there has been so much twisting and squeezing that all the forms of lamination read about in geologies are exemplified in countless places. In height the ridge is 50 to 300 feet above the surrounding country.

It should be added that there are masses and streaks of quartz (white) in the ridge, which in some places look suggestive of gold. In some places these bodies of quartz have been prospected but no gold of importance found, and the quartz itself suddenly terminated or gradually pinched out.

The Mines.—There are six producing mines in the Kolar field, all of which have been working with various vicissitudes for nearly 20 years. Another half dozen or so which were worked in the past are now idle. In some cases the idle mines had at one time good ore, which was worked out, while in other cases they used up their capital in prospecting.

All these mines are on the two principal veins, which have various short branches extending here and there from them. The principal veins are not entirely continuous either in quartz or in gold, the latter being mostly in "ore shoots" of varying vertical depths and lengths, all leading to the north along the veins.

The dip of the veins is about 30 degrees from the vertical, west, so that most of the mines have both inclined and vertical shafts.

Only one mine has sufficient water for its own needs. One does no pumping whatever—at all events it is called a perfectly dry mine, although down 300 feet.

The ore is free milling and each mine does its own crushing, amalgamating, and cyaniding. The process of ore treatment is identical at all the mines—stamping, amalgamating, and treating the tailing with cyanide solution. Details in treatment vary with the ideas of the superintendents rather than because of any essential difference in the ore. Some, for example, prac-

tice both battery and table amalgamation, and others only table. The slime is rather abundant and gives considerable trouble.

There is no opportunity to take advantage of gravity in arranging the milling plants, owing to the contours of the ground which furnishes no side hills, consequently the tailing has to be elevated to considerable height, the larger mines having tailing dumps as much as 50 feet high—often higher, and covering several acres. Mine labor is cheap; men, 9 cents a day; women and boys, 6 or 7 cents, above ground. So the tailing especially is handled by manual labor.

Any description of this field would be incomplete without mention of the great Mysore Mine, which began milling operations in 1884, with total amount of ore crushed of 454 tons, from which 454 ounces of gold was recovered. Two years later the mine paid $150,000 in dividends. The next year the dividends fell to $75,000, but since that have gone on increasing until the annual dividends have reached as high as $2,000,000.

ADDENDA.—At the thirtieth annual meeting of the Mysore Gold Mining Co., held in London, England, in March, 1910, the following information was given out: The Mysore government released the property to the company for 30 years at an additional royalty of 2½ per cent. of the output; however, the government reduced the price of electrical power from £24 to £10 per horsepower per annum, which probably offsets the increased royalty. The working costs, including royalty and income tax, absorb 33 per cent. of the total value of the ore. "The mine employs 10,000 men, women, and children, 3,000 of them miners, and the medical staff looks after 90,000 souls." "Whenever cholera breaks out, the healthiest place in the whole of India is Mysore camp." The ore reserve exceeds 1,000,000 tons, and the ore treated amounted to 234,500 tons, from which was recovered 228,249 ounces of gold, or 18½ pennyweights of fine gold per ton During the year, 1,053 feet of shafts and 754 feet of winzes were put down. The deepest point in the mine is 4,175 feet on the dip of the deposit. The mine has distributed since its commencement in 1880, £5,935,094 in dividends to shareholders. E. B. W

ORE MINING NOTES

The construction of the first practical gold dredge in California was in 1898. At present there are 63 gold dredges in the state, representing an investment of $8,995,000. From 1898 to 1908 over $25,000,000 in gold had been produced by gold dredging. With the advent of the modern dredge, handling from 250,000 to 300,000 cubic yards of dirt monthly at a cost of from 2½ to 3 cents per cubic yard, the industry has steadily expanded. The unsightly stone piles are broken up for macadam and concrete work, and the soil, which had been exhausted, was renewed by dredging. As an illustration, land that cost the dredging companies $25 per acre is now sold for agricultural purposes for $100 per acre, after it has been dredged and leveled. Eucalyptus and fruit trees grow on unleveled dredge tailing.—*Lewis E. Aubury.*

The Newhouse tunnel, 21,968 feet in length, is now completed. From the portal at Idaho Springs, in Clear Creek County, it extends northward under many of the principal mines of the oldest mining district in the state, to a terminal point in the Gunnell Mine at Central City, in Gilpin County. From the veins cut by the tunnel at depths ranging from 1,500 to 1,800 feet, the production of precious metals has been in progress for more than half a century. In many instances the operation of the mines finally became unprofitable on account of the expense involved in pumping water from the shafts. By connecting the lower workings of the mines with the tunnel, this expense can be eliminated, and the available ground for profitable ore production in Gilpin County practically doubled. Although the full benefits of the tunnel will not become apparent until the principal connections have all been made, a steady gain in the production of the mines affected may be expected.

The mining industries of Chili employ 60,000 and the railroads 65,000 people. Since the country's discovery gold has been mined valued at $222,923,005, silver at $311,093,058, copper at $658,575,153, and nitrate at $1,122,874,274. The 20,632 mineral claims cover 522,336 acres, of which 10,821 are copper, 3,893 gold, 904 silver, 86 gold and silver, 530 gold and copper, 173 iron, 99 manganese, 32 aluminum, 1 antimony, 1 nickel, 4 mica, 338 sulphur, 1,385 nitrate, 687 salts of potash, 399 salt, 4 diamond, 33 china clay, and 40 coal.

According to information received from the mining department, gold mining in private mines in the Orenburg district, Russia, is yearly increasing. In 1909 the amount of gold obtained was about 21,060 ounces, or 2,268 ounces more than in 1908. Reports from 83 gold mines state that in 40 work was done exclusively under the individual-effort system (pay according to the amount of gold mined by each miner); in the remainder of the mines 800 miners were employed under the boss system.

In making an excavation for a farm building near Hayford, Wash., gold nuggets were found. A chicken was killed and examined and other colors found. It is becoming tiresome to keep suggesting to Washington farmers that they should keep ducks on account of their scooping capacity.

The reorganization committee of the Ely Central Copper Co. has perfected the plan for reorganizing the company, and the details have been sent to the shareholders. The formation of a $12,500,000 company to be known as the Ely Central Development Co., which will take over the present $16,000,000 corporation, is the salient feature of the plan.

During the past year 30 miles of trenches were excavated in prospecting on the Nipissing property. Several veins were discovered, but in the future the surface will be prospected by hydraulicking.

In drifting in the Hudson Bay property, Cobalt district, Canada, at 150 feet in depth, a new silver vein from 2 to 5 inches wide was discovered. It is a solid compact vein worth 3,000 ounces to the ton. At the 100-foot level this company has what is termed the new Big Vein 12 inches wide, carrying around 6,000 ounces silver to the ton.

Because their car was delayed in unloading at the Deloro smelter the T. & H. B. Co. made a clear $3,000 profit. Silver rose while the car waited. There are many Cobalters who would be pleased to be held up in the same manner.

The mineral resources of Ontario are being developed by American capital. Large tracts of iron ore north of Kingston have been purchased by an American company, which is installing machinery preparatory to exporting the raw material to the United States. The actinolite mines at Bridgewater have passed into the hands of an American company. American machinery has just arrived here for a factory which will manufacture mica washers. Large exports to the United States are being made from the mica mines at Sydenham, owned and controlled by the General Electric Co. American capital is also invested in the feldspar mines near Verona, the total output of which is sent to American potteries. A lead mine a short distance from Kingston will be managed by an American and will have American machinery. The opening up of these various mines means an increased demand for American mining machinery, as well as coal. The Nova Scotian mine owners, however, are endeavoring to have the Canadian customs duty on coal increased, so as to shut out the American product, and to have the duty increased on pig iron.—*Felix S. S. Johnson, Kingston, Canada.*

The Negociacion Minera Santa Maria de la Paz y Anexas, located at Matehuala, S. L. P., Mexico, which is one of the largest mining companies in Mexico, has recently installed and just placed in operation two large vertical triplex Goulds pumps to handle their mine water. These are duplicates and each has a capacity of 250 gallons per minute against 700 feet working

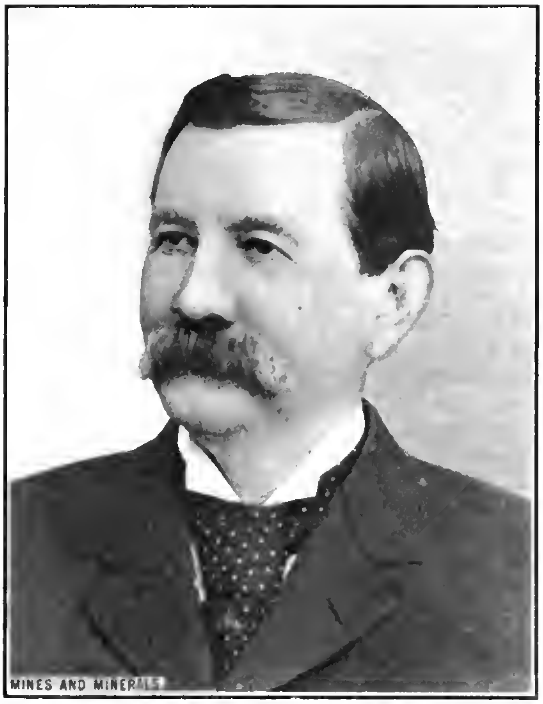
head. Both are operated by direct-connected electrical motors, one of the pumps being located at the bottom of the mine shaft, elevating the water half way to the top; the second pump handling the water from there to the surface. The motors employed are 75-horsepower Westinghouse. A generating plant on the surface supplies these motors with a 400-volt, 60-cycle current.

The Rio Plata Mining Co. has been chartered under Mexican laws; its subsidiary, the Compania Minera Rio Plata, will go out of existence. The mine operated by the company is in Chihuahua, Mexico, 85 miles from the Kansas City, Mexico & Oriental Railway. The output, amounting to about 85,000 ounces of silver a month, is carried by mule to Sanchez, the nearest railway station.

OBITUARY

HENRY FAIRCHILD DE BARDELEBEN

Henry Fairchild De Bardeleben, who was practically responsible for the Birmingham, Ala., iron and steel industry, died December 6, 1910, at his home in Birmingham, aged 69. He entered the Confederate army in 1861 as a dragoon; married



HENRY F. DE BARDELEBEN

Miss Ellen Pratt in 1862. He prospected the Birmingham, Alabama, district, in 1872, and becoming associated with Colonel Sloss and M. H. Smith, made the first ton of iron in Alabama at the Oxmoor furnace. Colonel De Bardeleben by industry, and perseverance in overcoming difficulties amassed a comfortable fortune and business. False friends in the Tennessee Coal and Iron Co. induced him to consolidate his interests with theirs, assuring him that they would lend him sufficient stock in addition to that which he received for his properties so he would control the company. His friends insisted on his signing an agreement not to sell his stock below a certain figure, then turned bears and hammered the stock loaned until he had put up all his own as margin. When that happened he was sold out. Most men at his age would have crumpled under such treatment, but not De Bardeleben; he started anew and succeeded. After the death of his first wife he married Miss McCrossin, of Birmingham, who with five children will miss one of the best of husbands and fathers.

THOMAS BELLIS

Coal men in Pennsylvania will regret the death of Thomas Bellis, which occurred November 21, at his home in Altoona. Mr. Bellis was born in Buckley, North Wales, and came to this country in 1880. He first located in Philipsburg, Clearfield County, where he engaged in mining with Thomas Barnes and other pioneers of that section. Later he went to Burnside, where with James Passmore, he operated the Bellmore Coal Co. Mr. Bellis had the distinction of being the first practical coal man in the Indiana County field and he superintended the opening of the first mine at Hastings.

CHARLES H. TUCKER

The late Charles H. Tucker, secretary and treasurer of A. Leschen & Sons Rope Co., St. Louis, who died in Clifton Springs, N. Y., October 30, was one of the best informed and most extensively known wire-rope men in this country, having been closely identified with that great industry in various capacities, for 26 years.

Mr. Tucker was born in New York City 50 years ago. As a ooy he took employment with the Western Union Telegraph Co., subsequently going into newspaper work, serving as a dramatic critic on the New York *World*. While yet a young man, he entered the New York office of John A. Roebling's Sons Co., growing steadily in their service until 1898, when he was secured by A. Leschen & Sons Rope Co., with whom he remained until his death.

STEWART WATT

Stewart Watt, vice-president and superintendent of the Watt Mining Car Wheel Co., died at his residence at Barnesville, Ohio, on December 10, at the age of 64. He was ill of bronchial pneumonia but a few days. Mr. Watt, with his brother, who died several years ago, was the joint inventor of the first self-oiling mine car wheel, and for the last 35 years has been actively engaged in the manufacture of mine-car wheels. He first operated a foundry in 1863.

WALTER L. PIERCE

Walter L. Pierce, who for thirty-two years had been connected with the Lidgerwood Mfg. Co., and for twenty-nine years its secretary and general manager, died suddenly at his winter home in the Hotel St. Andrews, New York City, on December 10, 1910. He was born at Dorchester, Mass., on June 8, 1855. He leaves a widow and son, Walter L. S. Pierce.

THE YEAR IN THE JOPLIN DISTRICT

Written for Mines and Minerals, by L. L. Wittich

The Webb City-Carterville camp, as has been the case for many years, led in the production of both zinc and lead ores in the Joplin district for the year just closed. Joplin was a not very close second, although the record for the year was encouraging and showed that the ore deposits lack a great deal of being worked out.

As a whole the 1910 shipments rank favorably with those of 1909, when the tonnage was the greatest in the history of the district, although the values in 1909 were not quite up to those of the record-breaking year of 1907.

The new year dawns with conditions favorable for another epoch of great prosperity. As was predicted at the beginning of 1910, the period has been one of unexcelled activity in this district, which includes more than 20 camps in Missouri, Kansas, and Oklahoma. The bulk of the zinc and lead production comes from the Missouri camps, although the newly-discovered Oklahoma mines, which have increased steadily in production, continue to be producers of a great tonnage of mineral, the lead ore output of this region being of especial note.

The year opened with zinc blende selling for $49, basis of 60 per cent. while the top price for choice lots running better

than 60 per cent. was $52 and the average price, all grades, was $46.50. The year closes with the basis price of 60 per cent. grades running about $47, while $50 is the maximum paid for extra choice qualities. Within these 12 months the basis price has been down as low as $39.50, for the week ending May 7, and this basis figure represents the highest basis paid. From this figure the price ranged down to $36 a ton, carload lots.

After that week the market showed indications of reviving and there is not another instance throughout the year when the high basis went lower than $41. Spelter, East St. Louis quotations, which started the year at $6.12½ per 100 pounds, dropped below $6 before the close of January and no more $6 metal was reported throughout the year, although it climbed up to $5.90 in November. At its lowest mark, spelter dropped to $4.90 for the week ending May 7.

Conditions in the zinc ore market remained about the same through the months of June, July, and August, the situation strengthening materially at the close of August when blende jumped to $43.50 basis, reaching $45 basis in September and $48 basis in November.

The shipments of blende have ranged from 3,400 tons per week to 6,700 tons a week, the heaviest production being noted in the closing months of the year. The total valuations for all ores sold, including blende, calamine and lead, have ranged from $189,114 per week, to $357,821 per week, and the total valuation for the year is in excess of $14,000,000.

While certain camps of the district have decreased in production, others have gained materially, the growth of the Alba-Neck City district in the north part of the field being attributed to the discovery of rich pocket deposits of high-grade zinc blende. The mines in this camp have produced a heavy tonnage during the past year, and the value of the ore has been above the average.

Galena, Kans., likewise has seen a revival of mining activities, and this old camp, which led the production in the pioneer days, but which has dropped to third place, has a showing that reminds the old timers of the early times.

The production of calamine has not been as heavy as expected and many small properties discontinued operations. In the production of this ore, Granby, in Newton County, Mo., has led the list by a big margin. Other camps that have shown a good production of calamine are Spring City and Duenweg, both being in Missouri. Calamine prices followed the general trend of blende offerings, the price being weak when the blende price slumped, and high when the price of blende was high. The year started with calamine selling for $28 a ton, basis of 40 per cent. and closed with the price at $27 a ton. Choice lots brought higher than these figures.

Lead ore brought $58 a ton at the opening of the year but the price slumped to $48 in May. Toward the close of the year the offerings became stronger, the price going to $58 a ton. The erection of a large smeltery in the Webb City camp is expected to increase the demand for the local product. East St. Louis pig lead quotations throughout the year ranged from $4.20 per 100 pounds to $4.70.

MEETINGS OF SOCIETIES

The annual meeting of the National Civic Federation is on January 12, 13, and 14. Great national problems will be considered and committees organized to propose legislation. The program includes discussion upon regulation of combinations and quasi-public utilities, compensation for industrial accidents, and mediation and arbitration laws. The Federation's compensation department will present a draft for model uniform state laws. Constitutional features are now being considered by uniform commissioners in 32 states. Application of Canadian arbitration law to industrial disputes concerning street railways and other municipal utilities through uniform state laws will be considered.

The School of Mines of the Pennsylvania State College is cooperating with miners' institutes in Pennsylvania. Practical lectures on the "Prevention of Accidents" are being delivered in various parts of the state by Dean W. R. Crane of the School of Mines.

ELECTRIC SIGNAL TO SHAFT BOTTOM, ENGINE, AND WEIGH ROOM

Written for Mines and Minerals, by M. M. Haley

Electric or other signaling appeals at all times to mine managers, but so far the most crude apparatus has given the best satisfaction. The electric signal described, is of more than ordinary interest, as it is controlled from the weigh room as follows: By placing the movable contact lever *a*, Fig. 1, on any one of the three contacts, *b*, *c*, *d*, the desired signal can be given immediately to both the hoisting engineer, the cager, and men at the shaft bottom. The signal system can be successfully operated as follows: By placing the contact lever on the *b* contact it will show the red light for "stop signal," on the *c* contact it will show the clear light for "all is well," and on the *d* contact it will show the green light for "did not dump," or "lost check," etc.

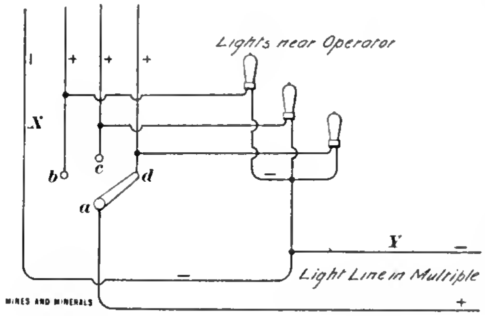


FIG. 1

By this method, if a car is being placed under the chute, or something happens that coal cannot be hoisted, the bottom man and the engineer are both aware of the fact at once and the cager will not be giving loaded signals while the top equipment is blocked. The lights are controlled by the weighman in the weigh office in the tipple.

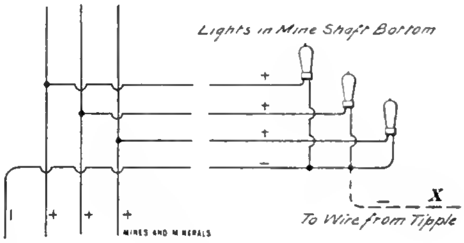

FIG. 2

In the event a mine is using a bonded rail, or a negative wire is close at hand, or at least closer to the bottom than the top of the shaft, the line *X*, Fig. 2, may be attached to same, thereby affording a light when the circuit-breaker falls on the bottom. When coupling out the rail or wire, the line *Y*, Fig. 3, may be attached to the negative of the lights if there be any in the hoisting room, or brought out and coupled to the line *X* coming from the bottom, or if the *X* line is not used, the former may be coupled to the *Y* line instead. The *X* line is only used when there is no rail or feeders accessible at the shaft bottom. It will be noticed that the lights should harmonize, otherwise the signal would be of no service, for instance, the red light on the contact in the weigh office should be on the corresponding contact to that of the red light in the shaft bottom.

EMPLOYERS' LIABILITY

Coal mine operators are becoming dissatisfied with insuring in casualty companies against loss from accidents in their mines. Statistics show conclusively that the premiums paid are out of all reasonable proportion with the amount of indemnity that reaches the sufferers, and frequently whatever is not paid involves a lawsuit. Under the present system of accident insurance, less than 40 per cent. of the premiums paid by operators is apportioned to those for whom it was intended, and nearly one-half of the 40 per cent. is taken as the result of an indirect method of disbursement in practice generally—that is, paying indemnity through the courts. This, however, is but one phase of the matter which, with others, has induced the National Civic League to attempt the passage of a uniform liability law. In nearly every state in the union more or less agitation along this line is being carried on which will eventually produce results.

The Cleveland-Cliffs Iron Co. and the United States Coal and Coke Co. have found the injustice of the present liability laws so intolerable, they have formulated plans and are carrying them out independently of the statutes provided for such cases. This speaks volumes for the need of a common law governing liability, that shall make it unnecessary for one or two corporations to make their own laws in order to have one worth while. R. P. Tarr has written an article for Mines and Minerals on "Compensation for Injury" which will appear in February, 1911, issue.

Murray M. Duncan's article on "Systems of Compensation to Workmen in Cases of Injuries Not Due to Negligence" was printed in volume 30, page 166, Mines and Minerals, under title "Insurance of Mine Workers."

Simeon Reynolds recently wrote an instructive article for the West Virginia Mining Institute, on "What Shall We Do With Our Industrial Wounded."

LEGALIZED SLAVERY

The United States Supreme Court will shortly decide whether that abomination called "the contract labor law" shall continue. The supreme court of Alabama holds that the law is legal, being a proper exercise of the police powers. While the Alabama contract labor law does not draw the color line, no white men are working as convict miners, showing that it was enacted to ensnare the negro laborers, that politicians might graft. Alabama has a law compelling coal mine operators to pay the miners $1 per ton for coal. The scheme is to force a contract on some ignorant farm laborer, then for some trifling alleged violation, drag the culprit into court and have him convicted for committing a misdemeanor, which may be punished by hard labor and long sentence. Once in jail the man is farmed out to a contractor who feeds him and works

him in the coal mine, receiving $1 per ton for all coal the convict mines.

Greenhorns from the farms are sent into gassy mines; and whipped if they do not dig their allotment of coal, and shot if they attempt to escape. Under trumped-up charges and such conditions they may be kept at work indefinitely. Some have tried to kill themselves, and others have run the risk of being killed by the guards rather than submit to the slavery.

The United States Department of Justice contends that this treatment of men is a form of peonage, and that the Alabama law was not enacted to prevent fraud, but to encourage law breaking and impose involuntary servitude. If the system is pronounced legal then it is up to the large corporations owned by northern capital to refuse to hire convicts as they are now doing.

PROGRESS IN LAND CLASSIFICATION

GREAT progress in public-land classification is being made by the United States geological surveyors who during the year 1910 classified 5,618,769 acres as "coal land" and who also appraised and placed its market value at $380,955,646. "At the minimum rates fixed by law the price would have been $87,816,599," the increase thus being nearly $300,000,000. "Here surely, is practical, productive work," the press bulletin states; evidently because the price of public coal land has been boosted on paper from $20 to $400 per acre.

Coal land in the East can be purchased for much less price. The editor is in a position to sell 1,500 acres of coal land to the government for $200 per acre, and as it has railroad transportation the government could put a conservation price of $400 on it. If "the practical productive work" continues in the West, the sale of coal lands will not pay for the Panama canal, but they will be conserved.

GUESTS ON MINING INSTITUTE EXCURSIONS

MOST mining engineers are as good fellows as their wives, and both believe in sharing the interesting and good times incident to mining engineers' excursions. This has been the custom since the establishment of the American Institute, and may it continue. In going over the list of those attending the American Institute Canal Zone meeting one will find that of the 120 in the party, 37 were ladies, and this is certainly as complimentary as anything that could be said for the members.

STARKVILLE—AN EXPLANATION

Written for Mines and Minerals, by Geo. F. Duck

Later developments show that some slight corrections should be made in the article which appeared in the December number of MINES AND MINERALS, describing the Starkville explosion.

The statement that the motor was found with power off and brakes set is not correct. It would appear that the motorman lost control of his trip near the top of the "hill," and that at that point or nearby it broke in two. This is sustained by the fact that the motor was found in parallel, with the controller in the fifth notch and the brakes off The motor was also off the track and into the rib.

Another interesting feature of the rescue work was the excellent discipline established shortly after the accident and maintained until the end. Soon after 10 o'clock that night the placing of electric lights at proper places near the drift mouth was almost completed, and before 6 the next morning comfortable sleeping and boarding quarters had been provided for all connected with the work.

Telephones played an important and interesting part in the work. Each rescue party was followed by another with canvas and they temporarily rebuilt the brattices. As soon as circulation was restored a party of linemen entered with necessary insulated wire and instruments, and it was generally not 2 hours before each rescue station was connected with a central exchange at the drift mouth. At each station a man to answer calls was left in charge with four helmets and 50 potash cartridges for emergency use. The rescue stations, in order of their establishment, were at the large fan at the fourth south, at the "booster" fan on the new haulage entry, and on one of the K entries further in, each station being abandoned as soon as the one further inby was established.

The coroner's jury, after being out 5 days, reported, charging gross negligence in not properly watering a dusty mine known to generate gas at times.

BOOK REVIEW

The first bulletin issued by the new Federal Bureau of Mines is entitled, "The Volatile Matter of Coal," and is by Horace C. Porter and F. K. Ovitz, who conducted their investigations at Pittsburg. The results of the fuel investigations, commenced several years ago by the Technologic Branch of the Geological Survey, showed that the work of determining the fuel values of the coals and lignites in the United States would be incomplete if it did not include chemical researches into the processes of combustion. This bulletin is a report of the volatile matter in several typical coals, its composition, and amount at different temperatures of volatilization. Quoted directly, the authors say: "The investigation has shown that the volatile content of different coals differs greatly in character. The volatile matter of the younger coals found in the West includes a large proportion of carbon dioxide, carbon monoxide, and water, and a correspondingly small proportion of hydrocarbons and tarry vapors."

GOLD DREDGING IN CALIFORNIA, Bulletin No. 57, compiled under State Mineralogist Lewis E. Aubury. Published by the State Mining Bureau, San Francisco, Cal. The bulletin contains 312 pages, 9 in. × 6 in., 235 illustrations, with 10 maps, and abounds in useful information, statistics of the dredging industry in California and its probable future. Bound copies of the bulletin can be had for $2, with 20 cents postage. Mr. Aubury says: "Should other gold forms of mining maintain their average, 2 years from now California will probably again recover its rank as the leading gold-producing state in the Union."

In a 96-page booklet entitled "High Efficiency of Centrifugal Pumps," the DeLaval Steam Turbine Co., of Trenton, N. J., have brought together some 75 charts, diagrams, photographs, and a vast amount of engineering information relating to such subjects as ways and means for testing centrifugal pumps, charts of the results of such tests, the interpretation of these charts for the purposes of the engineers, etc.

GEOLOGICAL MAP OF COBALT, fourth edition (enlarged), by Willet G. Miller and Cyril W. Knight, has recently been published by the Ontario Bureau of Mines, Ottawa, Canada. The fourth edition covers not only the geology embraced in that of the first, but it includes a complete map of the Gillies Limit, not heretofore published, and the map of South Lorrain, by A. G. Burrows, which was published a few years ago. Other areas, for instance, the Quebec shore of Lake Temiskaming, are included. The routes of the various power lines and other features have been added to this map. It naturally gives a more comprehensive view than the preceding editions of the geology of the Cobalt area.

"A MANUAL OF PRACTICAL ASSAYING," seventh edition, by the late H. Van F. Furman, revised and enlarged by W. D. Pardoe. In the new edition, the chapters that have been rewritten are on the determination of silica, lead, copper, cobalt, nickel, and vanadium, a method for the determination of uranium, as well as vanadium being given. Diagrams of the new Shimer crucible and train of apparatus used in carbon determinations have also been added. A description of the Pearce method for the determination of tin, the bromate method for antimony, a volumetric method for bismuth, Neher's method for arsenic, and additional methods for sulphur and tungsten have been incorporated. The book is so well and favorably known little comment is needed. Mr. Furman was the first to incorporate modern chemical analyses of the rarer metals in book form. His book instantly found favor in colleges and among engineers, so that at the present time it is a standard. The 1899 edition contained 463 pages; the present edition, 8vo., 530 pages, the price remaining the same, $3. The publishers are John Wiley & Sons, New York; Chapman & Hall, London.

THE BOARD OF TRADE MINE, WHEELING, W. VA.

THE BUSINESS PROSPECTS YEAR BOOK, 1911, is the name of a book published by the Business Statistics Publishing Co., 12 James Street, Cardiff, Wales. The Business Man's Guide, as it is also termed, was initiated in 1906, to deal with the conditions of trade in the past and as guide for the future. The contents are Coal, Iron, Copper, Tin, Tinplates, Oil, Money Market, Shipping, Rails, Wheat, Cotton, Rubber, Hog Products, Dairy Produce, Statistics. The book contains 279 pages and is 5 shillings net.

TESTING FOR METALLURGICAL PROCESSES. Much money has been lost by assuming that some particular process is adapted to an ore and then putting up a plant for that process. The wise man has his ore tested in a laboratory to ascertain if the ore is suited to a process, and on favorable reports has a carload or less tested on a commercial scale. James A. Barr has written a book descriptive of the apparatus and procedure in making laboratory tests, entitled "Testing for Metallurgical Processes." The contents of the book are the results obtained by experimental work, and the methods he recommends have been tested in practice. The book will appeal to engineers and students in metallurgy or chemistry. Where a man follows a certain line he is unable to keep all details in his head, and when comparatively new tests are to be made he must review, and often is compelled to read considerable unnecessary material to arrive at the details sought. This book does away with all that, provided the reader has a general idea of the subject. The book contains 216 pages and is illustrated. The price is $2 postpaid. The Mining and Scientific Press, San Francisco, and the Mining Magazine, Salisbury House, E. C., London, are the publishers.

THE WEST VIRGINIA INSTITUTE MEETING

The winter meeting of the West Virginia Mining Institute held December 6, 7, and 8, at Wheeling, W. Va., was well attended.

The papers presented dealt with practical matters that tend for economy and progress in coal mining. They were as follows: "Profit and Loss Account," Neil Robinson; "Application of Compressed Air to Mine Locomotives," C. B. Hodges; "Possibilities of a Federal Liability Law," Simeon Reynolds; "Commercial Classification of Fuel," Robert E. Rightmire; "American Language," J. F. Healy; "Mine Law of West Virginia," P. A. Grady; "Non By-product Retort Ovens," E. B. Wilson; "Mine Motors," Everett Drennen; "Local Geology of the Wheeling District," I. C. White; "Accurate Cost Accounting," J. C. McKinley. Demonstration in first-aid work was given by J. J. Rutledge and assistants.

The Wheeling Board of Trade, with aid of the Elks, entertained the visitors, as Dr. J. H. Holmes said, in a manner that, other cities in the state will have difficulty in duplicating. Visits were made Wednesday to the Wheeling Steel and Iron Co., Northwood Glass Co., Wheeling Stamping Co., Riverside and Warwick pottery companies, and other industries. The Board of Trade was assisted in the movement of the trolley cars conveying the excursionists by the Wheeling Cascaret and stogie companies. In the evening the Board of Trade entertained with a combined banquet, vaudeville, and mine explosion in the Elks auditorium.

The stage setting represented a West Virginia hillside in winter, with real hemlock and laurel covered with artificial snow.

To the left was a timbered drift mouth; to the right an engine house equipped with moving machinery and a live steam whistle. In the background between the two there was a mountain stream tumbling down the hillside.

George W. Lutz, president of the Board of Trade, acting as mine inspector, appeared at the mine mouth with a safety lamp,

spoke to engineer, Chas. F. Brand, who then called Mine Superintendent James P. Morgan with the whistle. Inspector Lutz left his safety lamp outside and with Superintendent Morgan entered the mine with an open light. After the inspection tour Mr. Lutz read his report, which was about 10 feet long of closely unwritten paper, he then became toastmaster. "He seen his duty and he done it." The guests having been served with an "oyster cocktail," Prof. H. M. Shockey, musical director, pressed the piano keys and put out the lights. Thereupon four dusky miners, A. H. Robinson, Wm. S. Leach, David Crawford, and Howard Nesbitt pushed a real mine car containing real coal out of the drift mouth, singing as they did so, "Down in a Coal Mine Underneath the Ground." "The Legend of the Coal Mine," with music and words arranged for the occasion by Judge Alan H. Robinson, was delightfully rendered by David Crawford and chorus. After repeated encores the audience were requested to join in singing "Down in a Coal Mine." The noise was so spontaneous that the professor took his hands off the piano keys and the lights went up. The impression prevails that Engineer Brand blew his whistle to hot water; "he seen his duty and he done it." During the next course the band and the diners made a duet from "Old Kentucky Home," "Old Black Joe," and other never-grow-old melodies. Again the lights went dim and Miner Robinson, leaning on the coal car, sang the "Stein Song." In the chorus to this song the quartet of miners hammered on drills. Were it not for the stage setting and the dim lights from the miners' lamps the spectators could have imagined they were listening to the Anvil Chorus sung by grand opera performers. As it was, they repeatedly encored the vocalists, until Mr. Shockey took his hands from the keys and turned the lights on so the members could assist the band in playing "Every little movement has a meaning all its own."

One of the hits of the evening was Mine Superintendent Morgan's monologue burlesquing several coal operators, and his leading the illustrated song "The Miner's Home." The vaudeville ended with the song "The Fire in the Mines." This was not all song: the mine blew up; flames shot from the drift mouth; the whistle blew itself to hot water; and during the excitement J. W. Kay, of the United States rescue service, equipped with helmet, rushed into the mine and brought out a supposed unfortunate.

The following officers were elected for the ensuing year: President, Frank Haas, Fairmont; First Vice-President, Neil Robinson, Charleston; Second Vice-President, Joseph Virgin, Plymouth, W. Va.; Third Vice-President, P. E Grady, Huntington; Fourth Vice-President, George Watson, Fairmont; Fifth Vice-President, J. C. McKinley, Wheeling; Secretary-Treasurer. E. B. Day, Pittsburg, Pa.; Executive Board, J. F. Healy, D. Howard, R. S. Ford, and Charles Connor.

The next meeting will be held in June, 1911, at the White Sulphur Springs.

ILLINOIS COAL STATISTICS

Summary for the Years Ended June 30, 1909, and 1910.

	1909	1910
Number of counties producing coal......	55	55
Number of mines and openings of all kinds	886	881
Total output of all mines, in tons of 2,000 pounds..........	49,163,710	48,717,853
Number of shipping or commercial mines	384	390
Total output of shipping mines, tons	47,958,562	47,225,201
Average days of active operation for shipping mines..........	189	179
Average days of active operation for all mines..........	168	171
Average value per ton all grades at shipping mines..........	$1.012	$1.016
Aggregate home value of total product...	$50,303,757	$50,204,207
Average value per ton all grades at all mines..........	$1.023	$1.031
Number of motors in use underground...	210	216
Number of mines in which mining machines are used..........	107	114
Number of mining machines in use......	1,246	1,291
Number of tons undercut by machines...	16,407,692	18,176,254
Number of tons mined by hand.........	32,756,018	30,541,599
Average number of miners employed during the year..........	50,834	39,069
Average number of other employes underground..........	13,788	28,137
Average number of boys employed underground..........	1,752	1,154
Average number of boys employed above ground..........	71	47
Average number of other employes above ground..........	6,288	6,227
Total number of employes..........	72,733	74,634
Number employed at shipping mines....	69,518	71,520
Number of persons at work underground.	66,374	68,360
Number at work on surface..........	6,359	6,274
Average price paid per gross ton for hand mining, shipping mines..........	$.583	$.597
Average price paid per gross ton for machine mining..........	$.460	$.462
Number of kegs of powder used for blasting coal..........	1,2[illegible]0,607	1,254,095
Number of kegs of powder used for other purposes..........	3,963	3,128
Number of men accidently killed (Cherry mine disaster 259)..........	213	390
Number of men injured so as to lose a month or more of time..........	894	737
Number of gross tons mined to each life lost..........	230,816	124,917
Number of employes to each life lost	342	191
Number of deaths per 1,000 employed...	2.9	5.2
Number of gross tons mined to each man injured..........	54,993	66.103
Number of employes to each man injured.	93	101
Number killed to each million tons produced..........	4[illegible]	8.0
Number injured to 1,000 employed......	10.7	9.9

EVOLUTION OF HOISTING

Written for Mines and Minerals, by E. B. W.

(Continued from December)

Hoisting Machinery for Deep Mines. Development of Electric Hoisting Machinery

Quite a number of mines have depths ranging between 2,000 and 3,000 feet, a less number whose depths range between 3,000 and 4,000 feet, and there are a comparatively few in the Transvaal, South Africa, and Keweenaw Peninsula, Mich., whose depths range from 4,000 feet to nearly 5,000 feet, vertical. Hoisting from depths greater than 3,000 feet is a problem that few mining or mechanical engineers are called upon to solve, and when they are, the experience derived from deeper shafts is studied with most satisfactory results, although the various designs show that a single type of hoister has not as yet satisfactorily furnished a standard that meets all requirements. This is due primarily to the miners' demands prevailing over the economical desires of the mechanical engineer, and as a rule direct-acting engines with cone drums of various designs are as common as when hoisting from less depths. The necessity of constructing machinery that may be controlled at great depths and will move the cages and loads with precision adds somewhat to the task, but strength and freedom from stoppages due to breakdowns or complicated parts going wrong are of greater importance to the designer.

When a shaft is down 4,000 feet its cost represents a cash outlay between $500,000 and $750,000, and the interest on this must be paid by hoisting a certain tonnage of ore daily; in addition, the fixed charges connected with mining, dressing and treating the ore require that another certain tonnage be hoisted, thus making it absolutely necessary that no shutdown shall occur from the frailty of the hoister.

Usually the mine is capable of producing a certain daily tonnage of ore, and the mill is designed to treat that tonnage; if anything happens to the hoister the mill and treatment plants must shut down, and although the capacity of the hoister is greater than the mine, the mill and mine cannot catch up with the lost time.

Fig. 39. Drum of Hoist, Osceola Mine

The Red Jacket shaft of the Calumet & Hecla Mine at Calumet, Mich., has six compartments 6 feet 3 inches by 7 feet, a length over all of 25 feet, and a width over all of 15 feet 6 inches. It is one of the deepest vertical shafts in the world, being 4,900 feet from the collar to the sump. The company is notable from the fact that it has paid $110,000,000 in dividends to stockholders, is most progressive, and has the finest machinery probably of any mining company.

This machinery for the deep shafts was designed by E. D. Leavitt, who adopted the Whiting hoisting system at the Red Jacket. There are two hoisting plants at the shaft, one for sinking, which has 7-foot diameter rope wheels, and the other, for hoisting ore, with 19-foot diameter rope wheels. In each plant the rope makes three half turns in the grooves of the rope wheels, and as there are two such wheels coupled with parallel connecting-rods, the rope has the bite due to six half turns.

Another innovation at this plant is the introduction of duplex, triple-expansion engines, with the high and intermediate cylinders acting on one crosshead, the low-pressure cylinder on another, the two crossheads being attached by connecting-rods to the opposite ends of a short triangular walking beam pivoted between two guides.

From the third point of the beam a connecting-rod carries motion horizontally to one crank of the main sheave. The cranks of the two engines are set quartering.

Probably nowhere else in the Michigan copper districts are expansion engines used, and here the ratio of rock hoisted per ton of coal is given as approximately 40 to 1. Other companies on the Peninsula favor the simple non-condensing engines for hoisters, that are direct acting and work at a steam pressure varying from 80 to 120 pounds per square inch.

These hoist in balance with drums having partly conical ends and using round ropes. The drum shown in Fig. 39 is that used at the Osceola Mine and is shown merely as an illustration of the size of a Michigan drum. Its size is 18 feet 6 inches long by 12 feet 6 inches in diameter.

The Tamarack shaft is vertical and No. 3 shaft is probably the deepest in the world, 4,990 feet. No. 5 shaft, which is 4,935 feet deep, has five compartments 7 feet 2 inches by 5 feet 2 inches, four of which are for hoisting, and one a pipe and ladder way. The hoister at this shaft, shown in Fig. 40, has four engines of the Corliss type, placed on a massive triangular frame and direct-connected to the drum, which is 25 feet in diameter at the center, and tapering to 18 feet at the ends. The crankshaft is 37 feet 5 inches long from center to center of crankpins, with single cranks at each end set 135 degrees apart. When one of the four engines is on a dead center, the effort of the other three engines is applied at 45 degree-, 90 degree-, and 135-degree points of the crank circle. From 18 to 20 trips an hour are made with this hoister, which is as accurate in stopping and starting as a small one. The engine was designed to carry 6,000 feet 1½-inch rope, but the load is 17,519 pounds of rope, 4,200-pound cage, 4,000-pound car, and 1,200 pounds of rock, or 18.85 tons, and this it hoists at a velocity exceeding 90 feet per second, or about a mile a minute. A trip from the bottom to the landing is made in from 70 to 90 seconds, but men and materials are handled as well as rock, so that, with the caging and landing, the average number of trips per hour is 19. At No. 3 shaft a supplementary hoist handles men and timber.

In the Transvaal a company can only follow the ore deposit to a point perpendicular to its surface boundaries. The first openings were made along the outcrop of the deposit which has a dip of about 35 degrees that flattens somewhat with depth, and as a matter of policy and necessity shafts are sunk for development work as shown in Fig. 41.*

The outcrop is at *a*; the first line of vertical shafts are at *b*; the second line of shafts at *c*, are known as deeps; and the third line at *d* as deep deeps, the latter reaching the deposit at between 4,000 and 5,000 feet. Other shafts are sunk to cut the deposit and then curve as in Fig. 42, going down the dip to avoid the necessity of an underground hoist. The illustration shows the method adopted for curving the east shaft of the Vogelstruis Consolidated Deep Co., with the objects of avoiding an underground hoister and enabling development to proceed with the least possible delay.† The skip used for hoisting runs from the incline into the vertical smoothly, and generally without increase of speed. On the curve, 45-pound rails are used and the skip is guided by 4″×4″×½″ angle iron. The center of the rope pulleys is on a 73-foot 6-inch radius, and the bottom of the rail on an 80-foot radius, thus giving the latter a 48-degree curve.

* J. S. Lane, Vol. 24, page 594, Mines and Minerals.

† Thos. Haight Leggett, page 970, Transactions American Institute Mining Engineers, 1901.

It is thought that this curved shaft can be used to 3,000 feet, but that after that depth independent methods of hoisting on the incline will need to be adopted.

At the deep mines of the Simmer and Jack group, located at Elandsfontein, about 12 miles from Johannesburg, South Africa, is a hoister designed and installed by J. S. Lane. The engines are cross-compound condensing, 28 in. × 50 in. × 72 in., designed to work with 140 pounds steam, and the following description furnished by Mr. Lane is of interest, showing as it does the numerous problems to be met.

Example of Deep Hoisting.—This plant is located at the Hammond shaft, Elandsfontein, about 12 miles from Johannesburg. The Hammond shaft is one of the deep mines of the Simmer and Jack group, belonging to the Consolidated Gold Fields of South Africa.

The hoist was furnished by Chapin & Manion, Ltd., Johannesburg, dealers in mining machinery and representing the Ingersoll-Sergeant Drill Co. The plant was designed and built in America. It is cross-compound condensing, 28 and 50 in. ×72 in., designed to work with steam at 140 pounds. Both the high- and low-pressure cylinders are steam-jacketed, both on the barrel and heads. The main object of steam-jacketing, in this case, is to keep the cylinders hot and in readiness to start promptly at any time without danger from water, as it is best to leave the steam in the jackets all the time day and night. The high-pressure cylinder exhausts into a reheating receiver, the exhaust steam passing through 2-inch tubes surrounded by steam at boiler pressure. Steam is admitted to the high- and low-pressure cylinders through balanced throttles, both of these throttle valves being connected to the same lever on the engineer's platform. A secondary throttle is provided by which live steam may be admitted, if desired, into the receiver, between the high- and low-pressure cylinders; but it is only necessary to use this valve when first starting for the day, or after an unusual stop during working hours. An automatic back-pressure valve permits exhaust steam to go to the atmosphere should the vacuum fail. Corliss valve gear is used, but there are no eccentrics, the wristplates being driven by rods connected to cranks on either end of a cross-shaft located between the drums and engine cylinders, and driven by a train of gears from the main engine shaft. The gears being fitted with an adjustment operated by an air or steam cylinder which reverses the engine by revolving the cross-shaft forward or back to give the proper reverse motion and valve lead. The main engine shaft is $17\frac{1}{2}$ inches in diameter in the cranks and $22\frac{1}{2}$ inches in diameter in the cast-iron center driving wheel.

The two cylindrical drums are loose on the shaft and bushed with composition bushings put in in halves and removable for repairs. Each of the four drum-hubs is fitted with eight arms made of 9-inch channel, each carrying steel drum flanges, on to which are riveted angle irons carrying the drum shell; on to the outer flanges of each drum there is riveted a cast-iron brake seat or ring. The shells of the drums are 14 feet in diameter and 51 inches face; they are in four sections with a spiral groove $1\frac{45}{100}$-inch pitch turned in them for the rope. The $1\frac{1}{4}$-inch rope is wound in two layers giving a capacity of 3,000 feet on each drum. The drums are each driven by a band friction driver which clutches them to the center driving wheel, the clutches and brakes being operated by cylinders using either compressed air or steam.

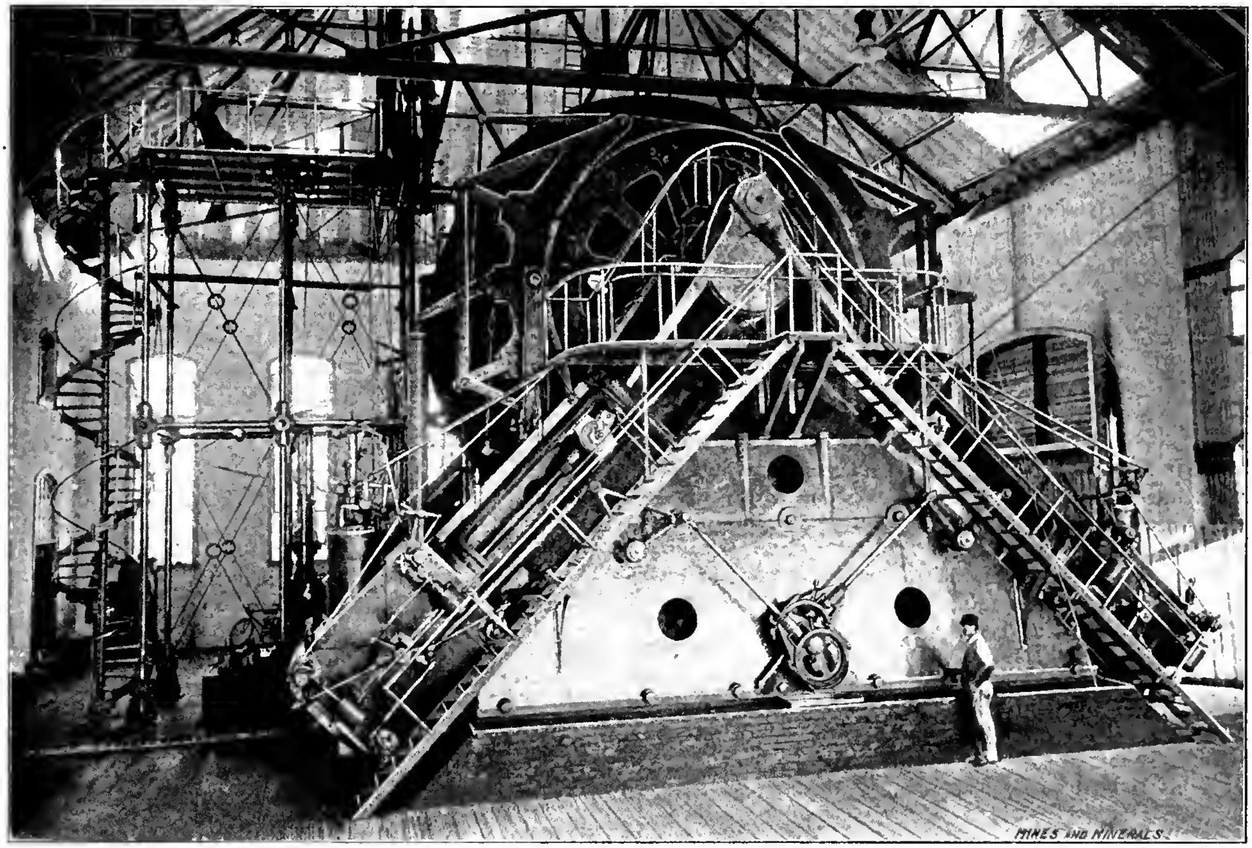

Fig. 40. Hoist at No. 5 Shaft, Tamarack Mine

The plant was designed to hoist in balance, the descending skip balancing the ascending skip, but the clutches were provided to permit adjustment of length of rope in order to change the hoisting from one level to another, and also to allow the operation of either skip independently in case of temporary derangement in either hoisting compartment.

The brake seats, or rings, on each drum are 10 inches wide. The post brakes are unusually heavy and move parallel simul-

taneously at top and bottom, and are put on by means of weighted compound levers, and released by cylinders which lift the weight. The combined weight is 1,850 pounds and the leverage 36 to 1, or equal to 66,600 pounds pressure of the brakes against the brake seat. There is a brake on each drum, and when hoisting in balance, as is usually the case, the brake levers

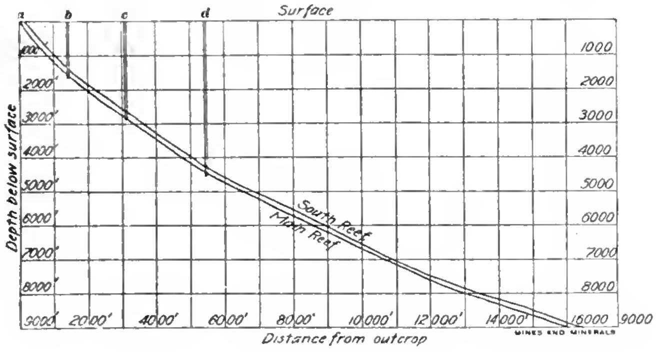

FIG. 41

are coupled together so that the motion of one moves both and the two pairs of brakes work as one.

Oil cataract cylinders are provided to regulate the motion given by the air or steam cylinders on both brake and reverse engines; the valves of both the air and oil cylinders are operated through a "floating valve motion" following the motion of the hand lever, stopping whenever the motion of the hand lever stops.

The point of cut-off can be varied by the engineer without interfering with the action of the governor when running slowly, and yet the governor will take control of the cut-off should the maximum speed be reached at any time.

There is one indicator for each drum, consisting of a light steel shell 24 inches in diameter. The surface of these indicator drums is painted black so that chalk marks and figures can be made indicating the different stopping points. A pointer moves up and down on a screw in front of the indicator drum. A spiral white stripe or line is painted on the surface of the drum, and the drum revolves with the hoisting drum, being connected by link belt and gearing; it makes a simple and graphic indicator, as only the marks on the front side of the drum can be seen at a time; a second pointer moves up and down by a vertical scale on the frame and indicates, approximately, where the skip is.

Should either skip be overwound the indicator nut comes in contact with a lever that disengages a weight, allows it to drop, and instantly, not only applies the post brakes, but also detaches all of the Corliss inlet valves, allowing them to close; nor can they again hook on to admit steam until the automatic stop is reset. The simultaneous closing of the inlet valves, closes the cylinders too, and the application of both post brakes' full power will stop the skip promptly. This device is especially valuable in case the engineer should by mistake open the throttle without reversing the engine; were it not for the automatic stop the skip would likely be against the head-sheave before the engineer realized what he was doing, but with the automatic stop the engine would be promptly stopped.

The engineer's platform, 7 feet square, on which are placed all the levers for operating the plant, is located between the cylinders.

Both high- and low-pressure cylinders have relief valves, all operated by a single lever on the platform. By opening these valves, steam is allowed to by-pass back and forth from one end of the cylinder to the other; these are used for controlling the speed in lowering men or timber, and may also be used for slowing after the main throttles are shut, thus saving the brakes.

The piston rods are extended through the back cylinder heads, and provided with slipper foot-guides. This is not usual in American practice but was required by the parties interested. The distance from center to center of engines is 21 feet 9 inches, and the length of plant 48 feet, including the tail-rod guides.

The shipping weight of this plant, not including the weight of condensers and foundation bolts, was 448,000 pounds; the net weight 415,000 pounds. This plant was designed to handle a total load of about 20,000 pounds including rope, skip, and rock.

ELECTRIC HOISTS*

The evolution of electric hoisting has been confined practically to Europe, where, due to the poorer natural resources, it has been necessary to introduce all technical advancement possible in order to meet competition. As far as electric hoisting for main shafts is concerned the beginning of serious work

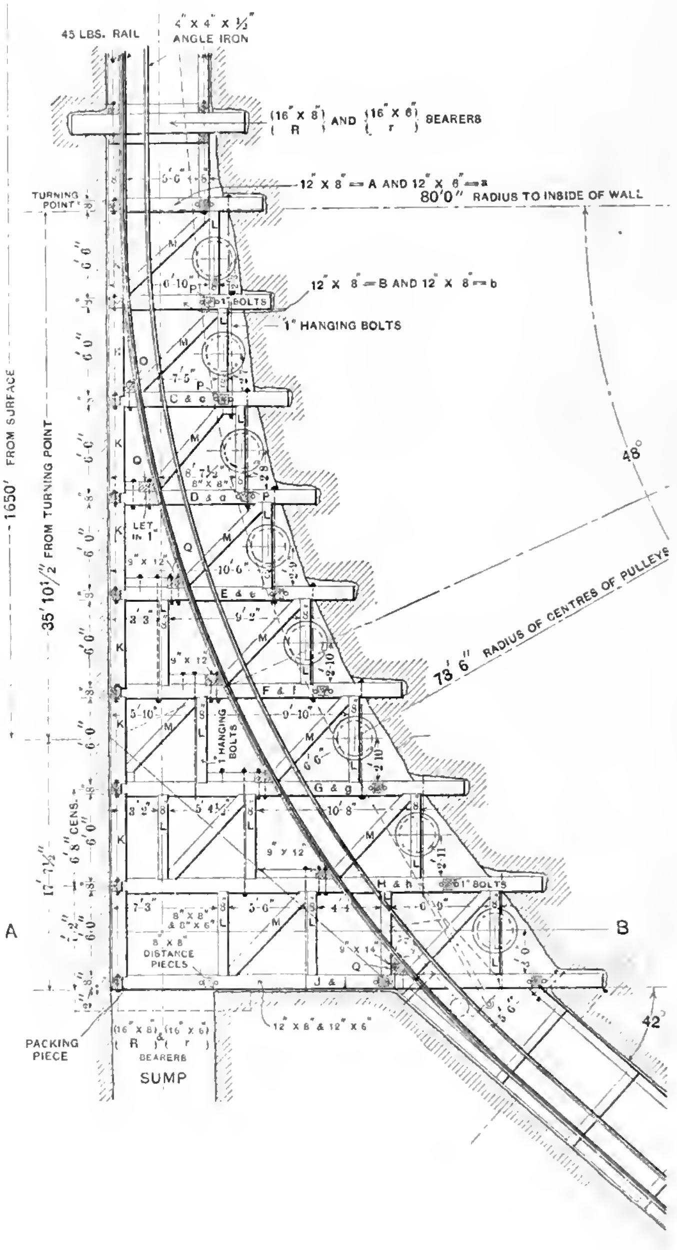

FIG. 42

dates from 1902. Before this time there were various causes operating for and against the introduction of electric hoisting. The mine operators who had electrified their properties were naturally desirous of using electricity for hoisting as well as for

*Written for MINES AND MINERALS by Wilfred Sykes, Elec. Engineer, Westinghouse Electric & Mfg. Co.

other operations. On the other hand, there was a feeling that electrical equipments had not proved to be sufficiently reliable or convenient in operation. The uneconomical performance of the then existing steam hoisting engines was also a very serious argument in favor of the introduction of electrical hoists, and the manufacturers of electrical apparatus were, of course, desirous of extending their fields of application. They were, however, reluctant to attempt this problem without considerable investigation as to the risk involved. From an engineering standpoint, the question of control was probably one of the most serious features to be overcome.

In previous articles on this subject, reference has been made to the local conditions with various types of hoisting plants. It will be appreciated that with steam-operated hoists, the acceleration and running speed are limited only by the size of the cylinders and drums, there being a great deal of latitude possible in the operating characteristics by varying the cut-off of the engines. In connection with electric hoisting plants, the thermal capacity of the motors makes it necessary to consider the maximum conditions when laying out a plant, and the

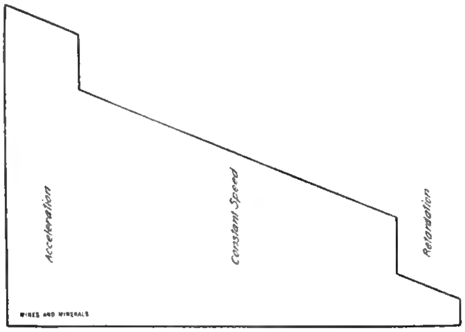

FIG. 43

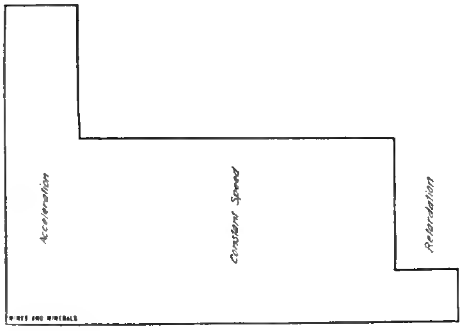

FIG. 44

question of acceleration is very much more important than is the case with steam plants. As the heating of machines varies approximately as the square of the load, it is important in order to reduce the size of the equipment to make the load during the operating period as uniform as possible. For this reason the development of electrically-driven hoists has also affected to some extent the mechanical design of hoisting plants. In Europe, the Koepe has been used to a very great extent with the object of reducing the inertia of the moving parts to a minimum, it being possible to do this on account of the even turning moment of the electric motor. With a plant of this kind, driven by steam engines it is necessary to counteract to a great extent the advantages by using sufficient flywheel effect to keep the angular irregularity to such a value that the rope will not slip.

The effects of the characteristics of the various types of hoists on the size of motors has led to a more careful study of load conditions than is usually made in connection with steam plants, and a brief statement of the characteristics of the various types of equipments may not be out of place.

Fig. 43 shows a characteristic load diagram for a double, cylindrical-drum, balanced hoist. The high peak load is due to the acceleration of the moving parts. After they have been brought to full speed the load gradually decreases, due to the variation in the weight of the suspended rope on the two sides. At the end of the hoisting period the energy stored in the moving parts becomes available during retardation and may be used in overcoming the static load or it may be necessary to

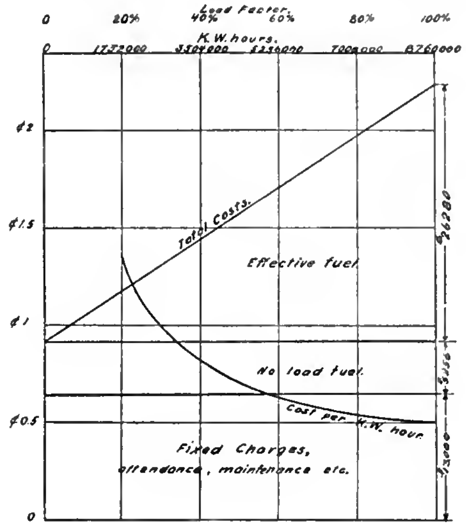

FIG. 45

absorb a portion of it with the brakes. With mines of great depth, the variation in load due to the varying weight of the suspended rope becomes very important and in certain cases it may be found necessary to use the brakes even before the beginning of the retarding period. The difference between balanced and unbalanced winding is that the static load when working unbalanced is greater than when working balanced and the change of load due to the rope is only half as great.

The second type of diagram covers the Koepe pulley, or a cylindrical drum using a tail-rope. It will be seen from Fig. 44 that the static load is constant, the accelerating peak being the prominent feature as before. This type of diagram also holds good for conical drum hoists providing that the drums are so dimensioned as to completely compensate for the unbalanced rope load. The reel hoist using flat rope also has the same characteristics providing the diameter of the hub is correctly

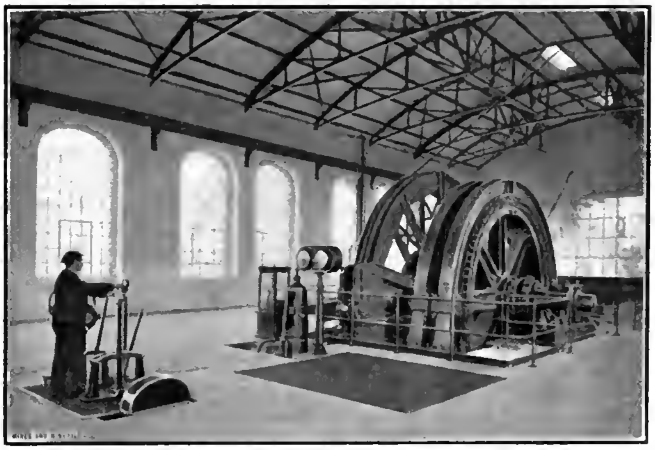

FIG 46. ELECTRIC HOIST, KOEPE TYPE

chosen with regard to the depth and the thickness of the rope used.

The effect of such loads upon the power house is obviously very severe when motors of several thousand horsepower are required to perform the work. The regulation of the power house, and consequently the operation of the other machinery

supplied with power from it, is very seriously affected by such fluctuations when the hoisting load bears a large proportion to the total capacity, as is generally the case. Under exceptional circumstances, where very large power hoists are used solely for industrial purposes, such fluctuations may not be of very great importance. The most serious feature of such a fluctuating load, however, is the effect upon the costs of producing

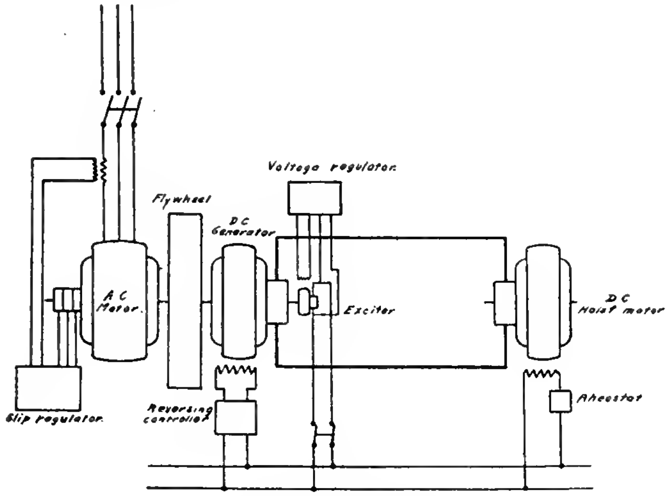

Fig. 47. Ilgner System

power. The average load in relation to peak loads may be comparatively small, and in this case the generating equipment must be run underloaded most of the time. When it is considered that the fixed charges of electrical plants very often exceed 50 per cent. of the total costs, the effects of running at light loads will be readily appreciated.

Fig. 45 shows the effect of varying loads upon a small industrial plant of 1,000 kilowatts capacity, this, of course, being applicable only for a certain case, but it indicates the effect of high-load factor. From this diagram it will be seen that the fixed charges, attendance, maintenance, etc. amount to $13,000 per year. The fuel and water required to run the plant light

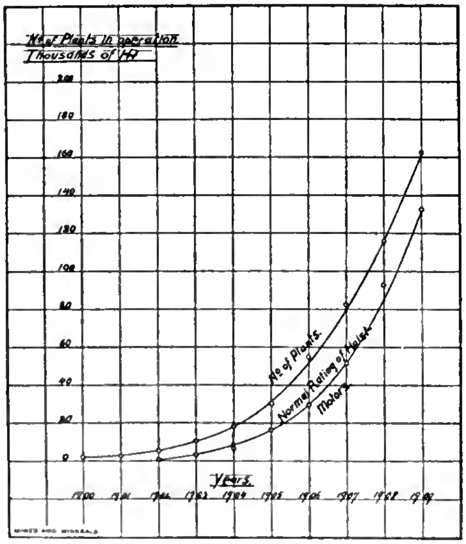

Fig. 48

loaded are taken as $5,256, so that if the plant ran without a load the total cost would be $18,256. The additional fuel required to operate a plant when generating power will vary practically directly with the load. In the case of the plant under consideration, the cost of fuel when running at 100 per cent. load continuously would be $26,280 per year. Coal has been figured as averaging $3 per ton delivered. From the curve drawn on this diagram showing the cost per kilowatt-horsepower, the effect of the load factor is very plainly shown—the power cost at 20 per cent. load being approximately 1.3 cents per kilowatt-horsepower, and at 100 per cent. load .5 cent per kilowatt-horsepower. The load factor of the ordinary hoisting plant seldom exceeds 20 per cent. so that the cost of power is high in relation to what it would be with the same continuous load.

In 1902 the Harpener Bergbau Aktien Gesellschaft installed the first large electric hoist, which is illustrated in Fig. 46. This hoist had a capacity of 4,800 pounds, and a full speed of 3,150 feet per minute, the motor having a maximum capacity of about 1,400 horsepower. It will be seen from the illustration that the hoist is of the Koepe type, being direct coupled to a three-phase induction motor with a wound rotor. The control apparatus for this motor is mounted below the floor level and operated by the levers shown in the illustration. The effect of the intermittent loads upon the generating station, which is of moderate capacity, is such that it is generally found necessary to run the hoist on separate generators, otherwise the regulation is so much affected that the operation of the other apparatus is seriously interfered with. This hoist has been working very satisfactorily since the installation, but the effects of the intermittent load upon the generating plant rather hampered the developments along these lines. The question of control was overcome by using a special liquid starter of very large capacity.

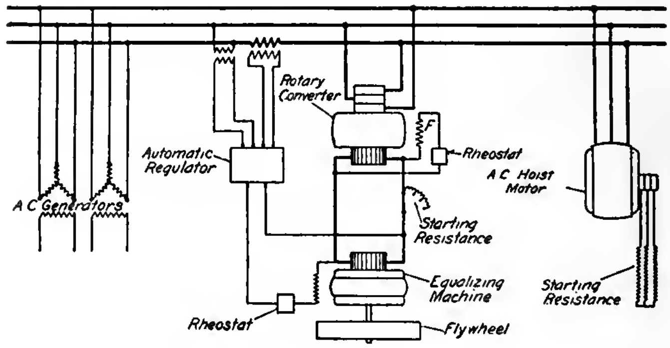

Fig. 49

About the same time, another hoisting system began to receive attention. This system employs a motor generator for supplying power to the hoist, the hoist motor being a direct-current, shunt-wound machine with separately excited field. The operation of the hoist is controlled by varying the voltage of the generator, to which it is directly connected electrically. By reversing the excitation of the generator the direction of rotation of the motor is also reversed. It will be seen that the control problem is very simple with such a system, as it is only necessary to handle a very small current. At the same time rheostatic losses are obviated, it being possible to run the hoist at any speed that may be desired. The characteristics of the shunt-wound hoist motor are such that when lowering materials it acts as a generator and returns energy through the motor generator to the line. This may also take place when the hoist is being retarded so that the mechanical brakes are only used to hold the load. This system was first used for hoisting purposes in the plant of the Gewerkschaft Hollertszug, which began operation in 1895. This arrangement does not obviate the intermittent nature of the hoisting load, but it eliminates the control problem, which is one of the most serious in connection with electrical-hoisting plants and at the same time it is somewhat easier on the generating plant, as the load is applied more gradually than is the case with direct rheostat control.

It was obvious, however, that electric hoisting plants could hardly be expected to compete with large steam-operated equipments unless some method was found to equalize the input so as to improve the load conditions on the generating plants.

In the beginning of 1903 the Ilgner system of hoisting plant was introduced. This system employs a motor generator set for supplying power to the hoist motor, which is of the shunt-wound type. The control is similar to the system previously supplied. Fig. 47 shows diagrammatically the essential features of the scheme. In addition, however, a flywheel is connected to the motor-generator set and arrangements are made to automatically vary the speed so that during peak-load periods the speed of the set is decreased, and part of the energy in the flywheel is used to assist the motor in driving the generator. When the load drops below a certain value the speed of the set is gradually increased and energy is again stored in the flywheel. By properly proportioning the flywheel, assuming that the cycle of operation remains constant, it is possible to keep the input to the hoisting plant within a few per cent. of the average load. It will be seen that this system overcame the principal objection to electric hoisting equipments and opened the way for the development of the largest equipments likely to be required in practice. The question of control, which was very troublesome, is also eliminated in the Ilgner system of operation. During the period from 1903 to 1906 a number of plants were installed working on this system, for maximum capacities up to about 2,000 horsepower. This time may be considered more or less as an experimental period, as the mine operators were anxious to obtain reliable data as to the operation of the various plants installed. In Fig. 48 the total number of plants and the normal continuous rating of the hoist motors used is shown for the various years. It will be seen that from 1906 onwards the rate of increase of electrically operated hoisting plants has been very great. The curves shown cover the plants in operation in Europe, and they represent an investment for electrical equipments of approximately $6,000,000. The curves show only equipments used for main-shaft hoisting and do not take into consideration haulage plants or small auxiliary hoists.

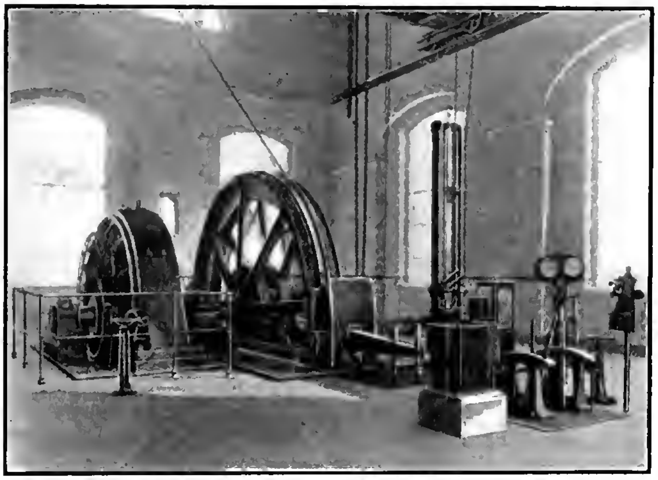

Fig. 50. Electric Hoist, Koepe Type

Fig. 51. Ilgner Type, Flywheel Motor Generator Set

Among the plants in operation may be mentioned that at the Gelsenkirchener Bergwerke A. G. which has a maximum capacity of 19,300 pounds and a full speed of 4,000 feet per minute, the motors having a maximum rating of 3,560 horsepower. One objection to the Ilgner system of hoisting is the expensive nature of the plant, the addition of a motor generator and flywheel increasing the cost considerably. To overcome this feature and still to provide for the equalization of the input, a system has been introduced by the British Westinghouse Co. which may be used under certain circumstances. This scheme is shown diagrammatically in Fig. 49. The hoist motor in this system may be either direct current or alternating current, depending upon the source of supply. The diagram of connections, Fig. 49, shows the arrangement of the plant with an alternating current source of supply. In parallel with the generators, an equalizing outfit is arranged, which consists of the direct-current machine coupled to the flywheel which is connected to the alternating-current system through a rotary converter.

This equalizing equipment can be located anywhere that may be convenient, it not being necessary to have it near the hoist. The operation is as follows: When the hoist load exceeds the value for which the regulator is set, the field of the equalizing machine is automatically strengthened, so that the speed tends to drop and the machine is driven as a generator by the flywheel and delivers energy through the rotary converters to the alternating-current system, the rate at which the energy is delivered being dependent upon the operation of the regulator. When the demand drops below the value for which the regulator is set, the field of the equalizing machine is automatically weakened and it then runs as a motor, absorbing energy from the alternating-current system through the rotary converter and speeding up the flywheel. In this way the demand on the alternating-current system is kept practically constant. When this system is used with a direct current source of supply the rotary converter is omitted and the equalizing machine connected directly to the line. It will be seen that this arrangement does not provide for controlling the hoist motor, as is the case with the Ilgner system, but it has the advantage that the equalizing machine has only to deal with the loads in excess of the mean value for which the regulator is set, and the cost is considerably reduced compared with the former system. It also has the advantage that, should any part of the equalizing equipment fail, it does not interfere with the operation of the hoist motor. The application of this system is practically confined to cases where the rheostatic control of the hoist motors offers no difficulties and where equalization of input is all that is required. In case of very large plants the control question is of such importance that the Ilgner system is used almost exclusively.

One important feature in connection with electric hoisting is the ease with which safety devices can be arranged to prevent overwinding or overloading. In connection with systems using either a motor generator flywheel or the Ilgner system of control, automatic devices have been arranged so that the rate of acceleration is limited and the hoist is automatically retarded independent of the operator, and as these devices are used every time the hoist is operated they are necessarily kept in order. With such arrangements, overwinding or starting up the hoist in the wrong direction is absolutely impossible, and in view of these features the German mining authorities have allowed the rate at which men may be hoisted to be increased from 1,200 feet per minute, which is the maximum with steam-operated hoists with the best safety gears, to 2,000 feet per minute with electric hoists, and the question has been under consideration for some time of increasing this limit to 3,000 feet per minute.

The value of such a feature will be particularly appreciated in connection with deep mines where the time required for getting the men to and from their work is of considerable importance.

One important feature in connection with electrical hoisting plants is their flexibility. In Fig. 50 an electric hoisting plant of the Koepe type with direct-current motor is illustrated. The capacity of this plant is 7,900 pounds at a speed of 3,150 feet per minute, the motor having a maximum rating of 1,250 horsepower.

At some later date, when the mine conditions are such that a greater output is required, a second motor will be added and the load increased to 15,800 pounds. It will be possible to do this without disturbing in any way the operation of the plant, a second generator being added to the Ilgner flywheel set which supplies energy to the hoist to take care of the additional load.

Fig. 51 illustrates a flywheel motor-generator set of the Ilgner type, and it will be noticed that the three-phase driving motor is considerably smaller than the generator, this being due to the fact that the motor is designed for the mean load and the generator must be capable of taking care of the peak loads. In large equipments of this type it is usual to mount the flywheel so that it may be disconnected from the motor generator set. This has the advantage that when only a few trips are required during periods of shut-down, the motor generator can be run alone and the hoist worked at slow speed so that the losses on the generating station are not excessive.

The experience obtained from the operation of the various plants in Europe has shown that electrical hoisting plants, when properly designed, are thoroughly reliable, the maintenance being practically negligible, plants having been in operation for several years, the only renewals required being brushes for the generators. Experience has been such that the operators state that they are not in a position to form any estimate as to the ultimate life of the plant, as indications are that it is indefinite.

(To be continued)

GAS BLOWERS IN COYOTE MINE

Written for Mines and Minerals, by A. A. Galloway, C. E.

The Coyote Mine of the Mexican Coal and Coke Co., Las Esperanzas, Mexico, develops a coal seam ranging from 3 to 6 feet in thickness, dipping 45 degrees from the horizontal,

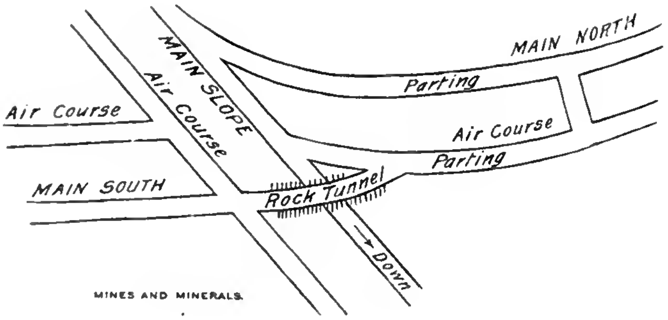

Fig. 1

and containing much gas. It is the same field as the ill-fated Palau Mine which, within the past year, has suffered two disastrous explosions.

Gas occluded in crevices of this coal seam and adjoining strata lets go with tremendous force when the entries approach near the pockets. During April, 1909, the miners working in the third north entry were several times forced to leave the mine because of an unusual quantity of gas suddenly entering the entry. One April morning, about 9 o'clock, gas, which had been occluded in the coal about 70 feet above the main entry broke out of its confinement and converted 40 tons of the intervening coal into slack, with which the entry was completely blocked. The two Mexican miners working in this entry were instantly killed by the force of the released gas. One miner was found stretched along the lower rib, the other in the middle of the track, and both were covered by tons of slack.

The ventilating current of the mine was not split, so that immediately after the blow-out so much gas was liberated that the entire mine was filled to the danger point, necessitating a close-down for that day. The next day all the workings were clear and no more trouble was experienced until the following June, when another pocket was encountered near the face of the main slope. Here ten more lives were snuffed out when the gas broke forth. Being two lifts lower than the third north entry, much more pressure was exerted on the restraining coal than the April release above described, and the increased number of fatalities is explained by the fact that two pairs of levels were being turned off the main slope at this point, hence more miners were within the danger zone.

Coyote Mine is developed by slopes driven on one-half of the pitch of the seam. This method of development permits of a larger trip, greater speed of trip, better track, and greater ease of ingress and egress for the miners, but the greatest advantage is the improvement in landing the trips on the partings, the one-half pitch slope permitting an easy curve and gradual grade changes in landing on the north side. For the south entries the empties are landed on the north partings and then passed to the south side through rock tunnels which pass over the main slope through the rock, reentering the coal seam after having passed the main slope. The method is well shown by the accompanying sketch, Fig. 1.

This method of driving slopes on the half pitch of heavily pitching seams was found so satisfactory that the engineer who had initiated it here introduced it into some Oklahoma mines in which he was interested.

CEMENT CONCRETE VATS AND TANKS

By Albert Moyer, Asso. Am. Soc. C. E.

Impervious, odorless, tasteless, and sanitary vats and tanks can be constructed of reinforced concrete, the reinforcing to be designed by a competent engineer, provided the interior surfaces are treated as follows:

After the forms are removed, grind off with a carborundum stone any projections due to the concrete seeping through the joints between the boards. Keep the surface damp for 2 weeks from the placing of the concrete. Wash the surface thoroughly and allow to dry. Mix up a solution of one part water glass (sodium silicate) 40° B., with four to six parts water, total five to seven parts, according to the density of the concrete surface treated. The denser the surface the weaker should be the solution.

Apply the water-glass solution with a brush. After 4 hours and within 24 hours, wash off the surface with clear water. Again allow the surface to dry. When dry apply another coat of the water-glass solution. After 4 hours and within 24 hours, again wash off the surface with clear water and allow to dry. Repeat this process for three or four coats, which should be sufficient to close up all the pores.

The water glass (sodium silicate) which has penetrated the pores has come in contact with the alkalies in the cement and concrete and formed into an insoluble hard material, causing the surface to become very hard to a depth of ⅛ to ½ inch, according to the density of the concrete. The excess sodium silicate which has remained on the surface, not having come in contact with the alkalies, is soluble, therefore easily washed off with water. The reason for washing off the surface between each coat and allowing the surface to dry, is to obtain a more thorough penetration of the sodium silicate.

TWO-STAGE AIR LOCOMOTIVES

Written for Mines and Minerals

Increased Economy of Two-Stage Compared With Single-Stage Compressed Air Locomotives

Single-expansion compressed-air locomotives are comparatively well known. In this type, air at a pressure of from 600 to 1,000 pounds is stored in a large reservoir from which the air is drawn through a reducing valve set to maintain a pressure of about 150 pounds at the throttle valve. The substitution of a reservoir for a boiler and the use of a reducing valve to regulate the pressure were the only features essentially different from a single-expansion steam locomotive.

From 1873 to 1908, these locomotives were built in gradually increasing numbers for operation in mines where the absence of fire, smoke, sparks, and electric wires was particularly desired. The handicap of a rather poor efficiency, in spite of which the single-expansion compressed-air locomotive has been found the best motive power for a variety of purposes, is to a large extent removed by the two-stage type, which will do from 40 to 60 per cent. more work with the same quantity of air, thus reducing the cost for power about 30 per cent.; reducing the size of the compressors and boilers 30 per cent.; reducing the first cost of installation approximately 15 per cent.; and increasing by 30 per cent. the distance which the locomotive will travel on one charge of air.

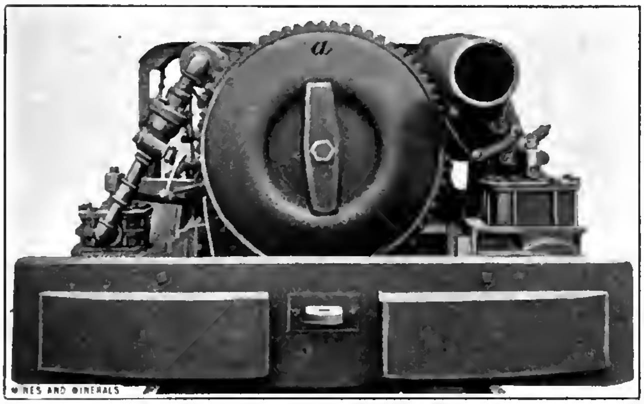

FIG. 1. FRONT OF TWO-STAGE LOCOMOTIVE

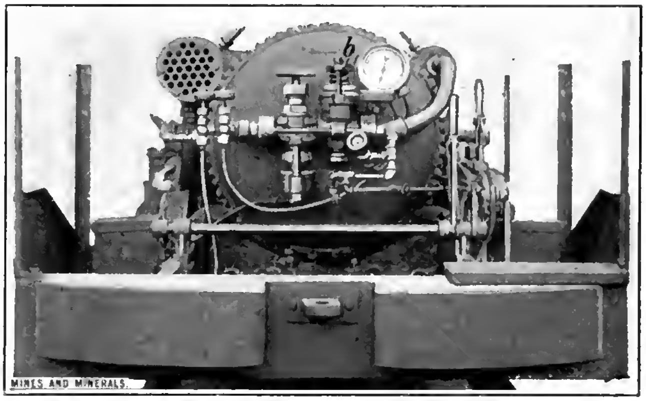

FIG. 2. REAR OF TWO-STAGE LOCOMOTIVE

In the two-stage locomotive the compressed air is expanded in two successive cylinders, providing for a wider range of expansion, with higher initial and lower terminal pressures, thereby securing many of the advantages which compound cylinders give where steam is used, except that in the case of air there can be no cylinder condensation. The effects of a wide range of expansion in a single cylinder, with the resultant great difference in temperature, are, none the less, of serious consequence, causing as they do a temperature of the cylinders and port walls considerably below that of the incoming air, with initial refrigeration and a serious shrinkage in volume. In addition to this, which is the principal reason for compounding with steam, there are various other considerations which render the expansion of compressed air in successive cylinders either vastly more advantageous or an utter failure, depending upon whether advantage is taken of the radically different conditions under which the two fluids operate.

These differences in conditions are due to the steam engine being a primary machine for the conversion of the heat derived from coal or other fuel into work. By application of heat, water or any other fluid may be vaporized, and if confined, will exert a pressure which can move a piston in a cylinder. To obtain the best results, all losses of heat must be avoided, as the pressure and vaporized condition has been caused by heating the water, and when the excess heat above that of the surrounding materials has been lost, the water again becomes inert and incapable of work. The excess heat of the working fluid above that of the surrounding natural objects is, then, the real source of power.

With air the sensible heat of compression and the sensible refrigeration of expansion are unavoidable evils which must be reduced to a minimum. If the heat of compression could be taken away fast enough to keep the air down to its natural temperature during the entire process of compression, and if heat could be supplied during expansion fast enough to prevent any cooling below that of surrounding objects, or if all of the heat of compression could be retained until the air reached the cylinders in which it is to be expanded and do work, compressed air would be 100 per cent. efficient, barring the losses due to friction of the compressing and expanding engines. Unfortunately, both plans are impossible, more particularly in the case of the locomotives. The air must be compressed and expanded so rapidly that there is no time either to extract the heat of compression while the air is in the compressor cylinders, or to prevent refrigeration while expanding in the cylinders of the locomotive; and any heat remaining in the compressed air after it leaves the compressing cylinders is unavoidably lost before it reaches the working cylinders of the locomotive, because of the necessity for storing the air for considerable periods of time in tanks and pipe lines in order that the locomotive may be charged promptly and at various stations frequently spread over an area of several thousand acres.

In compressing air, the first suggestion—compression without heating—has been approximated by performing the operation in successive cylinders of decreasing size, with intercoolers in which the heat due to the preceding compression is removed. The intercooler consists of a casing filled with small tubes through which cold water is circulated. The air passing through the casing and around the tubes is thoroughly cooled before it enters the next cylinder.

This rational, and therefore successful, method of preventing losses has been in general use since 1890, and all compressors for charging locomotives are of either the three-stage or four-stage type, with either two or three intercoolers, reducing the heat losses from 96 per cent. to 17 per cent., based on isothermal compression. With more stages the heat losses could be further reduced, but only at the expense of so much friction and complication due to the multiplication of cylinders and intercoolers that the reduction in heat losses would be more than balanced.

A great saving in the power required to compress air having been effected by intercooling with water at atmospheric temperature, it was only a short step to the reversal of this process—interheating with water after partial expansion in a high-pressure cylinder, before the air entered the low-pressure cylinder. This method of utilizing compressed air for driving pumps has

been adopted with marked success and greatly increased efficiency, as the water which the pump was moving could readily be circulated through the interheater. It was a longer step to the reversal of the process and the substitution of atmospheric air, the only available heating medium which could be drawn on continuously while the locomotive was in motion.

The problem was not satisfactorily solved until 1904, when the H. K. Porter Co. undertook a series of experiments leading up to the atmospheric interheater, with which their two-stage locomotives are equipped.

This appliance also made possible a number of incidental improvements. It provided for a higher ratio of expansion, with higher initial and lower terminal pressures, without unmanageable refrigeration, just as stage compression made possible higher pressures and higher ratio of compression without unmanageable heating.

In a steam engine, because heat is the immediate source of power, the steam should enter the working cylinders at the highest practicable temperature, be exhausted at the lowest, and all losses due to radiation or convection guarded against, in order that the largest possible percentage of heat may be converted into work. In a compressed-air locomotive plant, because the heat of compression is lost before the compressed air can enter the working cylinders of the locomotive, the best results are obtained by the closest possible approximation to compression without heating, and to expansion without cooling, thereby reducing to a minimum the extra work of compression due to heating, and the work lost due to the cooling of the air during expansion.

Because the performance of the compound steam locomotive has been thoroughly tested by many competent investigators, and the increased efficiency, as compared with the single-expansion locomotive, has been established at about 20 per cent., and as it has been previously stated that the two-stage compressed-air locomotive using many of the same appliances will be from 40 per cent. to 60 per cent. more efficient than a single-expansion compressed-air locomotive, a brief statement in parallel columns is given of the differences which justify another name for a similar apparatus, and in explanation of the greater gain in efficiency.

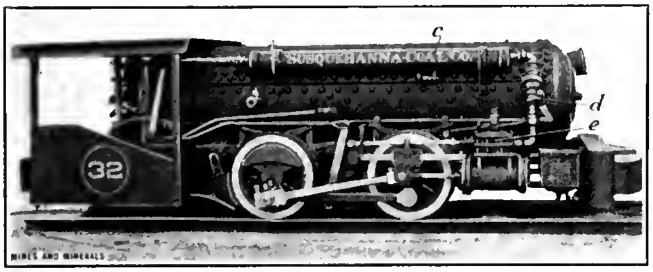

Fig. 3. Right-Hand Side of Two-Stage Air Locomotive

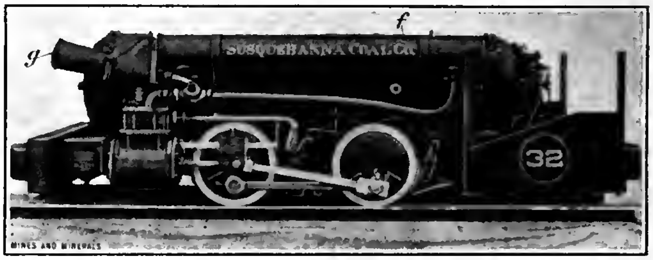

Fig. 4. Left-Hand Side of Two-Stage Air Locomotive

HIGHER PRESSURES TO OBTAIN THE ADVANTAGES OF COMPOUNDING

TWO-STAGE COMPRESSED-AIR LOCOMOTIVE

In order to store compressed air in sufficient quantities to avoid too frequent charging of the locomotive, the air must be compressed to about one-sixtieth of its normal volume and to 800 or 900-pounds pressure. This fundamental requisite provides for a higher pressure in the valve chest of the high-pressure cylinder without additional cost or other compensating disadvantages to obtain it.

COMPOUND STEAM LOCOMOTIVE

Higher steam pressures require a heavier and more expensive boiler; more coal to evaporate a given amount of water into steam at the higher pressure and temperature; more expense for repairs to keep the boiler in working order. The higher temperature of steam at a higher pressure requires better and more expensive lagging for boiler and cylinders to prevent undue losses due to radiation, and better and more expensive packing and lubricants.

REHEATING BETWEEN HIGH- AND LOW-PRESSURE CYLINDERS

The compressed air stored in the main reservoir is at atmospheric temperature because the heat of compression is necessarily lost before the air reaches the locomotive reservoir. For this reason the loss of heat due to the partial expansion of the air in the high-pressure cylinder carries it far below the temperature of the surrounding atmosphere (usually about 140° F. below), thereby rendering the atmospheric air an efficient and inexhaustible heating medium which costs nothing.

The steam in a locomotive boiler is at a temperature of from 350° F. to 375° F., and even after partial expansion in the high-pressure cylinder, is still at a temperature far above that of the atmosphere. It can only be reheated by burning more coal—and coal costs money.

EFFECT OF INITIAL TEMPERATURES

Compressed air enters the high-pressure cylinder at approximately atmospheric temperature, or below, and in expanding and doing work, becomes greatly refrigerated. If a high-grade ratio of expansion with high initial and low terminal pressures is attempted without restoring the lost heat while the operation is going on, refrigeration becomes so great that proper lubrication is impossible. This lost heat can only be properly restored by dividing the work into two stages and expanding the air in successive cylinders with a properly designed interheater between them. A high ratio of expansion and the resultant economies therefrom are therefore effectively possible in connection with two-stage or multiple-expansion cylinders only

Steam enters the high-pressure cylinder at a relatively high temperature, and as it loses heat due to expansion and work done, becomes cooler. But it is never cold enough to render lubrication more difficult at the lower temperature than the higher. Steam is expanded in two or more successive cylinders in order to reduce the range of temperature in any one cylinder, and to prevent cylinder condensation. There is no other reason why a compound or triple-expansion steam engine should be more economical than an engine in which the same ratio of expansion is obtained in a single cylinder.

The front of a two-stage compressed-air locomotive is shown in Fig. 1, the rear in Fig. 2, and both sides in Figs. 3 and 4. The supply of air is carried in the large cylindrical tank *a*, Fig. 1, which, when first charged, contains air at a pressure of about 800 pounds per square inch. From this tank

air is drawn through a reducing valve b, Fig. 2, which is adjusted to maintain a pressure of about 250 pounds in the small auxiliary reservoir c, Fig. 3. From this auxiliary reservoir the air passes through a throttle valve d, Fig. 3, located in a pipe leading from the front end of the auxiliary reservoir to the valve chest e, Fig. 3, of the high-pressure cylinder. The exhaust from the high-pressure cylinder is piped to the front end of the atmospheric interheater f, Fig. 4. From the rear end of the inter-

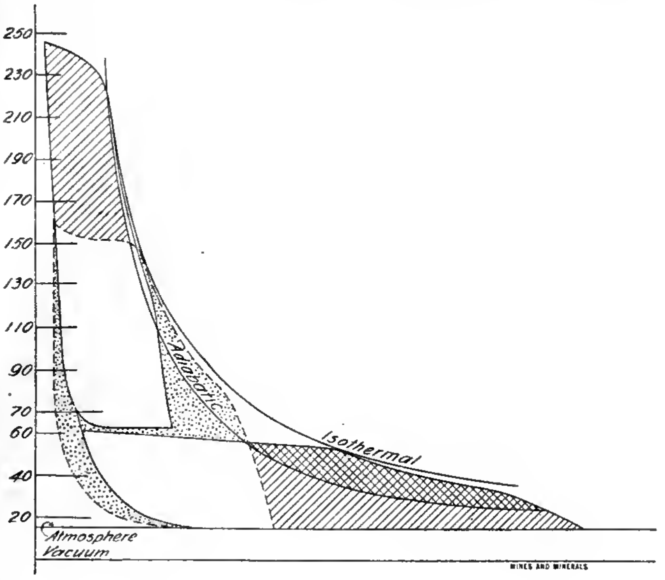

FIG. 5

heater another pipe leads to the valve chest of the low-pressure cylinder (on the left side of the locomotive). From the exhaust port of the low-pressure cylinder, still another pipe leads to an exhaust nozzle, located in and concentric with a slanting locomotive draught stack g, Fig. 4. For ordinary working conditions a cylinder ratio of 4 to 1 has been found most advantageous. During the partial expansion in the high-pressure cylinder, from 250 pounds down to 50 pounds, the temperature of the air ordinarily drops about 140° F., or from about 60 degrees above to 80 degrees below zero, so that on leaving the high-pressure cylinder the volume of the air is only $\frac{380 \times 100}{520} = 73$ per cent. as great as it would be if no refrigeration has occurred in the high-pressure cylinder. Without the interheater the volume of the low-pressure cylinder would only be $4 \times .73 = 2.92$ times the volume of the high-pressure cylinder if the initial pressure of 50 pounds per square inch in the low-pressure cylinder is to be maintained. The atmospheric interheating between the high- and low-pressure cylinders expands the air in its passage to make it fill a cylinder $4 \div 2.92 = 1.36$, or 36 per cent. larger than it could otherwise fill with air at a pressure of 50 pounds per square inch, and in so doing adds 36 per cent. to one-half of the work done by the air, or 18 per cent. to the total amount of work done by the air, due to the interheating alone.

The interheater consists of a cylindrical casing filled with small tubes. The partly expanded and refrigerated air on its way from the high-pressure to the low-pressure cylinder is passed through the casing and around and between the small tubes, while a violent current of relatively warm atmospheric air is being drawn through the small tubes by the partial vacuum created in the base of a slanting draught stack by the ejector action of the exhaust from the low-pressure cylinder.

With an interheater of the size shown in Fig. 4, practically all of the heat is restored and the air enters the low-pressure cylinder at a temperature within about 15 degrees of that of the surrounding atmosphere. The temperature of the surrounding atmosphere has no appreciable effect upon the relative economy of this type as compared with the single-expansion locomotive, because the air in the main tank is always at approximately atmospheric temperature, however low that temperature may be. The partly expanded air from the high-pressure cylinder is therefore always relatively cold as compared with atmospheric air which renders the latter, under all conditions, an efficient heating medium.

The preceding varied explanations of the cause and effect of the fluctuating temperatures of the compressed and expanding air in the operation of compressed-air locomotives are intended partly for the lay reader who ordinarily thinks that pressure does the work in steam or air engines and forgets that the pressure is derived from heat, and partly to assist the engineer in adjusting his thoughts to fit a rather unusual set of conditions.

Something over one hundred two-stage compressed-air locomotives have been built during the past 2 years, and their superior efficiency, desirable simplicity, and reliability, thoroughly demonstrated. In coal and metal mines the two-stage locomotive has been operated in comparison with single-expansion locomotives, and by the simple test of having first one locomotive and then the other haul the same train over the same piece of track, the added endurance on one charge of air and the superior efficiency of the two-stage machine has been established.

Operators who have been using single-expansion compressed-air locomotives for 15 years are having their single-expansion locomotives converted into two-stage machines, at an expense far in excess of the difference in the first cost of the two types, because there is a continuous saving in operating expenses, and because the first cost of converting the locomotives is less than the expense of additional compressors and boilers to provide for increasing tonnage and longer haul.

The results of two of the simple tests mentioned above, together with combined indicator diagrams, Fig. 5, of the two-stage with superimposed diagram of the single-expansion locomotive, are given in order to show the actual results which have been obtained. Both tests were made in the same way and without special preparations. Many others could be cited, but these two are sufficient when taken in conjunction with the manifest possibilities of the apparatus and the indicator diagrams. The two long curved lines are the isothermal and the adiabatic. The isothermal curve shows the relations of pressure and volume if the air could be expanded without any reduction in temperature; the adiabatic curve shows the same relations if the air were expanded without obtaining heat from any source except itself. The double-cross-hatched area is the gain due to the interheater alone. The single-cross-hatched

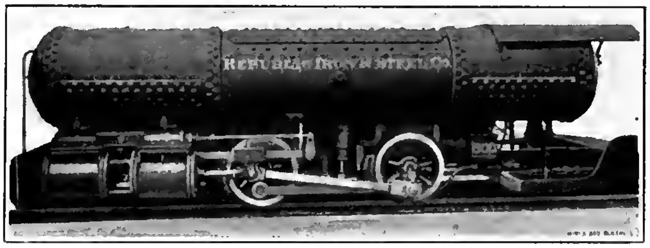

FIG. 6. COMPRESSED AIR LOCOMOTIVE, WEIGHT 34,000 POUNDS

area plus the double-cross-hatched area, minus the stippled area, equals the total gain due to the higher initial and lower terminal pressures, with a wider range of expansion in two successive cylinders, only possible in conjunction with the use of an interheater to prevent unmanageable low temperatures in the low-pressure cylinder.

An unavoidable loss occurs in the use of compressed-air locomotives, due to the high pressure to which the air must be compressed in order to reduce the bulk of the storage tanks

on the locomotive and to enable the locomotive to maintain its maximum tractive force for relatively long distances. In practice, the air is usually compressed to 1,000 pounds per square inch for storage in the stationary reservoir from which the locomotive draws its supply. The locomotive is usually charged to a pressure of 800 pounds per square inch. In the newer, two-stage type this pressure is reduced to 250 pounds before it enters the high-pressure cylinder; in the older, single-expansion locomotive it was reduced to 150 or 160 pounds for use in the cylinders. The consequent losses are not in direct proportion to this reduction in pressure, as might be inferred if the subject were given only superficial attention. To compress 100 cubic feet of free air in two stages to 150 pounds pressure requires 19 horsepower; 100 cubic feet in two stages to 250 pounds, 22½ horsepower; 100 cubic feet in three or four stages to 1,000 pounds, about 33 horsepower. There is, therefore, a loss of only one-third of the total power in reducing from 1,000 to 250 pounds, although the gauge pressure is reduced three-fourths. The reason for this is apparent when we consider that as the pressure increases the volume diminishes. In a three-stage compressor designed to compress the air to 1,000 pounds, the second-stage cylinder has about one-fourth of the volume of the intake cylinder, while the average pressure is four times as great, which makes the work in the second stage the same as in the first. In the third and final stage the average pressure is 16 times as great and the volume one-sixteenth of the intake cylinder, and the total work is again the same; so that only one-third of the total work done in compressing the air to 1,000 pounds pressure is thrown away in reducing the pressure from 1,000 to 250 pounds. It is this feature of air compression which makes the compressed-air locomotive a commercial success.

In addition to Figs. 3 and 4 which show the small compressed-air locomotive used by the Susquehanna Coal Co., Fig. 6 shows a 34,000-pound locomotive built for main haulage in the coal mine of the Republic Coke Works, Republic Iron and Steel Co.

Trials for Comparative Air Consumption.—The following method of making trials between single-expansion and two-stage compressed-air locomotives was employed in all cases: The same train was hauled by the single-expansion and two-stage locomotives the same distance over the same piece of track, with the same operator, giving the locomotives as nearly as possible the same work to do under the same conditions. In all cases the trains were started from a given point and were allowed to come to rest as near as possible to another given point without the use of brakes. Air consumed was determined by the difference in pressure recorded at the beginning and end of the trip by the gauge on the main reservoir. Running conditions were the same as would obtain in the regular hauling of coal in the mine.

Trial 1 was conducted at the Susquehanna Coal Co.'s No. 7 colliery, Nanticoke, Pa., in the presence of Mr. McMahon, Chief Engineer Susquehanna Coal Co., and Mr. C. B. Hodges, of the H. K. Porter Co.

Trial 1. Locomotive Data

	Single Expansion	Two-Stage
Weight	10,000 pounds	10,600 pounds
Cylinders, high-pressure, diameter	6 inches	5 inches
Cylinders, low-pressure, diameter		10 inches
Cylinders, stroke	10 inches	10 inches
Driving wheels, number and diameter	4—23 inches	4—23 inches
Working pressure, high-pressure cylinder	150 pounds	250 pounds
Maximum charging pressure	900 pounds	900 pounds
Capacity of main reservoir	41 cu. ft.	41 cu. ft.
Age of locomotive	8 months	1 month

Train and Road Data

Length of trial run, feet	2,200
Average grade, per cent	.96
Maximum grade, per cent	2.00
Track gauge, inches	42

Train consisted of loaded coal cars weighing about 9,500 pounds each.

REMARKS

The excessively high efficiency indicated on lines Nos. 4 and 6, hauling four and five cars down grade, may be due to the fact that considerably more air is wasted in the single-expansion locomotive when giving the train just a little assistance when the grade is nearly steep enough to cause it to run down by itself.

Lines Nos. 7 and 8 show additional trips up grade with the two-stage with five-car trips. The trip with the two-stage (line 5) was made with the reverse lever "in the corner," using the air full stroke all the way. The superior efficiency achieved on trips shown on lines Nos. 7 and 8 was the result of using the air as expansively as possible.

Taking the total pressure reduction of the three round trips with the single-expansion locomotive and two-stage locomotive (lines 1, 2, 3, 4, 5, and 6), we find that the two-stage locomotive used $\frac{1,245}{2,225}=56$ per cent. of the air used by the single-expansion engine under exactly the same conditions of service, this average per cent. for the entire test showing a saving of 44 per cent. of the air used by the single-expansion machine.

In making the test every care was used to obtain reliable results. The pressure gauge on the two-stage locomotive was removed and placed on the single-expansion locomotive during the test of this locomotive, and then shifted back to the two-stage for testing it. This gauge was a comparatively new one, and presumably correct, and if any error did exist, it would have been the same for both locomotives. The tanks were exactly of the same capacity. The same engineer operated both locomotives alternately during the trials.

Log of Runs

With Pressure Reductions and Percentage Used by Two-Stage Locomotive

Line	Single Expansion					Two-Stage					Percentage Used By Two-Stage	
	Number Cars	Gauge Pressure		Pressure Reduction	Time	Number Cars	Gauge Pressure		Pressure Reduction	Time		
		Start	Stop				Start	Stop				
1	3	690	280	410	3:15	3	680	400	280		68.3	Up grade
2	3	280	140	140		3	400	320	80		57.1	Down grade
3	4	770	180	590	3:30	4	570	250	320	2:40	54.2	Up grade
4	4	760	540	220		4	250	175	75		34.1	Down grade
5	5	805	200	605	2:55	5	710	290	420	2:50	69.5	Up grade
6	5	730	470	260		5	290	220	70		26.9	Down grade
				2,252					1,245			
	Total pressure reduction 2,225 pounds—3 round trips					Total pressure reduction 1,245 pounds—3 round trips						
7						5	610	220	390			Up grade
8						5	735	360	375	3:15		Up grade

Trial 2 was conducted at Orient Mine of the Orient Coke Co., Orient, Fayette County, Pennsylvania, in the presence of Mr. Chas. Opperman, of the Orient Coke Co.; Mr. G. E. Huttelmaier, of the H. C. Frick Coke Co.; Mr. C. B. Hodges, of the H. K. Porter Co.

TRIAL 2. LOCOMOTIVE DATA

	Single Expansion	Two-Stage
Weight	9,600 pounds	10,500 pounds
Cylinders, high-pressure, diameter	6 inches	5½ inches
Cylinders, low-pressure, diameter		11 inches
Cylinders, stroke	10 inches	10 inches
Driving wheels, number and diameter	4-23 inches	4-23 inches
Working pressure, high-pressure cylinder	150 pounds	250 pounds
Maximum charging pressure	800 pounds	800 pounds
Storage tanks	1	1
Capacity of main reservoir	40.26 cu. ft.	40.26 cu. ft.
Age of locomotive	6 months	2 months

TRAIN AND ROAD DATA

Length of trial run, feet	2,500
Average grade, per cent	.52
Track gauge, inches	44

In this run there was a reverse curve in a chute leading from one heading to a parallel heading. The train consisted of four loaded wagons, each about 7,000 pounds; and six empty wagons, each about 2,200 pounds.

LOG OF TRIAL RUNS

No. of Run	Type of Locomotive	Tank Pressures At Start	At Finish	Am't of Drop	Time (P. M.) Start	Finish	Elapsed
1	Single expansion	705	265	440	7:23½	7:27½	.04
2	Two-stage	740	420	320	8:06½	8:12	.05½
3	Two-stage	685	385	300	8:48	8:52¾	.04¾

No. 1 run: Very satisfactory.
No. 2 run: Very irregular; operator not so familiar with two-stage machine, hence decided to rerun.
No. 3 run: Much better and smoother than second.

DEDUCTIONS
Calculated by Mr. G. E. Huttelmaier, H. C. Frick Coke Co.

	Trial No. 1	Trial No. 2
Free air consumed, cubic feet	1,206.92	877.76
Drawbar effort {Loco. 97.92 / Trip 832.24}	930.16	{107.10 / 832.24} 939.34
Total work performed in ft.-lbs	2,325,400.00	2,348,350.00
Ft.-lbs performed per minute	581,350.00	426,973.00
Average speed {Feet per minute	625.00	454.50
Average speed Miles per hour}	7.10	5.17
Average horsepower developed	17.61	12.94
Ft.-lb. work per cu. ft. free air	1,926.00	2,676.00
Free air consumed per minute	301.70	159.59
Air per minute per horsepower	17.13	12.33
Percentage of air consumed as compared with trial No. 1	100 per cent.	72 per cent.
Amount of work per unit of air compared to trial No. 1	100 per cent.	1.38 per cent.
Saving of air effected over trial No. 1		28 per cent.

EXPLOSIBILITY OF COAL DUST

Geological Survey Bulletin 425, on the "Explosibility of Coal Dust," can be had by writing to the Bureau of Mines, Washington, D. C. It is by George C. Rice, with chapters by J. C. W. Frazer, Axel Larsen, Frank Haas, and Carl Scholz.

Mr. Rice reviews the experiments into the explosibility of coal dust in foreign countries and dwells at considerable length upon the attitude taken in France by the engineers, who, until the great disaster at Courrieres in 1906, which cost 1,000 lives, did not believe that coal dust would explode without the presence of firedamp. Since that terrible disaster a testing station has been established in France and now the French engineers are fully convinced of the dangers of coal dust.

"The coal-dust question in this country," continues Mr. Rice, "cannot be said to have awakened widespread interest among mining men until the terrible disasters of December, 1907, which resulted in the death of 648 men. In response to a demand by those interested in coal mining throughout the country, Congress, in 1908, made an appropriation for the investigation of mine explosions. The United States Geological Survey was charged with the investigation. A testing station was at once decided upon and was established at Pittsburg, Pa.

"While it is probable that for several years the leading mining men in the country have believed in the explosibility of coal dust without the presence of firedamp, yet until the public demonstrations were given at the testing station at Pittsburg, during 1908-09, and reports were received of similar tests made abroad, a large proportion disbelieved. These tests were so convincing to those who saw them, and such general publicity has been given to them, that it is now exceptional to find a mining man who does not accept the evidence of the explosibility of coal dust. The question of the day no longer is 'Will coal dust explode?' but 'What is the best method of preventing coal-dust explosions?'"

The following are some of the tentative conclusions of Mr. Rice on the dust problem:

"That coal dust will explode under some circumstances, both in the presence of firedamp and without it, is now generally accepted by mining men. The writer fully agrees with this and takes the following views of the explosibility of dust and the conditions necessary for explosion.

"Experiments at Pittsburg indicate that under ordinary conditions the dust must be from coal having at least about 10 per cent. of volatile combustible matter, though in certain foreign experiments it is claimed explosions were obtained with charcoal dust.

"Dusts with higher percentages of volatile combustible matter are more sensitive, ash, moisture contents, and size, being constant. This view is based partly on the preliminary experiments at Pittsburg and on the results of experiments of Mr. Taffanel and other foreign investigators. Where there is a large amount of dry coal dust, judging from the Pittsburg experiments, a humid atmosphere has little effect on ignition of dust or propagation of an explosion. A long continuance of the humid conditions renders the coal dust moist and inert, but the presence of moisture in the air at the moment of explosion is not sufficient to prevent an explosion; that is, not enough moisture is carried by the mine air to reduce materially the temperature of the flame. Fully saturated vapor at 65° F., an ordinary mine temperature in this country, weighs 6.78 grains per cubic foot (15.5 grams per cubic meter). Coal dust suspended in such a saturated atmosphere in a cloud of moderate density weighs, say, 200 grams per cubic meter. At the figures given, the weight of vapor is but 7.8 per cent. of the weight of dust. The Pittsburg experiments with wetted dust showed that several times this percentage of moisture in the dust, in addition to a nearly saturated atmosphere, was required to prevent propagation.

"Probably with a low dust density, the relative humidity of the air would be an important factor in tending to prevent the initiation of an explosion. However, the great purpose of artificially humidifying mine air is that it may serve as a vehicle for carrying water to the dust."

Mr. Rice concludes by reviewing the various remedies that are offered for the coal-dust problem, giving the good and bad points of each.

The world's production of calcium carbide in 1908 amounted to 200,000 tons, one-fifth of which was produced in the United States and Canada. The production in the other countries was as follows, in tons: Italy, 32,002; France, 27,000; Norway, 25,000; Switzerland and Austria-Hungary, 20,000 each; Sweden, 12,000; Germany, 9,000; England, 800. There were 70 factories employed in the manufacture of the article. The production has increased very much in recent years.

THE MINE LAW OF WEST VIRGINIA*

By P. A. Grady, Mine Inspector, Twelfth District of West Virginia

The purpose for which this paper is written is to show that the mine operators who are the most successful producers of coal in the state are the ones who do their utmost to observe every requirement of the mine law. They know that when their operations are in such shape that coal can be produced in the most successful and economical way, year in and year out, they are exceeding all the most important requirements made of them by the mine law.

Those most Successful in the Production of Coal Do Even Better than the Law Requires

Some of you have no doubt heard the statement made some time or another, by some so-called mining man, that he was put to an unnecessary expense by having to put his mine in such shape as to comply with the mine law, and that he considered such obligatory acts as unreasonable and a hardship upon the mining industry of the state. That such views are not entertained by many is attested by the great number who, in their zeal, have striven to exceed any lawful requirements that we can put on our statute books.

Among the very first laws on our statute books is the one calling for maps to be furnished every 6 months to the district mine inspector. Before the present requirement became a law, the writer, in glancing through some of the reports of the mine department, noticed in a few places where the maps of certain mines had not been extended for a period of a year and a half, and sometimes two years. No practical up-to-date manager could go for so long a time without having the workings extended on his maps, to show how the work was progressing under his charge.

How much different from this is the practice at our best mines, where the maps are extended quarterly and the inspector, instead of getting a copy every 6 months, can have it every 3 months if he so desires.

Some difficulty has been met with by the mine department in getting the second opening of some few mines in a condition so as to comply with the mine law. In such cases this second opening is generally used as an airway to the fan, and from the way it is blocked with roof falls and standing water, you would wonder how any circulation is maintained through it all.

Directly opposed to such a practice are the ones who have not only a second, but a third and fourth opening, kept in a clean condition for the men and mules to travel in from the interior of the mine. This third and fourth entry serves another excellent purpose in reducing the power that has to be applied to the ventilating fan.

One of the requirements in our state is to furnish no less than 100 cubic feet of air per minute for each and every person employed in a mine, and if it were not also required that there be as much more air furnished as the district mine inspector might require, that law would be considered farcical by those who have well-ventilated mines; for the standard they maintain requires at least 10 times as much as is required by law. By furnishing the workmen a plentiful supply of air they know that they can obtain more work than they could in a poorly ventilated mine.

To conduct this air-current the successful operator constructs permanent stoppings out of concrete, brick, or stone, and he prevents leakage of the air-current to such an extent that he has over 90 per cent. of the total quantity circulating around the head of the workings. Wherever he has an entry or a section of the mine that he thinks will outlive the life of a temporary stopping, he will have one constructed that he knows will be there until the mine is worked out.

The make-shift coal operator wants to construct his stoppings in such a way that you would think they were only supposed to last for a few months, and in the end he spends much more money in reconstructing them than would have been required to construct suitable ones in the first place. The amount of ventilation conducted around the head of the workings with such stoppings is only about 40 per cent. of the total volume.

In ventilating 11 mines which one of the largest coal companies in this state is operating, 1,285 horsepower in electric energy is expended in running the fans. The ventilating fans at these mines are of the best make, and every care is taken, by constructing the best stoppings, to prevent any loss of the air-current before it reaches the innermost workings. All the material necessary to conduct the air is furnished, with the result that they have nearly the whole volume of air in circulation around the working places.

If this company had constructed the poor stoppings mentioned above, the amount of electric energy expended on its fans in air wasted, would be about 60 per cent. of the total amount, or 771 horsepower, and the cost of generating this amount is $74,000 per year. This only represents one of the losses there is in constructing poor stoppings.

A state mine inspector, at a meeting of the Mine Inspectors' Institute, held in Chicago last June, was heard to remark that he was unable to get the operators of the mines in his state to make a proper division of the air-current, and to get away from the continuous-current system in ventilating their mines. If he had presented figures to them showing that an overcast, costing about $150 to construct, would do away with at least one trap door, with its attendant cost of about $20 per month, their knowledge of the amount to be saved in a few months would have made them decide to construct overcasts.

The successful coal operator of this state will not have a trap door on his main entries, but will split the air as much as the total quantity and the extent of his coal property will allow.

Mines generating firedamp or other dangerous gases are required by law to be examined by a competent fire boss before the men enter for work. The practice at some of our best mines is to have the workings examined before work commences, whether they generate dangerous gases or not. Such an examination is made for the purpose of discovering any loose overhanging top, electric wires that may be down, dusty working places in which shots should not be fired until made wet, and any disarrangement of the air-current that may have taken place.

Those who have such examinations conducted claim that it is worth much more than the amount of money paid for it.

Where gas is being generated in dangerous quantities, it is unlawful to use any mechanical power for ventilating, other than a fan. Whether the mine generates gas or not, there is no reason why it should be ventilated with an antiquated furnace, which will, in the labor expended on it, and the fuel burnt, cost more in 6 months than would pay for a fan that would give seven times the amount of air such a furnace will give. Surely the workmen in such mines could perform more labor and give better returns if furnished with a plentiful supply of air.

The law requiring two safety lamps to be kept on hand at every mine in the state, whether it generates explosive gas or not, is a good one The purpose of the law is to have such lamps on hand should occasion demand their use unexpectedly.

The operator who thinks he is complying with the law when he has two obsolete Davy lamps hung up in the blacksmith shop at the mine, in such condition that it would take weeks to get them in shape to be used should anything occur, is fooling himself very much.

Sir Humphrey Davy's invention for a safety lamp served the purpose well for a time, but today it should be replaced by the more up-to-date safety lamps, with which the leading operators have provided themselves, and which will stand the tests which they must undergo.

* Paper read at the Wheeling meeting of West Virginia Coal Mining Institute, December 6, 7, and 8, 1910.

When the law went into effect requiring mine foremen to measure the air-current of the mine, an educational step was taken which resulted somewhat in the betterment of the men engaged in such work.

When the Mine Department of West Virginia, with the cooperation of the leading operators of the state, inaugurated a system of examining mine foremen and fire bosses, and granting them certificates if found competent, a far greater educational step was taken; for it has fostered in the minds of such men a desire to study and learn more of their calling.

The best safeguard we can erect against mining accidents does not lie in excessive legislation, but in better training of miners and mine officials, which will produce a higher degree of intelligence and a more thorough state of discipline among them.

The encouragement given by the Y. M. C. A. to educational work among the miners in this state is to be heartily commended; and that it is appreciated is evidenced by the many reading rooms established at mines where the men can read and study and indulge in other wholesome pastimes.

Our leading operators in the state today not only provide the instruments required by law at the mines, but, to show that they are keenly alive to know conditions that may exist within the mines; they have hygrometers with which to determine the relative humidity of the atmosphere of the mine, and they have air samples taken in various places in the mine and analyzed, which will reveal to them any generation of explosive gas long before it can be detected with an ordinary safety lamp. Not a few have provided themselves with breathing apparatus which will, with the men trained in their use, prove invaluable in event of a fire or an explosion in their mines.

At some of our well-regulated mines, in addition to keeping stretchers and blankets, there is a first-aid hospital equipped, and the leading workmen are trained in rendering first aid to those who may be injured.

The impetus given to this humane movement by Dr. M. J. Shields, of the United States Army Medical Corps, is to be heartily commended by every mining man in the state. It is to be hoped that in the near future there will be organized classes at every mine under training in this work, which will prevent much unnecessary suffering, and sometimes death.

A system of checking the men in and out of the mine, and keeping a record of their names and the section in which they work, is in force at some of the best regulated mines. In case of a fire or mine explosion, it will prevent much confusion and uncertainty; for by means of it they will be able to tell when all the men are out of the mine, or show the sections in which they should be looked for.

Viewing this system from an economic standpoint, it reveals by a glance at the checking board on the outside any shortage of labor, such as a driver or trackman being off, which can be filled without having to chase all over the mine to discover it.

About one-half of the coal mined in the state is undercut with machines. The use of undercutting machines has a tendency to make the mining much safer; it does away with solid shooting, and does not make it more dangerous, as you sometimes hear some poorly-enlightened radicalist assert. Where the seam of coal undercut is thick, or has a heavy parting in it that would make the shooting dangerous, in so far as the ignition of coal dust is concerned, by firing too heavy charges of powder to bring it down, the best method, which is being practiced at some mines, is to shoot it down in two benches, using light charges of powder.

Regulations governing the shooting of coal so as to make it more safe have been put into effect by the Mine Department of the state. Those regulations, first of all, call for the adoption of one of the permissible explosives in use, or black powder must be used in such a way that the least possible danger will result from it.

To bring about such a result, it was required that shot bosses be employed, who would see that the coal was undercut, holes properly placed, the proper charge of powder used, and incombustible material used in tamping, and that the surrounding area is in a damp condition.

That these regulations have been proven to be valuable is shown by the results obtained, and if you would go to mines where the employment of shot bosses is required and ask the management their opinion of the requirement, they will no doubt tell you that under no consideration would they be willing to relinquish it; for as a result, they are securing a grade of coal that is not blown or shot into slack and dust as it was formerly, and the discipline obtained from the enforcement of such regulations tends toward the betterment of the mine in every way.

In conclusion the writer wishes to state that what has been outlined in this paper are observations made by himself, and he does not lay claim to knowing what the existing conditions are at every mine in the state. The assertion is made, however, that at the mines where the most money is being made by both the operator and workman, there you can find the mine law being complied with, and other safety precautions adopted which, if they had been embodied in our mine law a few years ago, would have been considered very radical indeed.

The practice obtaining at some of the mines in this state to protect the health and lives of persons working therein, and for the economical production of coal, would be a good guide to follow in drafting new laws that our legislative body might deem necessary to enact.

That there are many mines in this state whose condition and practice are better than what has been outlined in this paper, cannot be doubted. The Mine Department force of the state is doing its best to improve the methods at those mines that are not considered as good. To describe them all within the confines of this paper would be impossible.

THE ORGAN FEEDWATER HEATER

Written for Mines and Minerals

Originally feedwater heaters were intended to save fuel by using the exhaust from a steam engine to preheat the boiler feedwater. In ordinary practice there is a saving of .0909 per cent. for each degree of heat added to the feedwater.*

The saving for an assumed case where the boiler pressure is 100 pounds gauge, the original temperature of the feedwater 60° F., and its final temperature before entering the boiler 200° F., is calculated as follows: The total heat in steam, corresponding to a temperature due to 100 pounds gauge pressure, above 32° F., is 1,185 British thermal units.* The increase in heat units above 32° F., in the feedwater at 60° F. is 28, therefore the heat units in the steam above the original temperature of the feedwater are $1,185-28=1,157$. The increase in heat units in the feedwater heater is $200-60=140$ and the saving effected by the heater would be

$$\frac{140\times 100}{1,157}=12.1 \text{ per cent.}$$

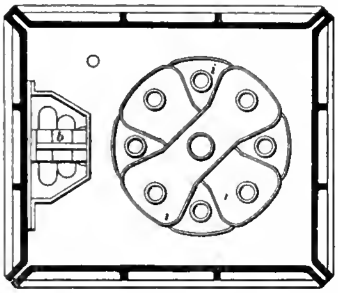
After the feedwater heater had been in use some time it was ascertained that where clear water was used for feeding the boiler, considerable sediment was precipitated. This was due to the change in temperature, and as this sediment was kept out of the boilers the name "purifier" was added to that of feedwater heater. Various experiments were next made to ascertain if it were possible, by means of feedwater heaters, to eliminate from feedwater chemical substances held in solution, as scale-forming chemical compounds were more injurious to boilers than sediments which could be blown off.

The Organ feedwater heater and purifier, shown in section, Fig. 1, is one of the results of such experiments and belongs to

* Kent's Mechanical Pocketbook.

the "open feedwater heater" class to distinguish it from the closed feedwater heaters in which the exhaust steam does not come in contact with the feedwater.

The construction of the heater is such as to interest engineers and steam users. In the Organ heater and purifier the exhaust steam enters the heater through the pipe *a* of the same size as the engine exhaust. The valve and cylinder oil used in steam engines gradually becomes vaporized, in which condition it travels from the cylinder with the exhaust steam. In order to economize in oil, also to keep oil from going into the feedwater, oil separators are used inside or outside the feedwater heaters of this type. As the steam enters the Organ heater



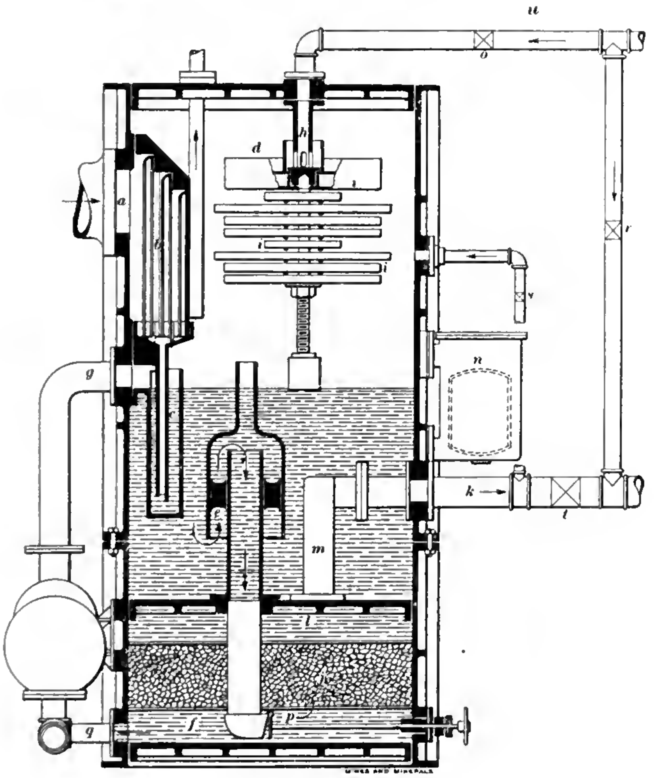


FIG. 1. THE ORGAN FEEDWATER HEATER

it impinges on the plates *b* whose edges are turned in to form channels. The oil held in mechanical suspension by the steam is deposited on the plates and flows down into the oil trap *c*, while the steam passes out to the heating chamber *d*.

Although this is an efficient arrangement it is augmented by a second trap or hood *e* which prevents any oil in the heating chambers going downwards. The water which accumulates in chamber *d* flows up through the trap *e* and then down a central pipe to the settling chamber *f*. Any oil that accumulates in the heating chamber will on account of its specific gravity float and be carried through the overflow *g* which acts as a skimmer. The feedwater enters the heating chamber through pipe *h* and enters the upper of a series of Maltese cross-shaped pans *i*, below the water level in the pan. The pans are arranged rosette fashion, as shown in Fig. 2, so that the water flowing over their rims falls on the pan below, and from the last pan to the tank.

The shape of the pans furnishes a large edge for the water to trickle over, thus bringing it as a thin sheet in contact with the exhaust steam and allowing it to absorb the heat quickly. This is particularly important when the engine is working under minimum load, and the boilers are worked to full capacity supplying live steam to the heating and drying systems. The amount of steam condensed and returned as pure water to the boilers is an important point to consider in the efficiency of any heater.

There is some settling of sediment in chamber *d* which communicates with lower settling chamber *f* by means of the hood and pipe *e*. The object of connecting the two chambers in this manner is to eliminate any disturbances that might prevent settlement of sediment. The water at this stage varies from 200° to 212° F. and much of the soluble salts and all sediment are deposited; thus, the scale-forming material is taken out before the water enters the filter *j*.

It will be noticed that filtering material is packed between two perforated plates and that the water is obliged to move upwards in order to reach the tail-pipe *k* of the feed-pump. From the top of the filtered heater chamber *l*, there are two uptakes *m*, which are in the water where its temperature is highest, and thus the heat amounting to from 2° to 6° F. lost in traveling down and then up is regained, a feature of importance, as every 11° F. added to feedwater saves approximately 1 per cent. In the cylinder *n* there is a float connected with the water-supply valve *o*, and with the shell of the heater below the water line, thus equalizing pressures and causing the float to respond quickly to the demands of the heater and automatically to operate the water-supply valve.

Cleaning doors are so placed that both the upper and lower settling chambers are easily accessible, and through them and hand holes the sediment is easily removed from the various places in which it settles. The trays may be loosened by slackening on the nuts, and each segment moved in front of the tray-cleaning door.

The filter is cleaned by closing the downtake tube from the upper to the lower settling chamber by means of valve *p* opening the blow-off *q* and the wash-out valve *r* and closing the vent valve *s*. This forces the water through the reheater down into the filtered-water chamber and filter into the lower settling chamber to the blow-off. The safety valve *t* relieves excessive pressure when cleaning the filter with reverse currents.

This is the only open feedwater heater and purifier in which the current of water under pressure is forced through the filter in an opposite direction to clear the filter bed.

All scum, oil, etc. collecting on the surface of the water in the upper filtering chamber is flushed off into the overflow by raising the water level in the chamber *d*.

Each part of the heater is provided with vents by which any air and gas liberated from the water may escape. The lower settling chamber *f* is vented by *e*; the steam chamber *d* by pipe *u*; and the filtered-water compartment *l* by the vent pipe and valve *s*.

These heaters are manufactured by the Exeter Machine Works, of Pittston, Pa., who guarantee them to a working pressure of 10 pounds per square inch, and test them to 15 pounds before shipment.

SWEDISH STEEL RAILS

The Swedish state railways have closed a contract with the steel combine of Germany for the delivery of 22,800 tons of rails during 1910 at certain seaport towns at \$29.48 per ton. They have also closed another contract for the delivery of the same quantity for the year 1911 at \$32.16 per ton, delivery to be made at certain seaports in the kingdom.

COAL MINING NOTES

The Pemberton Coal and Coke Co., of Affinity, W. Va., found it cheaper to install the alternating-current generator and the motor-generator set for converting the alternating into direct current for use at the company's mine 2 miles distant from Affinity, than to install a larger direct-current machine, and transmit the direct current to the other mine. The additional apparatus bought represents a smaller investment than that which would be incurred in maintaining the losses in transmitting the direct current to the mine 2 miles away.

The Avondale Colliery, historical from the fact that it compelled the first mine law to be enacted in the United States, is now being drowned out by an inrush of water, presumably coming from some cave. The Delaware, Lackawanna & Western Railroad are owners of the mine.

The long expected commission to revise the coal mining laws of the state of Colorado was appointed on November 14 by Governor John F. Shafroth. The membership consists of Dr. Victor C. Alderson, President of the State School of Mines; Prof. J. B. Ekeley, of the Colorado State University; R. D. George, State Geologist; and James Dalrymple, the newly-appointed chief mine inspector. Colorado has some very effective mining laws upon its statute books but they have not been enforced in the past, largely from lack of power on the part of the inspector so to do. It is the intention of the board to hold a series of public meetings at which all interested will have a chance to be heard, to be followed by visits of inspection to the various coal-mining centers of the state. After these public hearings and visits of inspection, during which the particular needs of Colorado are expected to be brought out, the codes of the older states will be studied and the results thus obtained embodied in a set of new laws which will be submitted to the next session of the legislature for its consideration. The attention of the commission is called to the fact that the chief difficulty to be overcome in Colorado coal-mining practice is that of handling dust in the prevailing dry climate. When the dust question is satisfactorily settled, practically all others will take care of themselves.

It is with sincere regret that Mines and Minerals has to announce the resignation of John D. Jones from the position of chief mine inspector of the state of Colorado, a place which he has filled with distinguished success since his appointment by Governor Peabody on February 6, 1903. While Mr. Jones' resignation was tendered during September, it was not publicly announced until the time of the Delagua accident when he was leading one of the exploring parties, and became effective on November 21. Mr. Jones leaves the service of the state to become General Manager of the Oakdale Fuel Co., at La Veta, Colo., a position which he will fill with the same signal success as he did that of chief inspector of mines. What is most to be admired about Mr. Jones, aside from his being a self-made man of the best type, is the fact that with him it was always "come on" and not "go in." Mines and Minerals joins all his many friends in wishing him a long and successful career in his new undertaking.

In a report prepared at the request of Governor Shafroth, Mr. John D. Jones, the retiring chief mine inspector, recommends that the state be divided into five instead of three districts as heretofore, and that each district should have its particular deputy inspector, all in charge of a chief, with headquarters at Denver. Mr. Jones' recommendation that the salaries of the chief be fixed at $5,000 and the deputies at $3,000 per year, with proper allowance for expense, seems a wise one.

Governor John F. Shafroth has appointed James Dalrymple as chief mine inspector of Colorado. Mr. Dalrymple is well known to the mining fraternity of the state and since leaving Irwin, Pa., 25 years ago, has filled responsible positions in and around mines on the Western Slope. He has appointed Harry Douthwaite, of Colorado Springs, as deputy mine inspector, to fill the position made vacant by his own promotion.

On November 22, what promised to be a greater tragedy than any that has yet overtaken the coal-mining industry in Colorado was averted through the coolness of David Griffiths, superintendent of the Bear Gulch or Fremont Mine of the Colorado Fuel and Iron Co., 2½ miles southeast of Florence, Colo. A fire broke out in the underground mule stables about 4 P. M., while Mr. Griffiths was at the surface. With a hastily-organized force he entered the mine and sent warning to each working place. The men were gathered at a point where the air was clear, and in squads of 10 and 12 were made to hold their breath long enough to pass through the smoke and reach the cage. All but two of the 173 men in the mine were brought up in this way and these lost their lives by refusing to stay with the party beyond the smoke zone.

Both the Colorado Fuel and Iron Co.'s rescue car and that of the Bureau of Mines were on the scene about 2 o'clock in the morning of the day after but their services were not required except to recover the bodies of the two dead. The value of telephones to mines was again clearly brought out in this case, where the engineer in charge of the pumping station, being in constant communication with the outside, was able to remain at his post until the last minute.

The experience of the past, that with the approach of winter explosions in coal mines increase in number, is borne out by the reports for November. On Saturday, November 5, 15 men were killed by what the evidence at hand shows to have been a dust explosion at the Lawson Mine, Black Diamond, Wash.; on Tuesday, 79 died from a dust explosion started by an underground fire at Delagua, Colo.; and on Monday, the 28th, 13 more were killed by what is said to have been the ignition of a pocket of gas at the Jumbo Mine, 20 miles from Antlers, Okla. On November 25, 11 miners were entombed in mine No. 3 of the Providence Mining Co., Providence, Ky. This makes a total of 118 for the month, to which total Colorado contributed 79.

Since the first of the year, 210 have died in Colorado, either from explosions directly attributable to dust or which were increased in intensity by this agent. Colorado coal mines are naturally not more dusty than those of other states, but the extreme dryness of the air causes the entering current to absorb the natural and acquired moisture of a mine more rapidly than elsewhere and points to the fact that more watering than heretofore done is necessary. This and the complete removal of all accumulated underground track refuse will almost entirely prevent a repetition of such accidents as have occurred recently.

Referring to the rescue work at the Providence, Ky., disaster, Chief Inspector of Mines Chas. J. Norwood states that the work was in charge of Thomas O. Long, inspector for the district. He first repaired the damaged fan by the use of canvas, and restored the air circulation. He then led the first party that entered the mine, using an oxygen helmet furnished from the United States Mine Rescue Station at Linton, Ind., as his new helmet just received from the manufacturer had not yet been adjusted. Assistant Inspector Jones, of the Central City district, was also present with his oxygen helmet and assisted in the work. In addition to the Kentucky inspectors, Barr and Jones, and volunteers from nearby, there arrived, quickly after the disaster, the car from the United States Mine Rescue Station, at Linton, Ind., in charge of Mr. R. Y. Williams, and accompanied by his assistants, A. A. Samms and John B. Shepherd, who with apparatus and advice furnished valuable aid.

Engineer Antonio Llambias de Olivar, the representative of the boring company subsidized by the government of Uruguay, informs the Minister of Industries, Labor and Public Instruction, that in the middle of August, in the fourth boring which the company is making in the Department of Cerro Largo, a bed of coal was found at a depth of 124 meters, more than a meter thick and of quality superior to that met in the boring of November, 1909, at a depth of 140 meters.

THE DELAGUA, COLO., EXPLOSION

Written for Mines and Minerals, by George F. Duck

An Account of the Conditions Existing at the Mine before and after the Explosion

The most disastrous accident in the history of Colorado coal mining, one in which 79 lives were lost, took place at the No. 3 mine of the Victor American Fuel Co., at Delagua (pronounced Del'-ah-wah), Las Animas County, Colo., about 2 P. M., Tuesday, November 8, 1910. About 1:30 to 1:40 P. M., a fire was reported at the abandoned door *a*, Fig. 1, some half-mile underground on the 4th north entry, and while preparations were being made to extinguish it the mine "let go."

Delagua is the terminus of a coal road 6 miles in length, running west from Ludlow on the Colorado & Southern Railway. Ludlow is 15 miles north of Trinidad, 82 miles south of Pueblo, and has an elevation of 6,295 feet above sea level. Delagua is about 20 miles north of the Starkville Mine, which exploded with the loss of 56 lives on October 8.

The seam worked, known as the Delagua, is in the upper part of the Laramie formation of the Cretaceous. It averages rather more than 6 feet in thickness with a persistent slate or bone parting near the middle from 1 inch to 6 inches thick.

The coal outcrops around the hillsides and has an average cover of 150 to 200 feet. The roof is poor and requires the use of much timber. The regular draw slate is not generally present but rather a soapstone, from 6 inches to 15 feet thick, full of slips which cause it to fall in irregular shaped pieces of no great size and with sharp edges. The coal is friable and will not bear stocking for any length of time. The composition is, essentially, 36 per cent. volatile matter, 8 per cent. ash, 2 per cent. moisture, and 54 per cent. fixed carbon. The sulphur is below 1 per cent., and when washed to remove fragments of the parting the coal makes a very satisfactory coke for furnace use.

It is stated that gob fires, blown-out shots and firedamp are unknown.

The surface plant, destroyed by fire on October 7, consisted of a wooden tipple of 2,500 to 3,000 tons daily capacity, a 600-ton washery, 600-ton storage slack bin, power plant, boiler houses, repair shops, etc. There are 160 standard beehive ovens in block. Five mines fed to this tipple, No. 3 producing about 1,250 to 1,500 tons daily. Since the fire, however, the production of No. 3 has been about 750 tons Delagua is known as the largest single coal producer in the state.

The system of working is the ordinary double-entry with rooms turned off both the main heading and air-course, or back heading as here known. There are four parallel headings, known as the 1st, 2d, 3d, and 4th north, respectively, driven on a course of 6° 45′ W, which were opened in the order given. No. 1 mine (not shown on the map) is 1,300 feet east of the No. 2 mine. It has its own fan and is independent of the other mines, but is connected with No. 2 at several points inside.

The No. 2 mine is 1,000 feet east of No. 3 mine and is also independent but is connected with No. 1 and No. 3 inside. Its fan is not in use, ventilation being secured through No. 3. The heading proper is 8,000 feet long.

The 3d and 4th north entries and their branches constitute No. 3 mine, the scene of the accident. They are driven from a slope *b* at present 2,600 feet long.

The 3d north entries, which leave the slope 675 feet inside, are 8,150 feet long, are advancing and have no rooms until those on the last pair of cross-entries are reached.

The 4th north entries are 650 feet west of the 3d, are 7,050 feet long to the face which is stopped in a fault or pinch. No rooms are working on these headings until near their end.

The main slope is not now advancing as the roof is being shot to bring the track to grade.

The 5th north entries start from the end of the slope and are working, headings being driven back to meet them from the 3d west and Rock Island, as shown in Fig. 1.

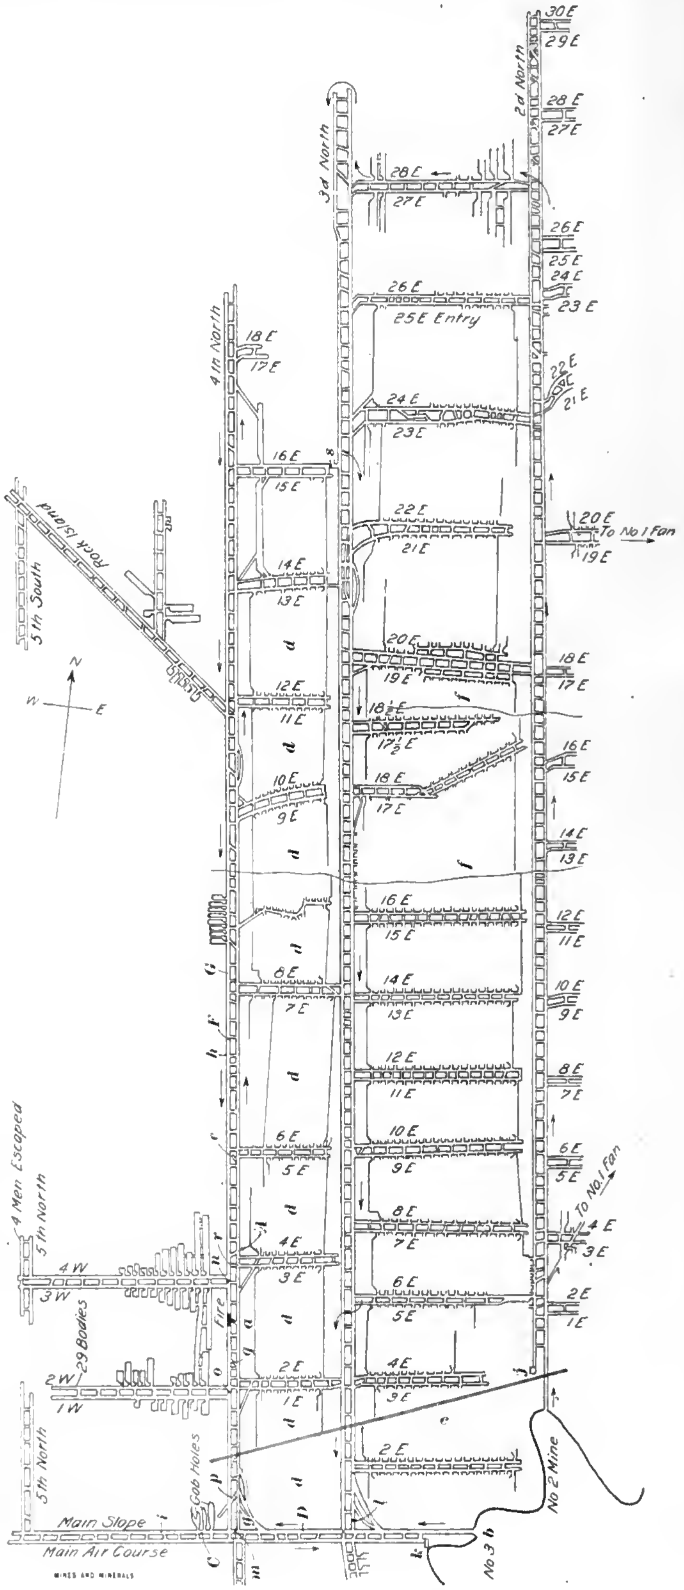

FIG. 1

A = slate forced into inby side of cap.
n = door blown outby.
C = slate forced into outby side of cap.
D = slate forced into inby side of cap.
l = door blown inby.
F = slate forced into outby side of cap.
G = slate forced into outby side of cap.

The bulk of the coal from the 4th north section comes from the rooms driven from the 1st, 2d, 3d, and 4th west entries,

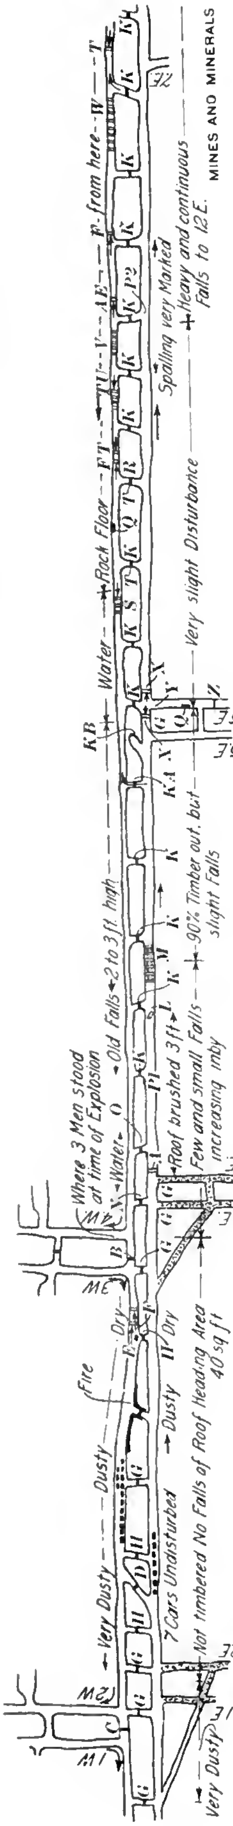

FIG. 2. ENLARGED SECTION OF ENTRIES AT FIRE AND COKING ZONE

A, slate forced into cap; *B*, door blown outby; *C*, curtain, unharmed; *D*, first west haulage door, slightly bulged into back heading; *E*, heavy coke on outby side; *F*, light coke on outby side; *G*, gobbed snut, not damaged; *H*, Bulged in toward back heading but not broken; *K*, entirely destroyed, blown into back heading; *L*, timber fallen outby; *M*, undisturbed timbering; *N*, brattice through which men escaped; *O*, upper ½ apparently out before fire; *P1*, electric pump not harmed but rheostat blown into back heading; *Q*, coke on rib 40 feet inby; *R*, the only stopping blown into haulage road; *P2*, electric pump blown 3 feet and rheostat 20 feet, very violent action here; *S*, three caps with center posts. Heavy coke on inby side of all members; *T*, coke on inby side; *U*, four sets caps, very heavy coke inby, some little outby; *V*, six caps unharmed; *W*, nine sets timber unharmed; *KA*, used as tool house by men working in 5th west; *KB*, fifth west started since November 1st on night turn; *X*, very heavy dust; *Y*, gob thrown into entry, fall, heavy spalling opposite mouth; curved arrows show direction of throw of heavy materials; small arrows show place of deposit of coke, slate or other materials; *Z*, Brattice blown inby; ▮▮ caps in place.

respectively. The 5th west was started at *c* opposite the mouth of the 5th east on November 1 and is worked nights.

The Rock Island entry, or more generally the Rock Island, is shown as starting 4,650 feet from the slope on the 4th north return air-course. Its name is derived from the fact that it is advancing into coal leased from the C. R. I. & P. R. R.

In Fig. 1 large areas marked *d* are caved, and although the pillars have not been drawn, the roadways and rooms are filled with falls of roof. It is said to be possible to walk or crawl over these old falls from the slope to the extremity of the workings. In this part of Colorado the dikes *e* and faults *f* as shown on the map, commonly give off marsh gas brought up from lower seams, so that it is by no means impossible that at intervals, at least, some little fire-damp is present in these abandoned workings.

The coal is undercut by the miner who also drills, charges, and tamps the hole, and after affixing a flag or marker, leaves the actual firing to the company's shot firers. While the introduction of "permissible" explosives is meeting with marked success among the more progressive men, the mine is largely a "black-powder mine." One-quarter of a keg of powder is allowed in one place at one time.

After being gathered to the various partings by mules the coal is hauled to the main slope by Jeffrey motors operated under 250 volts pressure, and up the slope by a rope The coal from the main slope below the 4th north is hoisted to the latter by an electric hoist at *g* in the cross-cut.

Some little water is met in the return air-courses which are to the dip of the haulage entries. This is handled by two small electrically driven pumps at *h* on the 4th north and a larger one at *i* on the slope.

As stated above, although connected with No. 2, No. 1 mine, the first pair of north entries, has its own fan. Also, No. 2 fan, at *j*, is not in use and has not been for some time.

The fan ventilating both No. 2 and No. 3 mines is that placed at *k*, the end of the return airway of No. 3. It is a Capel fan, 15 feet in diameter, driven by a motor on an independent circuit. At the time of the explosion 55,000 to 60,000 cubic feet of air a minute was circulating through the two pairs of entries.

The air is drawn in through No. 2 mine, passes up the 2d north its entire length, thence over to the 3d north entry of No. 3 mine, down it to near the main slope where it passes into the air course, across the slope in an overcast to the main return and out it to the fan. Thus, the 2d north is the intake and the 3d north the return for one split, the air traveling a total distance of 18,000 feet. Doors *l* are placed on the 3d north to separate it from the 4th north and also from the main slope.

The air for the 4th north comes in the main slope and is prevented from going down the same by a door *m* on the slope. It is thus drawn into the entry, to its face, back along the return to the 4th west cross-entries up which it is forced by a door *n*, a canvas curtain *o* forcing it up the 2d west, thence to the main air-course by way of the Rock Tunnel *p*, traveling a distance of 21,000 feet. The Rock Tunnel is shown in dotted lines between the 4th north entries. It is driven in rock and was intended for an overcast but the bridging at the slope has not been completed.

Sufficient air for the four men working in the 5th north entrles off the slope is thrown down by a regulator placed in the 4th north return between the slope and its air-course.

The Rock Island is ventilated by diffusion only, a comparatively few men being employed there.

Both the intake and return airways vary from 35 square feet to 100 square feet or more in area but average by several measurements about 50 square feet. This change in cross-section has the effect of rapidly increasing or decreasing the velocity of the air and had a marked influence upon the currents generated by the explosion.

Fig. 2 gives the details of the ventilation of the west entries.

The explosion at Delagua No. 3, whatever its origin, was unquestionably produced by coal dust, as at Starkville. Fire-damp undoubtedly did not figure in it at all, and it was not caused, independently of the coal dust, by the direct ignition of the hydrocarbons distilled from the burning coal. That the condition of the mine prior to the explosion may be understood certain definitions are permissible.

For the sake of clearness, a mine is defined as very dusty when the track and roadways are covered to the depth of at least an inch with fine, almost impalpable dust, most of which will float on water; as dusty, when the particles of dust are larger than in the above case, not so thickly deposited and when but a comparatively small percentage can be blown from the hand or will float; as dry, when the coal is in pieces up to ¼ inch in size with no evidence of moisture to the touch. The very dusty conditions are usually met at partings where the coal is churned into powder by the constant passage of men, mules, and motors; the dusty conditions along some well-traveled entry; and the dry, in rooms which have been advancing for some months. A dry mine is not quite safe, a dusty one is dangerous, and a very dusty one, highly so.

On the other side, a damp mine may be considered as one where the material in the roadways has no tendency to blow away when disturbed by the feet of men or mules and leaves a distinct impression of moisture to the touch; a wet mine, as one where the road cleanings may be moulded into balls by the hand, and where occasional patches of water are encountered; and a watery mine, as one where the track is deep in mud or

where standing water over an inch in depth is encountered generally throughout the workings. The damp mine is safe, and a watery one cannot explode. These definitions are not absolute and are modified by other conditions. Thus, a section of the mine marked as dry may be in a rock tunnel and hence absolutely safe.

According to the foregoing definitions the conditions in Delagua No. 3 mine as determined by observations made 36 hours after the accident were essentially as follows: All return air-courses were "safe," coming under the terms of damp and wet, and, in many cases, even watery. Standing water is frequently met in the air-courses which mostly have a rock floor from falls of roof.

No. 2 mine was not visited at the time of the accident, but was classified 10 days after the explosion as dry to dusty. The 3d north entry, from its face to the 8th east cross-entries, should be defined as damp to wet, having been so freely watered on Sunday that haulage was difficult on Monday. It was impossible to determine the exact conditions owing to the falls, but it is reasonable to suppose that this entry became dryer as it approached the slope where it was more constantly traveled.

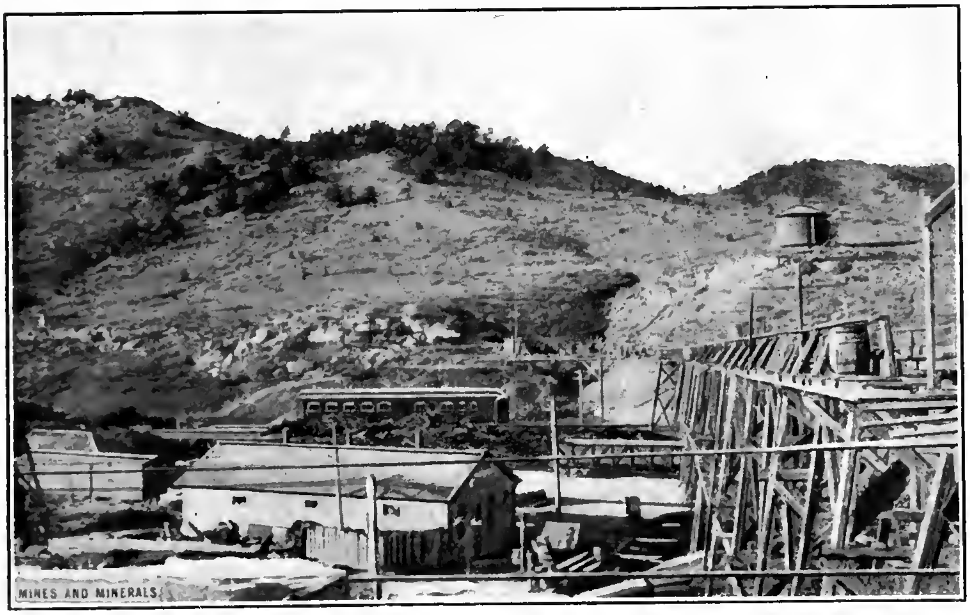

FIG. 3. DELAGUA NO. 3 MINE, SHOWING U. S. RESCUE MINE CAR, TEMPORARY TIPPLE, AND WATER TANK TO RIGHT OF DRIFT MOUTH

The 4th north entries, also watered on Sunday prior to the explosion, were dryer than the 3d north, and should be classified as damp to dry; that is to say, they were essentially safe. The Rock Island was damp and the two pairs of west cross-entries off the 4th north entries were the same. The partings on both the entries at the main slope, the 7th east and 10th east partings on the 4th north, some partings on the 3d north and the parting near the fire *a* on the return of the 4th north between the 2d and 3d west were dusty. In general, so far as the roadways were concerned the mine was safe.

The season has been an exceptionally dry one in Colorado. The Trinidad office of the Weather Bureau reports rain as follows: For August, .42 inch; September, .45 inch; October, 1.41 inches, and November, none. The October rain fell on the 16th, 18th, 19th, and 20th of the month, and except for a trace, less than .01 inch on the 26th, there was no rainfall for 19 days before the accident.

L. H. Dangerfield, local forecaster, in charge of the Weather Bureau at Pueblo, about 80 miles north of Delagua, and the nearest station thereto, has kindly supplied the observations for several days prior to the accident. As they are of considerable interest, the figures for 4 days are given.

Day	Temperature			Relative Humidity		Barometer		
	6 A. M.	Noon	6 P. M.	6 A. M.	6 P. M.	6 A. M.	Noon	6. P. M
5	36	48	48	80	41	25.48	25.46	25.42
6	23	69	61	82	10	25.42	25.31	25.30
7	30	67	58	34	17	25.31	25.23	25.20
8	54	70	65	13	6	25.13	25.08	25.02

Mr. Dangerfield gives as the mean of a 21-year period the following averages for November: Temperature, 43.9 degrees; barometer, 25.31 inches; and relative humidity for 6 A. M., 62.9 per cent., and for 6 P. M., 41.0 per cent., a daily mean of 52 per cent. It will be noted that prior to the explosion from 6 P. M. Sunday, the temperature was slowly rising and the barometer and relative humidity rapidly falling. The high temperature, which is about the annual mean of the place, while favorable to preserving the moisture in the mine was more than offset by the abnormally low humidity. The air was practically dry and greedily absorbed every drop of available moisture.

The accident at Delagua must be studied from the two propositions, that of the explosion, which happened about 2 P. M., and that of the fire which certainly was burning as early as 1:15 P. M.

Had some one not been careless, there would have been no fire; had the mine not been dusty, there would possibly have been no explosion. The two hypotheses, while undoubtedly connected, could have happened independently.

The fire occurred inside a disused door in a cross-cut between the 4th north entries. This door is 230 feet from the 1st west door *q* and 330 feet from the 2d east entry.

The door was built of ordinary 1-inch plank, had an area of about 30 square feet, and was placed about 20 feet in from the haulage road and 12 feet from the return, where the parting for the west entries was made. It was the custom of the drivers to eat their dinners on some benches just inside the cross-cut, and not infrequently other company hands used the opposite or the haulage side for the same purpose. There was probably the usual mine refuse in the place, chips, pieces of board, paper, and fat from dinner buckets and the like. This door was entirely destroyed by the fire, except the two side posts, and before the fire zone was cleaned up, from measurements made, it was seen that the fire burned 100 feet south and 80 feet north from this point on the return airway. The fire did not quite reach the haulway. It is evident that the fire started on the return airway side of this abandoned door. The effect of the fire was almost entirely on the rib nearest the main entry, which in places was burned and coked to a depth of 6 inches.

The time when the fire started and how it started, since no electric wires were near the door and the first observers of the trouble are dead, will probably never be solved, although there are a few fairly-well established times and a few apparent facts bearing upon its origin.

It is stated that Jos. Boyd, a fire boss of experience, and a competent man, passed the place at 12:05 and noticed nothing out of the way. The fire was undoubtedly not started at that time.

At 12:50 a miner from the 4th west went to the parting to inquire if more cars would be given after dinner, it being election day and the mine not running full. He found the two colored drivers, Sampson and another, eating their dinner, not at the usual place, but leaning against the cars 30 feet from the cross-cut and on the heading. If the drivers had fired the place at an earlier hour and supposed they had put it out they did not mention the fact to the miner. In any event, shortly before 1 o'clock, the miner, an intelligent Austrian, who subsequently saved himself and numerous others through his coolness, noticed nothing wrong. At this time, any previously started fire was by those possibly implicated supposed to be out. The miner returned to his place in room 6 on the 4th west and "in a few minutes" received a car which he and his buddy loaded and dropped down 150 to 200 feet. After talking over the possibility of more cars, one of them hunted up the driver on his heading, Sampson, and being advised that he would have none until 3:30 p. m. returned to his place and with his partner, gathered up their tools, clothing, and buckets, and prepared to go home. At the switch to their room they met the driver who asked if they had water in their buckets as there was a fire at the "old door."

All this took time and it was probably fully half an hour from when the miner left the parting where he inquired for cars to when, satisfied that no more would be received within a reasonable time, the two decided to go home and were then advised as to the existence of the fire. What happened in this 30 or 35 minutes is merely conjecture. The men on the 4th west cross-entries being on the intake side did not notice the smoke and of those on the 1st and 2d west cross-entries, where the smoke traveled, all but one, an Italian driver, are dead. The 3d and 4th west entry drivers were also killed.

The 2d west driver says he started to work at 12:35 (which appears a little early) and on the third trip out noticed smoke, etc. If he made four trips an hour, his mule would be handling over 80 tons a day, which is not bad work for the distance covered. This would make it about 1:20 when he noticed the smoke on the airway. It must be remembered that the men first referred to were inside the fire and each party knew nothing of the other's movements. Why none of the men on the 1st and 2d west entries when first noticing smoke, and it must have gone to their places in a very few minutes, did not attempt to escape, is as much of a problem as why the driver, Sampson, did not get water from the "water hole," but 80 feet away in the 4th west return, or why he did not notify the pit boss, Llewellyn Evans, who, in making his rounds by way of the 3d north, had supposedly reached the 10th east parting on the 4th north, 3,000 feet inside the fire.

The two miners inside the fire zone, after being notified, went in that direction and opening the door, noticed the "smoke rolling over and over and 'swishing' back and forth." After trying to get through under the smoke they returned to their places, notified the men in the 4th and 5th rooms, gathered up their outfits and with axes came back to the entry. They again looked through the door and found the fire was growing dull red and that the agitation of the smoke was more violent than at first. They again failed to get past under the smoke and after deciding not to try the return, proceeded to cut and scrape a hole through a brattice *r* just inside the 4th west door. As but one man could work at a time, they estimated that this would require 4 or 5 minutes. After relighting with difficulty the lights which, with the exception of an acetylene lamp, had all gone out, they crawled through the brattice and noticed the smoke within 10 feet of them on the main heading.

After trying to pass the fire on the haulage road side they turned into the mine and near the 10th east cross-entries met the pit boss and the nipper on their way toward the fire. Going further, they picked up the drivers from the Rock Island and warned many others, most of whom treated the matter with indifference, crossed over to the 3d north by way of the 16th east cross-entry, went out it to the 26th or 27th east cross-entry and to the 2d north entry and had just turned out of it for the No. 2 opening, when they felt a slight jar of the air which they afterward learned must have been caused by the explosion. As they were afraid of an explosion while on the 4th north, they probably ran as far as the 10th east, but from there in they walked in a more leisurely fashion. It is 2,750 feet to the 10th east from where they broke through the brattice and 4,000 feet by the usual route from there to the 2d north Making all allowances for running and for stopping to talk to men on the way, it must have been about 1:40 p. m. when they met the pit boss at the 10th east, about 1:35 when they broke through the brattice, about 1:30 when they started to do so, and 1:20 to 1:25 when they were notified of the fire by Sampson and after which they gathered up their companions, etc.

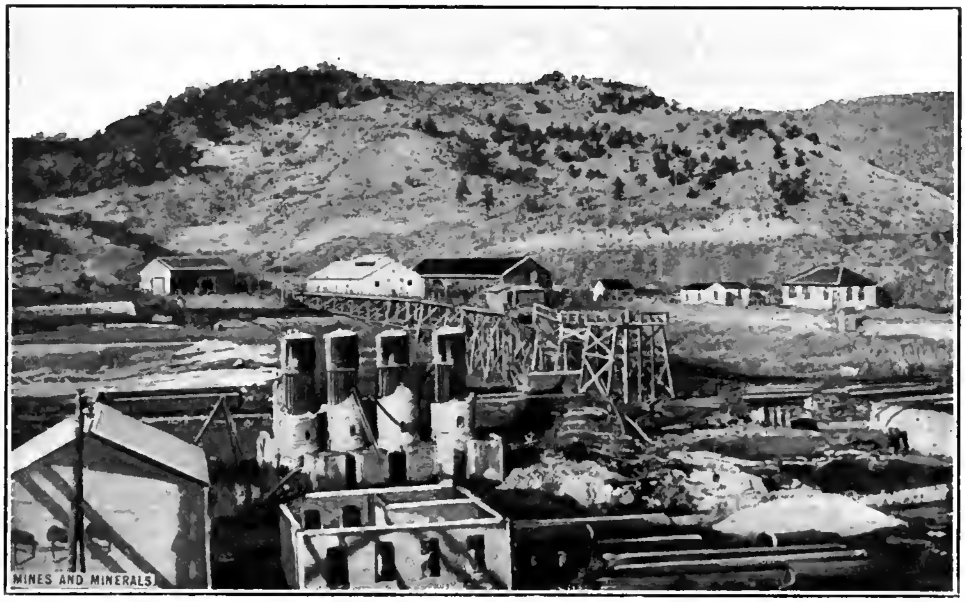

Fig. 4. Delagua No. 3 Mine From Hillside Opposite Fig. 3. Shows Temporary Tipple From No. 2 Mine. White Building is Blacksmith Shop. No. 2 Opening is to Left of Blacksmith Shop

On the return beyond the fire zone the time figures out fairly well. The 3d west driver, mentioned before, at an estimated time of 1:20 p. m. met the motor man, Bennett, at the 1st west door *q*. After some examination of the fire and a trip on the part of Bennett, it was decided to send the nipper, "Red," in to the 10th east to notify the pit boss. He must have been sent prior to 1:35 p. m. as by that time the miners on the inside could not get through the smoke on the haulage road, and also these miners met him and Evans at the 10th east parting about 1:40 p. m. It must then have been about 1:30 when Bennett, sent the boy back to inform the pit boss, whom he must have just left at the parting mentioned.

Outside the mine, at about 1:30 p. m. the smoke was noticed coming in thin clouds from the fan which was supposedly on fire. Thirty thousand feet of air a minute through an airway with a cross-section of about 50 square feet was traveling from the

fire to the fan a distance of 3,900 feet. This requires $6\frac{1}{2}$ minutes for the air to reach the fan and establishes the time at 1:23 P. M. when the fire was noticeable. This agrees with the figures obtained inside.

William Lewis, the superintendent, and his assistant, W. J. Evans, were in the office about 1:35 P. M. when notified of a supposed fire at the fan. After hastily investigating this and finding the fire to be inside and after making arrangements for a party to get water in barrels and for others to follow them, Lewis and Evans, started in "on the run." On the way they met the slope pumper, Smith, who reported a fire in the 4th north, "somewhere." Smith went back with them. It was some time after 1:40 P. M., perhaps nearer 1:45 P. M., that they reached the fire. On opening the 1st west door *q*, Evans remarked, "the 1st west is gone, we had better get out." Lewis, seeing that the fire could not be reached with buckets, sent the motorman out with his empty locomotive for hose. This must have been about 1:45 or a little later, for the motorman had time to drop his trip, set his switches, to stop twice on the way out, the distance being about 2,750 feet, and to help 3 to 5 minutes on the outside after his arrival there, before the mine "let go."

It seems more than a coincidence that the time. figured from such diverse starting points, both backwards and forwards, should agree so closely. It may be considered as settled that at any time between 1:20 and 1:25 P M. the fire was beyond control and that as late as 1 o'clock it had either not started, or having started was supposedly out.

After sending the motorman out, Lewis, who had supposedly been joined by several other of the officials, waited at the fire until something happened, perhaps the fall of the old door, to convince them that they were in immediate danger and that nothing further could be done. It may have been as late as 1:50 when the party hurriedly left the fire. Some believing they would be, safer from the impending explosion turned into the 3d north, but Mr. Lewis in company with several others continued out the slope and were overtaken by the blast about 400 feet from the mouth where they were as badly crushed and burned as were their companions in the side heading. Some comment has been made as to why the men were not warned in time to escape and the answer is obvious; no one knew of the fire until too late. Being on the outlet and near the fan it was not noticed by the only official inside until his attention was called to it by a boy, the nipper, "Red," who probably told him. "Bennett says there is a fire at the door and you had better come." Evans had only a child's statement for the fact and lost his life in the endeavor to get through. Lewis knew nothing definite of the fire until within 17 minutes of the explosion, when it is possible that those on the 1st and 2d west were already dead, and the others could not be reached through the fire. No one was killed on the 3d north entries except the officials mentioned as Lewis' companions, and three men who were asphyxiated in attempting to get through. It seems probable that, instead of attempting to escape, Lewis sent his companions through the 3d north in an effort to warn the men of the fire, while he and the others continued on out the slope to hurry up the hose, fire extinguishers, and other needed apparatus? This is the more charitable and, from the known courage of all the dead, the more probable view.

The explosion took place, as nearly as can be determined, at 1:57 P. M., and this time has been taken as correct in our estimates of the fire. The relative time alone is of importance.

A few seconds before the explosion an extremely dense cloud of heavy black smoke came out the fan, almost immediately turning to a light gray only to be followed by the shock. This was severe but not accompanied by any great noise. The fan was not damaged except by the blowing off of the roof and continued in motion until the current was turned off. This want of damage to the fan is undoubtedly due to the sudden increase in area of the return from about 50 to nearly 200 square feet near the mouth so that the gases had a chance to expand, to the roof being light and offering little resistance, and to the further fact that the airway being damp and having a rock floor afforded nothing for the explosive energy to feed upon.

At the drift mouth the blast came with great violence, the fall of the timbers and roof completely blocking the entrance. The casing of Bennett's motor was torn off and blown 350 or 400 feet and he and two others were killed by the flying stones and three others more or less injured.

In the mine the damage was confined to the blowing down of the timbers and consequent falls of roof on the main slope from the 3d north entries to daylight, on the 3d north from the 2d to 4th east cross-entries, with smaller and decreasing falls out to the 7th east, and on the 4th north entries from about the 7th east to the 12th east cross-entries. None of the air-courses were harmed, but with one exception, the air stops were all blown from the haulage roads into the return airways. Little or no damage was done to the slope below the 3d north entries, none at all to any of the four west entries or to the Rock Island, and the force was so slight at the ends of the 3d and 4th north, that many men continued at work until the rescue parties entering through No. 2 mine warned them of the accident.

Twenty-nine dead were found on the 2d west cross-entry at the last cross-cut and four more between that point and the fire on the 1st west entry. All these were asphyxiated, possibly by smoke prior to the explosion. Two were found on the slope at the 4th north; five on the slope between the 3d north and daylight; six on the 3d north not far from the slope; three on the 4th north back return not far from the fire; and others at various partings on the 4th north. Of the 135 miners and 22 company hands who entered the mine on the morning of the eighth, 88 either escaped after the explosion, between the time of the fire and the explosion, or had left before the fire started. The death list came to 79, of whom one was a visitor at the drift mouth, two who went inside out of curiosity, and Willis Evans, in charge of the C. F. & I. rescue car, who lost his life in bringing out 4 men imprisoned on the 4th west by the afterdamp. Thus, of the employes of No. 3 mine, 75 were killed, and as 6 of these can hardly be classed as company hands, 69 of the 157 going into the mine that morning are dead.

The evidence afforded by deposits of coke as to the direction taken by the explosion is conflicting and at best only confirmatory. The best evidence is afforded by the throw of heavy materials.

On the main slope several pieces of slate were found driven into the dip side of a cap about half-way between the 4th and 3d north entries and it is known from this that from the 4th north the explosion moved outwards to the mine mouth. Just below the 4th north, the door *g* across the slope was shattered and a piece found 195 feet down the slope. Also a short distance inside from this door slate was found forced into the pitch side of caps. Therefore, on the slope section, the force went both ways from the 4th north. On the 3d north, the door *l* across the entry was broken and blown 30 or more feet inwards. A timber further in was found blown inwards. Hence the explosion went into the 3d north from the slope.

At the mouth of the 4th north entry, a piece of timber has scarred the lower rib, while flying outward. At the Rock Tunnel, the gob was forced outwards from the haulage road. Just inside the 4th east cross-entry, a piece of slate was forced into the dip side of a cap. One hundred and twenty feet further in a heavy timber was plainly thrown outwards. From the 6th to the 10th east cross-entries, 45 posts are standing with their heads inwards and 22 with heads outwards along the left rib, and along the right rib 29 have the heads pointing outwards and 9 inwards. At the 7th east parting, 3 cars of a 7-car trip are off the track and "bumpered" in such a way that the force of the explosion must have been inward.

On the 3d north entry air-course no evidences of direction were apparent, but from the slope to the 12th east cross-entry,

all the brattices that were not gobbed shut, and even some that were, are forced from the haulway into the return airway.

The main slope air-course was not injured from the 4th north except that the brattices were blown in.

The 4th north entry air-course, however, does show marked evidences of direction. The door between the 3d and 4th west cross-entry was blown 30 feet toward the fire, and plastered with mud which could only have come from the water hole 80 feet farther inside. On this same air-course and 550 feet in the 6th east cross-entry, slate is found forced into the outby side of a cap. Slate is also found in the same position in another cap 450 feet farther in. As to brattices, all from the 4th west entry to some little distance beyond the Rock Island, with one exception, are blown in from the haulway to the air-course.

Starting somewhere on the 4th north main entry within a space of 610 feet from, and probably near, the 5th east cross-entry, the explosion traveled in two directions. That going north gathered up the dust at the 7th east cross-entry parting, probably resulting in a second explosion, and a third took place at the 10th east cross-entry parting. Meeting the wet and new section of the mine at the 12th east cross entry the explosion stopped for want of material. Entering the air-course at about the 5th east cross-entry the explosion also traveled north, forcing slate into the caps as noted, but doing no great harm as this heading is wet to watery and has generally a rock floor due to falls of roof.

From its origin, the explosion passed south to the slope, on its way forcing slate into a cap piece, blowing the brattices into the air-course as far as the fire, beyond which point none were destroyed and only a few bulged into the return. Passing the Rock Tunnel the explosive force threw several carloads of material into it. Coming to the network of dusty sidings at the slope, there was another explosion, but having room for expansion it did little harm. At this point the force divided, one arm turned down the slope, destroying the door, but was stopped at the "gob hole" by the water and by a large amount of rock dust on the floor. The other arm turned up the slope, forcing slate into the caps on the pitch side, but again, owing to the large cross-section, did little damage until it met the 3d north siding, where, meeting fresh supplies of dust, the final explosion occurred. The force extended but a short distance into the 3d north entry owing to the heading being wet. It was this last explosion, the one at the 3d north that did the most damage to the mine.

On the 4th north entry return air-course, the force entering near the 5th east cross-entry passed over the rock floor and water and knocked down the door between the 3d and 4th west. Why this branch did not explode in the presence of so much dust just outside the fire is a mystery, as deposits of coke are found between this door and the fire, indicating intense heat action.

These different points of probable explosion are clearly indicated, not only by the known condition of the mine at each place, but also by the presence of coke on caps and ribs. Coke is found in large quantities on the 3d and 4th north sidings and opposite the 7th east parting in the return. It is also found in the 6th east entry above an old fall 40 feet in from the 4th north. It is found on the return between the 3d west door and the fire in one place. All the places where the coke is found were either very dusty or near places that were. No coke was found near the 10th east cross-entry, probably because it was not looked for and it may possibly be found if careful examination is made.

While there were undoubtedly a series of explosions, the time interval between them was but a minute fraction of a second, so that to observers the action appeared instantaneous.

Several theories have been advanced as to the cause of the explosion and its place.

The first supposes that it was caused by the ignition of the heavy hydrocarbon gases, resulting from the burning of the coal in insufficient air and that it was done by the lamps of one of the two men whose bodies were found on the slope at the at the 4th north on opposite sides of the door. In any case, the man outside could not have lighted it, as a heavy door was between him and the return, and had it been ignited by the man inside, the door would have been blown out and not down the slope. For every reason this theory is untenable.

Another theory suggests that the gases at the fire, meeting sufficient fresh air when the burning door fell, combined with the increased supply of oxygen with explosive violence. It may be admitted that such a *minor* explosion is possible and that it may have been the cause or starting point of a dust or other wave of disturbance, but that it, and it alone, without extraneous aid was the cause of the loss of life and wrecking the mine, is impossible. Aside from the fact that we have no knowledge to prove that the coal was not burning to CO_2 direct, the explosion, the actual detonation, did not and could not have taken place at the fire or near it.

Explosive energy radiates in all directions from its point of origin along lines of least resistance. A study of the map proves that what little energy is encountered near the fire is all toward it and not away from it as it would be the case had the explosion taken place there. On the west, none of the headings are disturbed in the slightest degree. Even such light objects as cigarette papers are where left by the owners. On the north, the door at the third and fourth west entries is blown in toward the fire, but above all, three men standing 10 feet inside the mouth of the fourth west entry 240 feet from the fire, were merely knocked down by the concussion, and a companion 200 feet further up the fourth west entry was not jarred. On the east, the brattices were bulged in toward the return, but not broken, and on the slope side of the fire were not even harmed. On the south, the canvas curtain between the second and first west cross-entries was unharmed. The point of explosion must plainly be looked for elsewhere.

All indications point to the fourth north not very far from the mouth of the fifth and sixth east cross-entries as being the point of the initial, but by no means the most violent, of the series of explosions which occurred. Just beyond this point the energy is proven to have gone inward and just before it, outward. The brattices beyond the old falls 90 feet up the fifth and sixth east entries are shattered to pieces and blown inward, and intense heat is proven at this point by a small deposit of coke on the rib of the sixth east 40 feet in, as well as by the spalling action on the roof opposite the mouth of the fifth east. No coke is found in the air-course immediately opposite this point, but it begins a few feet farther in and is found in numerous places to a point beyond the seventh east cross-entry. Perhaps there was but one explosion at this point and not two, as the writer supposes, but indications point to one at the fifth east and another at the seventh east parting.

Because of lack of damage at the fire, it was first thought that it and the explosion were entirely independent. It seemed possible that a short-circuiting of the trolley wires brought about by a fall might have ignited the dust and that the fall, if not otherwise caused, might have been produced by the jar to the air caused by the sucking in of the door at the fire, the journey of the current being suddenly changed from one of 20,000 feet to less than 4,000. It also seemed possible that some stranger to the mine might have climbed into the 6th east entry with a naked light and ignited standing gas brought in there from the dikes mentioned. Another view was that the night shift working the newly started 5th west entries had left a full supply of powder behind, which was carelessly ignited by some passerby. Any one or all of these causes could have ignited the dust, and except the second, independently of the fire. But a thorough investigation into the gas question immediately after the accident, the accounting for all of the missing, and want of knowledge as to any powder being present, compel the abandonment of this view for one advocated, in part at least, by

some of those on the scene shortly after the explosion. It is freely admitted that there are weak points, largely ones of time, in the argument, but in want of definite knowledge it is given for what the reader may think it worth and the objections frankly stated. This is an attempt to connect a fire on the return with an explosion which took place 1,000 feet beyond it on the intake. The difficulties are obvious. This view supposes that the danger became imminent when the motorman left at top speed for outside, which we have shown was 10 to 12 minutes before the explosion. The hurrying motor stirred up vast clouds of dust at the slope parting 1,000 feet outwards from the fire. As the evidence shows that the fan was slowed down shortly before the explosion, the air was probably not traveling with its normal velocity of 600 feet per minute. Assuming 300 feet, it would require 3 to 4 minutes for the bulk of the dust to go up the 4th past the fire. By this time the door had burned partly through and the air was beginning to short-circuit. What dust passed through the openings was burned inside and the quantity of entering dust constantly increasing, it began to "backfire" into the haulage road. Perhaps it was this backfiring that convinced the party at the fire that danger was imminent.

The door, disintegrating more and more rapidly by reason of fire on both sides, finally burned down and the sudden short-circuiting of the entire air-current of this section of the mine threw still larger volumes of dust into the fire from the roadways, and possibly by suction from the gob holes and cross-cuts, thus producing more intense inflammation. While this was going on, the major portion of the dust was continuing up the 4th north, growing warmer and warmer until it finally began to distill gases. The falling of the door and the short-circuiting of the air caused increased volumes of dust to go out the 4th north, the air already having a tendency to go in. The gases were distilled more and more rapidly until when the 5th east was reached the action was so intense as to cause an explosion. Traveling inward the gases met fresh volumes of dust at the 7th east and 10th east partings and exploded, but stopped at the 12th east cross-entry for want of fuel. Going outward from the 5th east cross-entry the gases traveled with intense velocity through the rifle-like section of the entry, in some places of but 35-feet area, until, encountering the dust at the slope partings, another explosion occurred, but did little damage by reason of the very large cross-section of the mine at this point. The explosion did not travel down the slope, as it was wet, and did little damage between the 4th and 3d north because of the large area. At the 3d north sidings, where there were large volumes of dust, the final and largest explosion occurred. Going in along this entry, its cross-section diminishing rapidly, the place was completely wrecked, but for no great distance, the force being stopped in that direction by the watering received the Sunday before.

This view likens the affair to the ignition of a train of powder, the fire being the match and the points of explosion being occupied in this case by dusty places in the roadway.

The chief difficulty in accepting this view is finding an explanation why the explosion did not start as soon as the motor stirred up the dust on its way out. Part of the time may be accounted for by showing that it took several minutes for the dust to reach the fire, but there seems to be no explanation other than that already offered to account for the 5 minutes that presumably elapsed between the time Mr. Lewis and his party left the fire and the explosion. It would greatly simplify matters if it could be shown that the actual determining cause of the dust ignition was at the 5th east cross-entry.

The explosion killed all those in immediate authority, and while some little confusion naturally resulted, it was but 20 to 30 minutes until ventilation was restored in the mine. This was accomplished by placing a canvas brattice across the mouth of No. 2 mine, opening the doors between it and Nos. 1, 3, and 4, and covering the roof of the No. 3 fan. As soon as this was done a helmet party was able to enter with brattice cloth and close up the destroyed brattices along the main slope as well as to install a regulator below the 3d north entry. This forced the air up both the 3d and 4th north entries through No. 2 and out the No. 1 fan, which was speeded to its full capacity. By 6 P. M. the first rescue station was established at the upper cross-cut next to the 4th north entry on the slope, and by 6:30 P. M. the second was established at the fire which had been so dampened by extinguishers that it could be walked over.

About 6:30 P. M. the rescue car of the C. F. & I. Co., with a hastily gathered force, arrived and their trained helmet men went in. About 7, this party, noticing a light in the 5th north entry off 4th west cross-entry found four men behind a canvas brattice at the end of that entry, which they had built to keep out the firedamp, and it was by giving up his helmet to one of these men who was partly overcome, that Willis Evans, in charge of the C. F. & I. car, lost his life. Being left behind he was overlooked in the confusion, and when found was in practically a state of coma and died about 6:30 the next morning, despite the most vigorous efforts to resuscitate him. When the fire was quenched it was but a short time until the dead were reached and the bodies began to be brought out. The mine was thoroughly explored by Thursday noon and all but one of the dead definitely located. About 10:30 A. M. Wednesday 15 men came out of the 2d north mine opening who had been marooned on the Rock Island since the explosion and who had kept sufficient air in circulation by moving their jackets fan-fashion to sustain life. About 5 A. M. the morning after the explosion, the United States rescue car which had been at Golden, arrived, and rendered important aid with helmets and pulmoters. The work of restoring ventilation, by reason of there being a second fan, was simple and the rescue and recovery work after the air was restored proceeded with great rapidity.

In conclusion, while this was undoubtedly a dust explosion, the connection between it and the fire is not quite plain, by reason of the length of time from the origin of the probable impelling cause to that of the explosion.

The writer wishes to thank all the many officials of the Victor American Fuel Co. for unfailing courtesy; Jos. Boyd, the fire boss, for kindly accompanying him through the mine on many trips and for his patience in answering many questions. His thanks are especially due to J. C. Roberts, enginer in charge of United States mine rescue car No. 2; to Thos. W. Tweedale, car foreman; and to Thos. C. Harvey, first-aid miner, for many kindnesses, and for their kindly suggestions and criticisms.

TARIFF ON BRECCIA

In paragraph 112 of the existing tariff law breccia wholly or partly manufactured is put in the same class and subject to the same rate of duty as marble, onyx, and alabaster. In paragraph 111, which covers marble and onyx in blocks, rough or squared, there is no specific provision for breccia, but being expressly excepted from the provision covering building stones not dressed, hewn, or polished, subject only to 10 cents per cubic foot in paragraph 114, it would seem that Congress intended to put it in the same class with marble, especially since it is under paragraph 111, classed with and subject to the same rate of duty as marble manufactured.

There is ample evidence to show that breccia is similar in texture and uses to marble. It is crystalline and is used extensively in the form of columns, mantels, wainscoting, and general interior decoration. This is merely another perversion of geological terms by lawyers; breccia is a rock composed of angular pieces, and may be quartz breccia which has no resemblance to marble and could not be used as marble. The rock under consideration was probably "breccia marble," somewhat similar to Taconic marble.

ANSWERS TO EXAMINATION QUESTIONS

Written for Mines and Minerals, by J. T. Beard

Fire Bosses' and Hoisting Engineers' Examinations Held at Terre Haute, Indiana, August 17, 18, 1910

CORRECTION

Attention has been called to an evident error in the statement of Ques. 18, page 184, MINES AND MINERALS, October, 1910. The thickness of steel forming the boiler shell, as given in the printed copies of the examination sent us, is .045 inch. This is an evident error and should probably read .45 inch. In the solution of this question we have inadvertently omitted the factor of safety, which for mining practice should be 6. The solution of this question should be as follows:

$$d=\frac{2\,S\,t}{f\,p}=\frac{2\times 60{,}000\times .45}{6\times 150}=60 \text{ in.}$$

Then,

$$\frac{x}{.45}=\frac{22}{60};\ \text{or } x=\frac{11}{30}\,(.45)=.165 \text{ in.}$$

FIRE BOSSES' EXAMINATION*

QUES. 3.—(*a*) What is ventilation? (*b*) Why is ventilation necessary in coal mines? Points 6.

ANS.—(*a*) Ventilation in mining relates to the maintenance of a sufficient quantity of pure air so conducted throughout the mine by means of suitable doors, stoppings, brattices, and air-bridges as to render the mine atmosphere everywhere wholesome and safe. (*b*) Ventilation is necessary to insure the health and safety of the men and animals employed in the mine and the security of the mine with respect to the noxious and dangerous gases generated therein.

QUES. 4.—(*a*) Name the gases commonly met with in coal mines. (*b*) Give the symbol, chemical composition, and specific gravity of each gas. (*c*) State how each of these gases is formed. (*d*) Where is each to be sought? (*e*) What are the dangers to life of each of the gases mentioned? Points 20.

ANS.—These questions are all fully answered in reply to Ques. 4, 5, 6, and 7, page 350, MINES AND MINERALS, January, 1910.

QUES. 5.—(*a*) Describe how the different mine gases may be detected. (*b*) In what proportion in the air are they dangerous to life? Points 8.

ANS.—Marsh gas is detected in mine air by its effect in lengthening the flame of a safety lamp. When present to extent of from 2.5 to 5 or 6 per cent. in mine air, this gas produces a scarcely visible, pale-blue flame cap varying in height from ½ inch to 4 inches, according to the percentage and character of gases present and kind of lamp and illuminant used. Hydrogen sulphide is detected by its disagreeable odor. Carbon dioxide is detected by the dim burning of the lamps and their complete extinction when the gas is present in sufficient proportion. (*b*) More than 1 per cent. of marsh gas in the air of a dry and dusty mine or more than 2 per cent. in mines free from dust may be considered dangerous; but very much will depend on numerous other conditions that tend to increase or decrease the danger. One-half of 1 per cent. of carbon monoxide, or 1 per cent. hydrogen sulphide may prove fatal to life when breathed for some time. Carbon dioxide added to the air breathed becomes fatal when the gas forms 18 per cent. of the mixture, provided the oxygen of the atmosphere has not been depleted; but a much less percentage of this gas may prove fatal where a portion of the oxygen has been consumed.

QUES. 6.—Describe in full your method of examining a mine for firedamp, beginning with your preparation before entering the mine; and explain each step taken till the examination is completed and report made to the proper mine officials. Points 11.

ANS.—Clean, fill, trim, and light the lamp before going into the mine; examine the gauze and chimney carefully and observe that the lamp has been put together properly. If possible, test the security of the lamp by placing it in a box or chamber where it will be surrounded by an explosive atmosphere. Having carefully prepared the lamp, ascertain that the fan is running at its usual speed, and then enter the mine and proceed at once to the intake air-course in the district or portion of the mine in charge. Observe first that the usual quantity of air is passing at this point, and then proceed to examine carefully and in order each working place, following the course of the air throughout the district, from the intake to the return. Mark the date of the examination with chalk plainly on the coal or roof at the face of each place examined. If gas is found in quantity to endanger the workmen in any place, fence off the entrance and place a danger signal there to warn persons not to enter. If brattice at the face is down, replace it before proceeding further. Having completed the examination of the entire district, return to the shaft or mine entrance, remove the danger signal, which the fire boss should always leave there on entering the mine, enter the daily report of the examination on the book kept for that purpose, and report to the mine foreman the results of the same.

QUES. 7.—A heading 8 feet wide, in a 5-foot coal seam, is driven 50 feet past the last breakthrough. An examination shows 12 inches of gas (CH_4) at the face and tailing out to ½ inch at the inside edge of the breakthrough. (*a*) If this body of gas was thoroughly mixed with the air inside of the breakthrough what would be the explosive condition of the mixture? (*b*) What quantity of fresh air added to the mixture would render it harmless? Points 6.

ANS.—(*a*) Assuming (which, however, could never be true in practice) that the body of gas mentioned is pure marsh gas, unmixed with air or other gases, the volume of gas is $\frac{8\times 50\ (.5+12)}{2\times .12}=208\frac{1}{3}$ cubic feet. The volume of the mixture of gas and air would be equal to the volume of the entry inside of the breakthrough, or $8\times 5\times 50=2{,}000$ cubic feet. The percentage of gas in this mixture is then $208\frac{1}{3}\times 100\div 2{,}000=10.4$ per cent., or somewhat above the maximum explosive point. (*b*) The danger point will depend much on the character of the mine with respect to dust, the size of the workings, and manner of mining. In soft coal, when the coal is dry and the mine is highly inflammable, the percentage of gas in the mine air should not exceed 1 per cent. In this case, the quantity of air to be added to reduce the gas to 1 per cent. would be $208\frac{1}{3}\div .01-2{,}000=18{,}833+$ cubic feet. The conditions of this question are not practical; because, owing to diffusion, it would be impossible to have such a body of pure gas and pure air together at the head of an entry; or to measure the quantity of air required to dilute it below the danger point, whatever this may be.

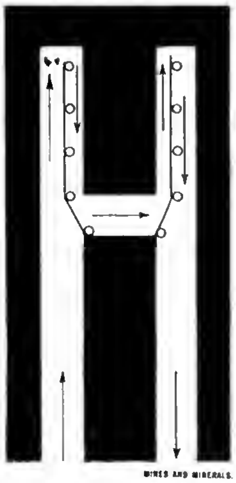

FIG. 1

QUES. 8.—Referring to the above question, state how you would proceed to remove this body of gas, and continue to advance the face till a breakthrough had been made. Points 4.

ANS.—It will be necessary to erect a temporary brattice of boards or canvas nailed to posts set in line about 2 feet from the rib. This line of brattice (Fig. 1) should start from the outby corner of the breakthrough and be extended toward the face only as fast as the gas is carried away. The intake airway must be cleared of gas first and then the return, the work always being performed on the fresh air side of the brattice.

*All miners and employes in and about mines should have a copy of the state mining laws, which they can obtain from the mine inspector's office, Indianapolis, Ind., upon request in writing.

Ques. 9.—What influence does coal dust exercise on mine explosions? Points 4.

Ans.—The fine dust of coal floating in the mine air adds fuel to the flame of a mine explosion. It intensifies and extends the explosion, which is fed by the gas distilled from the dust. As a result, an otherwise local explosion in a mine is extended throughout the entire workings by reason of the dust blown into the air by the force of the initial explosion.

Ques. 10.—If you were employed as fire boss in a mine where the coal is being blasted off the solid, the mine being very dusty and generating a small percentage of firedamp, what precautions would you advise to reduce the liability of explosion? Points 6.

Ans.—If practicable, abandon the practice of shooting off the solid and have all coal mined and, if necessary, sheared or side-cut before a shot is fired. In any case, before firing, have all shots inspected by competent men authorized and instructed to condemn any holes that would, in their judgment, be unsafe. Make and enforce with suitable penalties strict regulations in regard to the charging and firing of holes, and permit no shot to be fired till the place has been examined and pronounced safe. A system of spraying the entries, especially the haulways, and sprinkling the face before firing, should be adopted. All fine coal and slack should be loaded out and each working place regularly cleaned of such accumulations.

Ques. 11.—What dangers would you expect to encounter on entering a mine after an explosion? Points 5.

Ans.—The violence and extent of the explosion will determine the dangers to be encountered. The chief danger arises from the afterdamp that fills large portions of the workings if not the entire mine. The afterdamp consists of a variable mixture of poisonous, suffocating, and in some cases inflammable, and explosive gases. The mine atmosphere, as a result, is unbreathable and dangerous. In addition to this the roof supports have in many cases been displaced leaving the passageways and rooms blocked with heavy roof falls. Doors and stoppings have been generally destroyed and the circulation of air cut off from the workings.

Ques. 12.—What are the essential features of a safety lamp to be used (*a*) for testing purposes, (*b*) for general work? Points 10.

Ans.—(*a*) All safety lamps should be as simple in construction as their requirements will permit. For testing purposes: (1) The lamp should have a free upward circulation of air to insure the same gaseous condition within the combustion chamber as exists in the atmosphere surrounding the lamp. Otherwise the test, however accurate, does not truly indicate or gauge the gas in the mine air. (2) The lamp should be shielded, but not bonneted (except as may be required in special cases where the gas is particularly sharp or the current strong); but the upper portion of the chimney should be protected by a gauze cap, or a double gauze chimney should be used. (3) The lamp should not burn a volatile oil, owing to the danger of the lamp being extinguished and therefore requiring an igniter in the lamp; and further, because a volatile oil gives higher indications after remaining in gas a short time, owing to the effect of the gas in heating the lamp and vaporizing the oil more rapidly. (4) The lamp should be able to detect accurately as low as 1 per cent. of gas. The indication should not depend on the ability of the observer to see the flame cap. The old flame test does not meet present-day requirements. (*b*) For general use, the lamp should be (1) simple in construction to avoid arousing the curiosity of the user; (2) it should give a good light, burning a good quality of non-volatile oil; (3) should be well bonneted to protect the gauze from dust and dirt and the lamp against strong air-currents; (4) should be provided with a simple lead-plug lock, sealed, with the date stamped on the seal.

HOISTING ENGINEERS' EXAMINATION

(Selected Questions)

Ques. 2.—What do you consider the most essential qualifications of a hoisting engineer?

Ans.—He should be faithful in the performance of his duties; alert, closely observant, industrious, temperate in habits, self-reliant, and determined. He should be well informed on all that pertains to the mechanics and operation of his engine, the generation of steam, care of boilers and machinery in his charge, and master of every detail of his work.

Ques. 5.—Describe two ways of setting boilers and explain what provision is made for their expansion and contraction.

Ans.—Cylindrical flue or tubular boilers are either hung by hooks and rods from I beams that span the brick side walls, or are supported by cast-iron knees or angles riveted to the sides of the boiler. To allow for the expansion and contraction of the boiler, the rear angles rest on cast-iron rollers, which roll slightly forward and back over cast-iron plates resting on the side walls, while the angles at the front end of the boiler rest directly on the iron plate itself. In the same manner, when the boiler is hung the swing of the hooks allows sufficient freedom for expansion and contraction in the boilers.

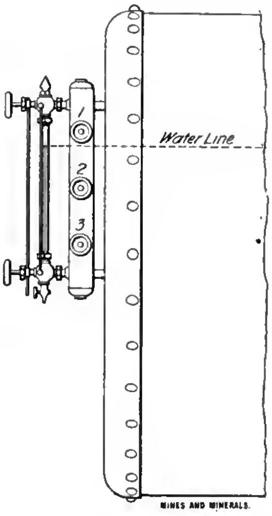

Fig. 2

Ques. 6.—Do the flues or tubes used in boilers increase or diminish their strength? Give reasons.

Ans.—The flues or tubes strengthen the boiler by the firm support they give the boiler ends. They act as rods to tie the two ends of the boiler together, and prevent their bulging outward under the great pressure of the steam.

Ques. 7.—(*a*) Where should water gauges be placed on a boiler? (*b*) Why are steam gauges necessary?

Ans.—(*a*) The water gauge should be at the front end of the boiler and may be mounted on the boiler end of a plain cylindrical boiler as shown in Fig. 2; or the connections may be made on the boiler shell of flue or return-tubular boilers. The position of the gauge must be such that the glass reaches above the high-water line and below the low-water line in the boiler. The upper end of the gauge is always connected with the steam space and the lower end with the water space and is supplied with a plug cock at each end to shut off the steam and water in case the glass is broken. In Fig. 2 the gauge is shown as mounted on a larger tube, called a water column, which in turn is fitted to the boiler in the same manner as explained above for an ordinary gauge. The purpose of this water column is to reduce the effect of the violent ebullition in the boiler to cause a wrong indication of the water level in the glass. Three try-cocks or gauge-cocks, *1*, *2*, *3* are attached to the water column to test the correctness of the water level as shown in the glass. (*b*) Steam gauges are necessary to show the steam pressure in the boiler, as a check upon the action of the safety valve, which might be stuck and refuse to open when the pressure has reached the safe limit.

Ques. 8.—(*a*) Describe three different kinds of grates with which you are familiar. (*b*) Describe the principle of the safety valve.

Ans.—(*a*) The common form of fire-grate consists of parallel cast-iron bars, made in the shape shown at (*a*), Fig. 3, the lugs cast on the sides of the bars, at the middle, and each end keep the bars a uniform distance apart. Cut (*b*) shows a form of rocking or shaking grate. The front and rear sections of the grate are operated separately by the levers shown in

front of the furnace. At (c) is shown a form of step grate for burning fine coal and slack, which is introduced into the furnace at the opening at the top of the grate, and gravitates slowly to the bottom.

(b) The most common form of safety valve is the ball and lever valve. In this valve, the upward pressure of the steam acting on the valve is transmitted by the valve stem to the lever. The moment of this pressure with respect to the fulcrum of the lever is balanced by the moment of the weight of the lever acting through its center of gravity and the moment of the ball. By sliding the ball out or in on the lever its moment is increased or decreased, and the steam pressure required to lift the valve is correspondingly increased or decreased.

QUES. 9.—The shell of a plain cylinder boiler is 30 inches in diameter and 20 feet long, and is made of single-riveted, wrought-iron boiler plate $\frac{3}{8}$ inch thick; what pressure will this boiler safely carry?

ANS.—Assuming the safe tensile strength of the iron as 8,000 pounds per square inch, the safe pressure for this boiler is $\frac{3}{8}\times 2\ (8{,}000) \div 30 = 200$ pounds per square inch. The length of the boiler is not considered in making this calculation.

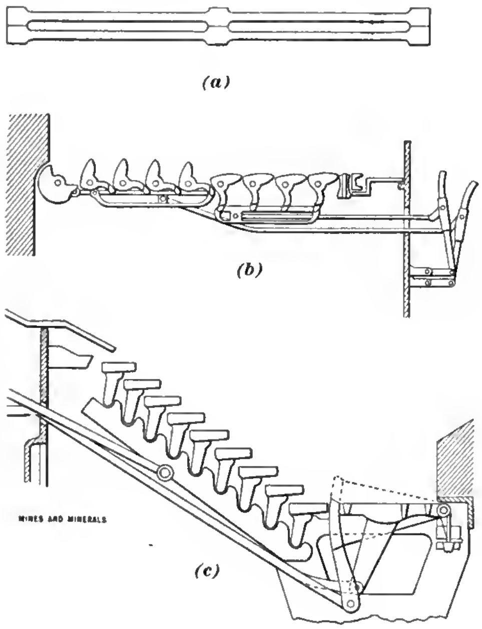

FIG. 3

QUES. 10.—(a) How is forced draft produced in a boiler furnace? (b) What determines the thickness of fire in a furnace?

ANS.—(a) Forced draft in boiler practice is produced by a steam jet, or small blower, or a blast from the air receiver of an air compressor. The greatest economy is obtained by heating the air before blowing it into the furnace. (b) The thickness of the fire is determined, in practice, by the draft, quality of the fuel, area of grate, and rate of combustion required. A forced draft increases the necessary thickness of fire, while a superior quality of fuel, large grate area, or demand for more rapid combustion decrease the same.

QUES. 11.—What should be the smallest rope used to hoist 2 tons of coal per hoist, the car, cage, and rope weighing 3,500 pounds?

ANS.—Adding $\frac{1}{10}$ of the gross load hoisted for friction, the total load on the rope is $1.1\ (4{,}000+3{,}500) = 8{,}250$ pounds. Then, assuming a six-strand, 19-wire, crucible cast-steel, hoisting rope, the required diameter of the rope for this load, using a factor of safety of 5, for a moderate depth of hoist, is

$$d = \sqrt{\frac{5\times 8{,}250}{39\times 2{,}000}} = .727, \text{ say } \tfrac{3}{4} \text{ in.}$$

QUES. 12.—An expansion joint is to be placed in a line of steam pipe that is 450 feet long; how much movement should it allow?

ANS.—The coefficient of expansion of wrought iron is .00000648 per unit of length and per degree Fahrenheit. The range of temperature to which a steam line may be exposed will depend on conditions not mentioned in the question but may be estimated as, say 400° F., which will allow for a fall of temperature below zero and a rise due to a steam pressure of 200 pounds per square inch, at sea level. This would necessitate an allowance in the expansion joint for a possible movement of $450\times 400\times .00000648 = 1.17$ feet, or say 14 inches. It would be well to be liberal and allow for a movement of say 18 inches.

QUES. 13.—(a) What different means are in use to fasten wheels and pulleys rigidly to shafts? (b) How does the reverse link of an engine produce the desired result?

ANS.—(a) Setscrews, keys, and feathers are in use, in a variety of forms and modifications adapted to different work. (b) By means of the reversing link both the direction and the amount of throw of the valve can be changed without any alteration of the eccentric or changing the length of the valve rod. As a consequence, not only is it possible to reverse the engine, but to alter the cut-off as may be desired.

QUES. 16.—What pressure per square inch is exerted on the plunger of a pump that is raising water 175 feet of vertical height?

ANS.—The static pressure due to this head is $.434\times 175 = 75.95$ pounds per square inch. When the pump is working, however, there is an additional pressure due to the friction of the flow of water in the discharge and suction pipes, which depends on the quantity of water handled and the diameter and length of the pipe. For a discharge of 400 gallons per minute through a 5-inch pipe, say 200 feet long, the friction would be practically

$$h = \frac{.01\times 200\times 400^2}{8\times 5^5} = 12.8, \text{ say 13 ft.}$$

which must be added to the actual head, making in this case, $175+13=188$ feet. The working pressure would then be $.434\times 188 = 81.59$ pounds per square inch, under the assumed conditions.

QUES. 17.—What steam pressure would be necessary to do this work if the diameter of the steam cylinder is 6 inches and that of the plunger 4 inches, making no allowance for friction or suction head?

ANS.—Ignoring the friction and assuming the discharge head is 175 feet, the pressure on the plunger when lifting this water column is, as previously found, 75.95 pounds per square inch. But in pumping, the pressure per square inch in the steam and water ends of the pump is inversely proportional to the areas, or the squares of the diameters. In other words, the pressure ratio is equal to the square of the inverse diameter ratio. Call the required steam pressure x; then,

$$\frac{x}{75.95} = \left(\frac{4}{6}\right)^2 = \left(\frac{2}{3}\right)^2 = \frac{4}{9}; \text{ and } x = 75.95\times\frac{4}{9} = 33.75 \text{ lb. per sq. in.}$$

In practice, the friction head and the suction head are both added to the discharge head and their sum multiplied by .434 to obtain the total pressure against which a double-acting pump operates. Thus, if the maximum suction head is 25 feet, the total head, for a discharge of 400 gallons per minute through a 5-inch pipe, is $175+25+13=213$ feet; and the pressure against which the pump, if double acting, operates, is then $213\times .434 = 92.44$ pounds per square inch. The required steam pressure, in this case, is

$$x = 92.44\times\tfrac{4}{9} = 41.08 \text{ lb. per sq. in.}$$

instead of that found above.

NOTE.—Ques. 18, 19, and 20 are fully answered in reply to Ques. 23, 15, and 18, pages 337 and 338, MINES AND MINERALS, February, 1909.

Ques. 21.—(a) What keeps the rod from running off the crankpin of an engine? (b) What should be the size of the steam pipe and what the size of the exhaust pipe for any size of cylinder?

Ans.—There is either a head turned on the crankpin, or a heavy washer having a diameter larger than that of the crankpin is secured to the latter by a setscrew; a dowel pin prevents the washer from turning. (b) The size of the steam pipe is usually designed for a velocity of steam, of say 6,000 feet per minute; and the exhaust pipe for a velocity of 4,000 feet per minute, the calculation being based on the volume of steam consumed, which will depend on the size of cylinder, piston speed, and cut-off.

Ques. 22.—In case the throttle valve should come loose from the steam and prevent steam from entering the valve chest, what should be done?

Ans.—Close the stop valve between the throttle and the boiler and then proceed to repair the throttle valve.

Ques. 23.—(a) What causes the wristpin in the crosshead and the crankpin to wear the way they do? (b) If the crosshead or crankpin brasses become "brass-bound" what should be done?

Ans.—(a) The reciprocating action of the crosshead causes the pressure to be thrown alternately on the two opposite sides of the wristpin each stroke of the engine, which causes this pin to wear in an oval shape. Owing however to the rotation of the crank or crank-disk the pressure due to the alternate push and pull of the driving bar is always exerted on one side of the crankpin, causing the pin to wear in an oval shape on one side only. Also, owing to a slight spring of this pin the wear is a trifle greater at the foot of the pin or close to the crank or disk than it is at the top of the pin. (b) If the brasses become "bound" or their edges touch each other owing to the wear of the pin or the brasses, they must be taken out and their edges cut or planed down.

Ques. 24.—(a) What should be done in case the eccentric slipped around on the shaft? (b) Is the principle of valve setting the same on all engines?

Ans.—(a) This question is fully answered in reply to Ques. 12, page 241, Mines and Minerals, November, 1909. (b) Yes, the principle involved in the setting of the valve is practically the same for all engines, but the method employed varies in different types of engines.

Ques. 25.—(a) How is the dead center of an engine found? (b) If it is necessary to run the engine in the opposite direction from that in which it is running, how can this be done? (c) Is the piston in the center of the cylinder when the centers of the crankpin and the crank-shaft lie in the same vertical plane?

Ans.—(a) Starting at about the middle of the forward stroke turn the flywheel till the piston is near the end of its stroke. In this position draw a fine line square across the crosshead and guide; also, before moving the engine, make a mark on the circumference of the crank-disk or on the rim of the flywheel, near the supposed dead center, by means of a scriber resting on a point of the engine frame which is marked. Now, from about the middle of the back stroke turn the flywheel backwards till the marks on the crosshead and guide again correspond; and, with the scriber in the same position on the engine bed, again mark the circumference of the crank-disk or rim of the flywheel. Bisect the distance from this mark to that previously made, and continue now to turn the flywheel till this bisecting mark reaches the scriber. In this position the engine is on dead center and a permanent mark should be made on crosshead and guide. (b) If there is no reversing link, the eccentric will have to be turned on the shaft so that it will lead or follow the crank an equal amount in the opposite direction. (c) It is not; because of the angularity of the driving bar.

New Inventions

Complete specifications and drawings for any of the following patents can be obtained from the Commissioner of Patents, Washington, D. C., at the following rates.

Single copies	5 cents each
Copies by subclasses	3 cents each
Copies by classes	2 cents each
At entire set of patents	1 cent each

PATENTS PERTAINING TO MINING ISSUED NOVEMBER 1 TO NOVEMBER 29, 1910, INCLUSIVE

No. 974,423. Coke oven, Walter Winstanley Peck, Manchester, England.

No. 974,690. Miner's lamp, Dominick Miglio, Calumet, Mich.

No. 974,632. Process of undercutting in mines, Frank Billings, Cleveland, Ohio.

No. 974,645. Mining machine, Alfred U. Davis, Lutherville, Md.

No. 974,395. Ore concentrator or separator, George Chandler Kidder, Salt Lake City, Utah.

No. 975,213. Mining measure, Anthony Cronwell, Sterling Run, Pa.

No. 975,084. Concrete timbering for tunnels, Thomas H. Stanley, Denver, Colo.

No. 975,468. Mining machine, Frank L. Sessions, Columbus, Ohio.

Nos. 976,043, 976,044, and 976,045. Treatment of precious metalliferous ores, John Collins Clancy, New York, N. Y.

No. 976,425. Apparatus for washing, grading, and classifying coal or other material, Frank D. Baker, Denver, Colo.

No. 976,785. Miner's lamp, Martin James Curtis, Billings, Mont.

No. 976,835. Mining machine-bit, Ralph E. Noble, Chicago, Ill.

No. 976,419. Ore jig, George H. Williams, Chicago, Ill.

No. 976,175. Ore-roasting furnace, John B. F. Herreshoff, New York, N. Y.

No. 976,769. Annular ore-roasting kiln, John Zellweger, St. Louis, Mo.

No. 977,119. Apparatus for handling coke, etc., William Clark, Mitchell, Sydney, Nova Scotia, Canada.

Nos. 976,931 and 976,935. Coke oven and door therefor, Frederic W. C. Schniewind, New York, N. Y.

No. 976,930. Coke oven and heating arrangement therefor, Frederic W. C. Schniewind, New York, N. Y.

No. 976,929. Burner for coke ovens, Frederic W. C. Schniewind, New York, N. Y.

No. 976,934. Coke-oven discharging apparatus, Frederic W. C. Schniewind, New York, N. Y.

No. 977,348. Regenerative coke oven, Emil Wagener, Dahlhausen-on-the-Ruhr, Germany.

No. 977,302. Waterpower mining drill, Carl A. Hanson, Seattle, Wash.

No. 977,275. Mining needle, Patrick F. Costello, Vintondale, Pa.

No. 977,087. Ore and coal washer, Henry W. Falkner, Ashland, and Franklin Schultz and John F. Wagner, Tamaqua, Pa.

No. 976,943. Ore screen, Philip R. Stanhope, Denver, Colo.

No. 977,096. Treatment of ores, Charles Morris Johnson, Avalon, Pa.

According to T. P. Bruce there is an undesirable conservation of natural resources in progress in the Western States.

"Our roads and some of our mining claims are being covered by agricultural filings. They wire up the exits and make us make a detour of 4 or 5 miles; build a shack worth \$20 to \$25, plow up 3 to 4 acres, take up a crop of less value than the seed and labor costs, get 160 acres of mineral land, where the hematite or 'bog iron' is looking at them out of the ground, while I, as I am patenting a mineral claim adjacent, have to fork out something in the neighborhood of \$165."

Between government reservations, corporation absorptions and farmers, the natural resources are aviating away from the prospector.

Mines and Minerals

Vol. XXXI—No. 7. SCRANTON, PA.—FEBRUARY, 1911—DENVER, COLO. Price, 25 Cents

CONSOLIDATED FUEL CO., UTAH

Written for Mines and Minerals, by R. J. Turner

Method of Gravity Haulage for Mine Cars With Standard Gauge Coal Cars on Same Road

The coal production of Utah has increased from 50,000 tons in 1877 to 1,967,651 tons in 1907, and even this latter tonnage did not cover the demand, as 979,152 tons were imported. Utah also produced 324,692 tons of coke in 1907. All coal mined in Utah with the exception of 151,488 tons came from Carbon County.

In 1907 the Utah Fuel Co., the Independent Coal and Coke Co., and the Union Pacific Coal Co. were about the only coal operators in Utah.

Since the construction of the Southern Utah Railroad, the Consolidated Coal Co. has opened mines at Hiawatha, Utah, 18 miles southwest from Price. These coal beds have been known long and favorably, and it was due to lack of transportation that they were not earlier developed. Located as they are 8,100 feet above sea level, and high above the present railroad, there is an abundant supply of good water and a fairly good supply of timber.

Carbon County coal beds belong geologically to the Laramie beds of the Upper Cretaceous, and while high in volatile hydrocarbons, are low in ash and sulphur.

The Consolidated Fuel Co.'s mines on Miller Creek, in the southwest edge of Carbon County, are opened on two beds of coal, one 18 feet and the other 6 feet 6 inches in thickness. These beds vary slightly in their volatile matter, ash, and sulphur contents in different parts of the field, as could be expected, the highest ash being 5.38 per cent., and the lowest 1 64 per cent. The analysis of Carbon County coal as a whole is as follows:* Moisture, 3.20; volatile matter, 45.67; fixed carbon, 47.22; ash, 3.35; sulphur, .56.

Fig. 1. Mine Mouth No. 1, Hiawatha Mine, Utah

Several features in connection with the Consolidated Coal Co.'s property make an account of the mines and the methods followed in moving the coal to the railroad cars interesting. The Consolidated Fuel Co.'s mines have been developed so rapidly that few people realize how important they have become. The Southern Utah Railroad was completed on January 19, 1910, when the first car of coal was shipped. Previous to this, little development work had been done on account of lack of transportation. At this writing the mines are capable of producing 2,000 tons of coal daily.

Owing to the steep grade where the mines are located, it was found necessary to convey the coal 2 miles from the mine to the tipple by means of a self-acting incline. This was accomplished by the usual gravity inclines, as the grade was an ideal one of from 6 to 9 per cent., but another feature had to be worked out. On account of the camp being at the mines it was found necessary to establish a standard-gauge road up to the mines so that supplies could be more economically handled. On account of the narrowness of the cañon it was decided to run a standard-gauge track between the mine-car tracks and use the same rails. This would have been feasible had the incline been a straight one, but it comprised three long curves of from 7 to 10 degrees each, and to run up the standard-gauge railroad cars meant keeping the rope in the middle of each track at the curves. This was only accomplished after a long series of trials and troubles, when a spring curve roller was finally designed that successfully fulfilled its purpose.

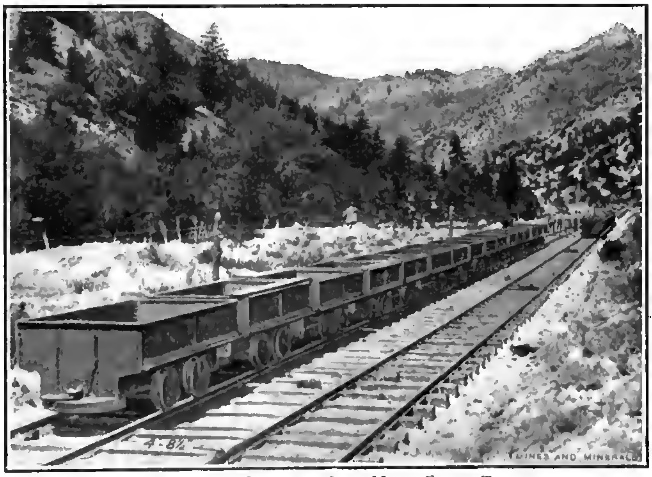

Fig. 2. Trips Passing One Mile From Tipple

The mine car adopted is of steel with Hyatt roller-bearing wheels and a capacity of 3½ tons of coal. These cars are made up in trips of 16, which in going down the plane attain an average speed of 1,000 feet per minute.

One of the two mine openings is shown in Fig. 1. It is like mine No. 2 in the lower coal seam which averages 18 feet thick, as shown by the portal.

Fig. 2 shows two trains of mine cars midway between the

* Utah Conservation Commission Report, page 86.

mine and the tipple. The curve in the background shows one of the difficulties to be negotiated in this country.

The apparatus for handling the trips on the incline consists of two 6-inch drums set tandem and coupled together with suitable gearing and friction clutch to an 82-horsepower General Electric induction motor. By means of the clutch the motor can be thrown in and out of gear at will. It is only necessary to use the motor when starting or stopping, and this only to have better control of the trip and be able to stop and start on the smallest margin possible. Each drum is equipped with two powerful brakes that have 12-inch face rims and are operated by hand by a worm-feed arrangement that gradually brings the drums and the trip to rest, thus relieving the rope and machinery of any severe strain due to the sudden stopping of the moving trip. It further gives full control of the trips as they near each end, the speed being kept down by the brakes until it corresponds to the speed of the motor, which is 400 feet per minute. The friction clutch is then thrown in and the trips all landed by the use of the motor controller, which affords a more reliable method of landing.

Fig. 3. Tipple at Hiawatha, Utah

The rope has three full turns around each drum and runs in grooves cut in the drums about 3 inches apart. Each rope runs off the lower side of the front drum, and to keep the rope in place for its respective tracks a large horizontal sheave wheel is placed to receive the rope from the drums. The rope used is a 1-inch, 6-wire, 6-strand, plow-steel, Hercules, a little more than 2 miles long. As the rope feeds on the drums and feeds off

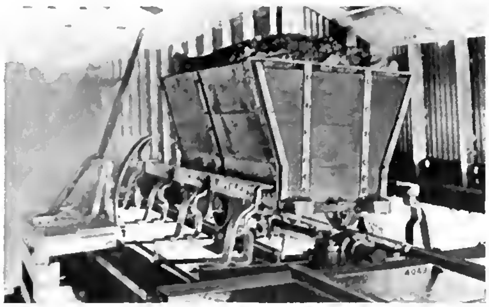

Fig. 4. Car Ready to Dump

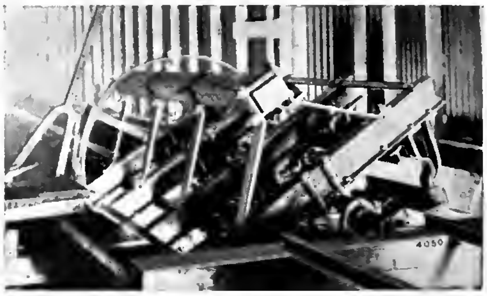

Fig. 5. Dumping

as fast, there is only a small piece of the rope on the drums at any time.

The tipple shown in Fig. 3 is shipping coal, although at the time the photograph was taken from which the cut was made the tipple was under construction. The tipple equipment was furnished by the Link-Belt Co., who also installed a rotary side dump, shown in Figs. 4 and 5, in order to do away with end doors on the coal cars. There is no question but that this was a wise move as a safety device in preventing wrecks on the plane, which are due every so often when end doors with latches are used. The mine cars discharge into a hopper shown in Fig. 3, from which the coal is fed uniformly on to the shaking screens by an automatic feeding device.

Five sizes of coal are made between the hopper and the cars, the coal all moving by gravity.

The tipple machinery is driven by a 75-horsepower General Electric induction motor. The power plant is near the tipple and comprises two direct-connected, alternating, three-phase units of 200 horsepower, carrying a voltage of 2,300. This current is carried to the mines by means of a pole line shown in Fig. 1, and there converted by means of a generating set into direct current of 250 volts, after which it is used for the various purposes of hoisting, pumping, hauling, etc., in and around the mines.

The mines are worked on the double-entry system, both to the rise and dip of the main entries, the rooms being turned from cross-entries in the usual way. Entries are driven 12 feet wide, 7 feet high, with 62-foot-thick pillars between. Rooms are driven 22 feet wide, 18 feet high, except the 30-foot room neck, which is driven entry width and height. The seam is clean throughout, has regularly defined cleavage, and has a smooth parting 7 feet from the floor, which makes an excellent roof for the entries. The roof above the coal is a heavy sandstone and no timber whatever is required in rooms or entries. The main dip of the seam is 2 per cent. in a southwesterly direction, consequently the haulage is done by electric locomotives. Two 12-ton Goodman locomotives, one in each mine, serve the purpose of hauling from the level-entry partings to the tramway, and one 5-ton Goodman gathering locomotive gathers all the coal cars in No. 2 mine. The coal cars in No. 1 mine are at present gathered by horses, which, on account of the light grades, is easily accomplished.

Ventilation is carried on by the aid of two Jeffrey reversible fans driven by electric motors. The ventilating current is split at each pair of cross-entries, and by means of an overcast each pair of entries have their own individual system of ventilation. All breakthroughs between entries are closed with sandstone masonry laid in cement, the sandstone for the purpose being brought into the mine. This arrangement forms a permanent

and effectual air stop which under ordinary circumstances should last so long as the mine.

As yet the mines give off no firedamp, but ample precaution has been taken in planning the workings to assure perfect safety if at any future time they should do so. An electric shooting system is being installed similar to the one used by the Utah Fuel Co., explained in these columns some months ago. A perfect sprinkling system is in operation to allay dust and make these mines as safe to work in as any in the state.

STEEL SUPPORTS IN COAL MINES

*Written for Mines and Minerals, by R. B. Wooodworth, M. Am. Soc. C. E.**

Durability of Steel Supports. Different Styles Used in Various Coal Mines

Within recent years a number of coal-mining companies have adopted the use of steel for supporting those underground excavations which are to remain open until the extraction of the coal is completed and the mine abandoned. Experience gained in the actual designing and use of steel mine timbers and steel shaft supports has convinced engineers who were once skeptical as to the use of steel within the mines, and has corroborated the correctness of the general conclusions advanced more than three years ago by the writer in the proposition that for permanent work steel is superior to wood in supporting underground excavations and is its logical successor.

Attention has frequently been called to the increasing cost of timbering mine excavations with wood, which is due to the rapidly decreasing supply of timber suitable for this purpose. For the past 40 years engineers have urged the importance of the antiseptic treatment of the timber which goes into the mines in order to prevent its destruction by disease. The suggestion, however, has gone almost unheeded, as only one or two companies in the anthracite region have adopted timber preservative methods on anything more than an experimental

FIG. 1. STEEL MINE TIMBERS, ROBY COAL CO. DRIFT NO. 2, ADENA, O.

stage. Timbers treated with tar products, though they may be immune from disease, are not increased in strength or made fireproof. In consequence, the logical engineer familiar with the real values of materials of construction turns to steel wherever permanence in mine supports is required.

The suitability of steel for supporting roofs in coal mines was demonstrated in England and in Europe years ago, and numbers of installations have been satisfactorily executed in the United States, some of them of many years standing, so that the adoption of steel for such purposes in this country has been merely a question of cost.

The substitution of steel for wood is simply the substitution of a material known to have great strength and longevity for a similar material of less strength and unknown endurance. The

FIG. 2. STEEL MINE TIMBERS, FLORENCE MINE, Y. & O. COAL CO., MARTIN'S FERRY, O.

forms of wood in timber sets that have proven suitable for mine timbering can exactly be duplicated in steel; a set of steel entry supports can be alternated with wooden sets; steel shaft frames may be alternated with wooden frames, or wooden timbering may be replaced by steel timbering, and vice versa. Wherever tensile and bending stresses are to be resisted, wood and steel find their true field of usefulness, with this difference: that the substitution of steel for wood avoids those elements of economic waste to which wood is liable, namely, the waste in sizes of timbers due to practical considerations which make legs and collars of the same cross-sectional area or diameter, waste in framing, and waste from destruction by decay.

The final collapse of mine timbering may be due to several causes:

1. Long continued stresses which may cause a permanent set near the elastic limit of the material so that slight increases in weight cause rupture.

2. Unequal distribution of the load due to the fracture of the strata above, unexpected side pressure or imperfect jointing and chocking.

3. Riding of the strata which produces a squeeze that nothing so far attempted has stopped.

4. Absolute weight of the overlying strata whose pressure is greater than the timber can sustain.

5. In the case of wood, final destruction of material of sufficient strength when first installed may be hastened by various diseases to which mine timber is subject if not antiseptically treated.

The load to which the timbering may be subjected in any particular mine varies with the pitch of the strata, the thickness of the cover, the density of the rock, and other causes, the total effect of which is hard to reduce to calculation. Experience in the use of mine timbers will alone determine what sizes should be used. The comparative values of the various species of timber used in mine supports to resist bending or compressive stresses may be obtained from the pamphlet entitled "Steel Mine Timbers," issued by the Carnegie Steel Co. and prepared by the present writer, and so also may the corresponding sizes of steel section. In the absence of such tables the strength may very readily be computed by the following simple methods:

1. *Rectangular Beams.*—Multiply the width by the square

* Engineer with Carnegie Steel Co.

of the height and divide the result by the length in feet. The quotient multiplied by 133, 89, 111, or 67, will be the uniformly distributed load in pounds for yellow pine, white pine, or spruce, white oak or hemlock, respectively.

2. *Round Beams.*—Divide the cube of the diameter by ten times the length and multiply the quotient by the same constants as for rectangular beams to obtain the uniformly distributed load.

3. The safe uniformly distributed load in tons on standard steel sections may be obtained by dividing the following constants by the length in feet: 15-inch 42-pound beam, 314; 12-inch 31.5-pound beam, 192; 10-inch 25-pound beam, 130; 9-inch 21-pound beam, 101; 8-inch 18-pound beam, 76; 7-inch 15-pound beam, 55; 6-inch 12.25-pound beam, 39; 5-inch 9.75-pound beam, 26.

4. The computation of loads in compression on the legs of 3-piece timber sets or the buntons of shaft sets is not so simple, as the strength of the material, whether iron or steel, decreases as the ratio of the length to the width (ratio of slenderness) increases; consequently a simple easily remembered formula cannot be put down. The general formula for the compressive unit stress in pounds per square inch of oak is

Fig. 3. H-Section Roof Supports Adrian Mines, Rochester & Pittsburg Coal and Iron Co., Punxsutawney, Pa.

$900 - 17\frac{L}{D}$, long-leaf yellow pine $1{,}000 - 18\frac{L}{D}$, and white pine or spruce $800 - 15\frac{L}{D}$, where L is the unsupported length of the leg in inches and D is the least diameter or width in inches. The steel **H** beams, which are the best fitted for use in mine timbering to resist compressive stresses, are generally employed where the length of the member is not more than 22 times its width. In such cases the safe load in tons may be obtained by multiplying the weight per foot of the section by 1.75. Where the length of the member exceeds this value, reference must be had to the general formulas.

So far as known to the writer, single props of steel have not been used in the United States, and where props remain in position until broken by the subsidence of the roof, there seems to be no economy in endeavoring to make a substitution of steel for the cheap wooden props now used in mining operations. With the introduction of longwall methods of mining, such as are more common in England and on the Continent, and to some extent in the middle Western States, with the consequent withdrawal and reuse of the props, it would seem that in such workings metallic props could be used in this country with as much economy and satisfaction as in European mines.

The numerous methods of placing steel mine timbers which experience has shown to be best suited for existing roof pressures are given in the following illustrations descriptive of typical installations:

The simplest use of single steel supports in mines is shown in Fig. 1 in the **I** beams spanning the roadway. The excavation is the Roby Coal Co.'s No. 1 drift at Adena, Ohio. "These mines have a very tender roof and at one time the haulways were considered the most dangerous in the district. Conditions were so uncertain that those in charge could never tell when they started in the morning the length of time the mine would be in operation, as a fall was liable to occur any time, suspending operations for the day. Under the able management of the present manager and his assistants conditions have changed, and these mines will now compare favorably with any in the district. At No. 1 drift the main entry is timbered with 833 steel **I** beams and 398 8″×10″ oak timbers; south face, 1,140 steel **I** beams and 594 8″×10″ oak timbers; north face, 160 steel **I** beams and 40 8″×10″ oak timbers, making a total in this mine of 2,133 steel **I** beams and 1,032 8″×10″ oak timbers. No. 2 drift, north and main entry, 818 steel **I** beams and 733 8″×10″ oak timbers; first south, 607 steel **I** beams and 198 8″×10″ oak timbers; second south, 65 steel **I** beams and 12 8″×10″ oak timbers; total, 1,490 steel **I** beams and 943 8″×10″ oak timbers. The management informs me that the cost of production is a great deal less than when they attempted to operate

Fig. 4. Three-Piece Steel Set Used by Susquehanna Coal Co.

without properly timbering the haulways and taking the risk of no one being there when a fall occurred." (35th Annual Report Chief Inspector of Mines, State of Ohio, page 430.)

Owing to the small bearing and lack of compressibility in steel it is customary in cases of this kind to rest the ends of the steel beams on wood. In breakthroughs or cross-roads the roof supports rest on **I** beams carried by short timbers, as shown to the left in the illustration.

The method of supporting a roadway through a territory where one side has been robbed and abandoned while the other side is a solid rib of coal is shown in Fig. 7. All pressure in this case is practically downward, hence the wooden legs are vertical while the steel beams are horizontal. In the mines of the Alden Coal Co., at Nanticoke, Pa., there are extensive installations of this kind where the 15-inch **I** beams used for collars rest at one end on the rib and at the other on a wooden post notched out to take the flange of the beam. In the mines of the Youghiogheny & Ohio Coal Co. unmortised wooden posts are used successfully as shown. At the Amsterdam Mine, 1,086 steel beams have been placed for roof supports from the first of June, 1908, up to December 31, 1909.

Another method of using one steel and one wooden support in a wide excavation is shown in Fig. 2, Florence Mine, Youghiogheny & Ohio Coal Co., where a branch road turns off to another portion of the mine. In this situation props are placed under the steel beam at the junction of the road, but out of the way. When a prop is so placed under a beam, it reduces the span

and thus materially aids in sustaining the pressure from a bad roof.

Where 3-stick supports are required, pressure may come on them from all three sides, or the sides of the excavation may be soft and might crumble under the weight of the collar. In the Adrian mines of the Rochester and Pittsburg Coal and Iron Co., at Punxsutawney, Pa., 4-inch **H** beams weighing

Fig. 5. Steel Gangway Supports, Allport Coal Co., Barnesboro, Pa.

13.6 pounds per foot replaced as many 8-inch square collars. These **H** beam collars were the first of their size rolled in the United States and were spaced 4½-foot centers, their ends resting on round wooden legs, as shown in Fig. 3. In the illustration a wedge will be observed driven between the top of the leg and the beam. This protects the leg by preventing splitting or fiber brooming, when the rock weight settles on the beam. It is of course as necessary to chock steel beams as wooden collars against the roof to prevent unequal distribution of load and bending at the ends over the posts.

The use of steel collars for roof supports in connection with wooden legs is strictly in line with good theory and practice, steel being relatively better adapted to resist bending stresses under transverse loads, while the compressive strength of wood is very much greater than its resistance to bending.

In Fig. 4 is shown the 3-piece all-steel set which was designed by Mr. R. V. Norris and installed in many collieries of the Susquehanna Coal Co. and its subsidiaries. These sets are spaced on centers by rods and gas pipe placed between them at the upper corners and at the sides. At the same time the arrangement prevents the sides from moving out of alinement. It will be noticed also that the sets are backed with lagging, which may be either plank or concrete slabs or old rails. The I-beam collar in this set rests on two pins to separate the two steel channels that go to make up the legs and which are also connected together by short pieces of gas pipe through which a bolt is passed and fastened by nuts on the outside.

In Fig. 5 is shown the main heading of the Allport Coal Co.'s mine at Barnesboro, Pa. There are 85 sets in this mine similar to those shown. Each set weighs 372 pounds, or about one-third the weight of the necessary 3-stick wooden set. These sets were lagged with wood and concreted up to car height. The installation was conducted by ordinary mine workers and complete sets erected in 8 minutes each by the watch. The construction is fireproof, fool-proof, and germ-proof.

Up to this point comparatively narrow single-track excavations have been shown, but the economy of steel as compared with wood increases much more rapidly than the length of the span. In Fig. 6, Oak Hill colliery, Minersville, Pa., there are two tracks with heavy steel roof beams supported at the ends by steel legs without central posts, thus making a longer span than was safe or economical with wooden beams. In the rear of the steel sets are shown the heavy 3-stick sets with intermediate posts to stiffen the collars, and the illustration shows very clearly the relative mass of the wood and its additional area of surface exposed to fire. The appearance, irrespective of the longer life and increased safety of the steel, is worth almost the difference in cost between the two.

The first use of steel in any form within the mines was doubtless the use of old rails at points of local danger. The scientific use of steel dates from about the year 1875 when I-beam shaped girders were used to support the roof at the bottom of the shaft in the Cambois colliery in Northumberland, England, in order that the great loads might be carried in the same way as had been possible theretofore with timber. For the collar of a square timber set there is no form of section rolled more economical than the standard **I** beam used in ordinary construction. For the legs and props, where loads have to be carried in compression, the highly economical integral section was not rolled in the United States four years ago. The **H** beam, which is the closest practical approximation in the form of a rolled shape to the section of the largest compressive resistance in proportion to its weight, has been found the section best fitted for use both as single props and for legs of the 3-piece gangway support, and its introduction can be said to mark an era in the history of American mine timbering as it did when introduced in England by the Darlington Iron and Steel Co., in 1885. The use of this section has been extended to include the framing of mine shafts. When used for wall plates of a mine shaft the **H** beam has the advantage of a large bearing surface as compared with beams or channels of the same depth, and for buntons and compartment separators the advantage of a large compressive strength combined with a comparatively high moment of resistance against bending.

The experience of three years indicates that a steel gangway support set need not be any more adjustable than the 3-piece set as framed in wood. A few adjustable sets were installed in one of the copper mines of the far West where the ground is heavy and the conditions severe. These sets failed under service, largely because of errors made in the substitution of steel for wood, the legs not being sufficiently heavy for the service they might reasonably have been expected to perform. It is significant that this is the only failure which has occurred

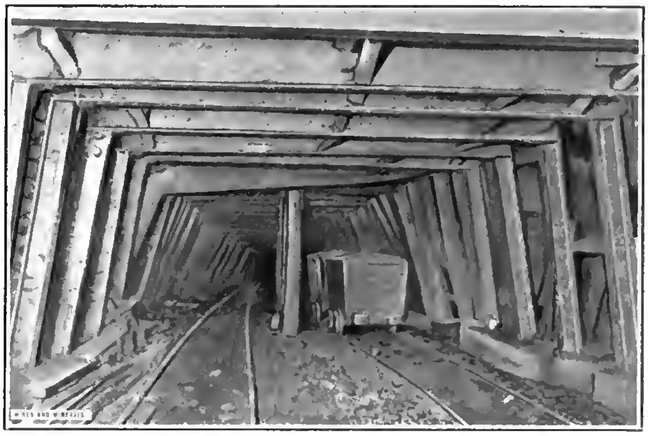

Fig. 6. Steel Gangway Support, Oak Hill Colliery, Minersville, Pa.

in three years; all the other installations, which have been quite numerous, have been entirely successful and satisfactory.

The use of steel in place of wood will not solve all the mine timbering problems. There are conditions encountered in mining with which the most careful foresight cannot entirely cope. The removal of the coal over wide areas necessarily entails an adjustment of the overlying strata to meet the new conditions, however well the timbering may be put in place.

The settlement of the superincumbent strata in level workings brings upon the timbers nothing but a direct bending or compression. When the strata are inclined, however, as in the West and in the anthracite regions, this movement causes squeezes and other disturbances of a similar character, which bring upon the timbering compression stresses in the horizontal members and bending stresses in the vertical or inclined members, together with crushing stresses on all, producing inevitable distortion and permanent deformation. Under such conditions steel will sustain its position better than wood, for the reason that its strength remains unimpaired over long periods of years unless its elastic limit is exceeded, whereas wood is continually deteriorating under such repeated stress and the influence of moisture and temperature conditions.

A careful series of experiments has been instituted to determine the extent of corrosion that may be expected and

Fig. 7. Steel Mine Timbers, Barton Mine, No. 3 Entry, Y. & O. Coal Co., Barton, Ohio

the best materials for the preservation of the steel against such corrosion. Samples of mine water were obtained from 24 mines in the bituminous and anthracite districts. They were carefully analyzed for total solids and for free sulphuric acid, and these analyses compared with a number of analyses made by coal companies and by the United States Geological Survey. The analyses showed that the acidity of mine water had been very much overstated, the worst sample showing only 3,320 parts of free acid in a million or $\frac{33}{100}$ of 1 per cent. It was found by further investigation that the worst condition is probably that in which a small percentage of ferrous sulphate is found in a water containing free sulphuric acid. On the basis of these investigations a series of laboratory experiments were conducted by immersing $\frac{1}{2}$-inch round rods painted with 50 various pigments in 120 combinations as to first and second coats in a standard solution containing 2.6 per cent. of free sulphuric acid and 4 per cent. of ferrous sulphate, or approximately 10 times worse than the worst sample of mine water. Further details of this investigation may be found in Cushman and Gardner's work entitled "The Corrosion and Preservation of Iron and Steel," page 224. These experiments were continued for 163 days, the results tabulated and compared and the pigments rated in accordance with their endurance under test and the condition of the material at the end of the period. These experiments indicate that only the simplest means are necessary for the absolute guarantee of an extremely long life for steel in underground mining conditions.

The steel should be painted before it is placed in service. If the paint is well chosen and applied with care, there need not be any fears as to its durability or as to its protective value. The first coat applied at the shop should consist of a practically inhibitive pigment to prevent the inception of corrosion in the steel, and the second coat should be put on in the field to protect the first from atmospheric and temperature conditions, to fill up thoroughly any voids which may occur therein and to cover surfaces abraded in shipment. To meet these requirements a good grade of red lead or a natural oxide of iron well applied will be sufficient for the first coat. For the second or excluding coat there seems to be nothing better today than a first-class graphite although the natural hydrocarbons, such as elaterite and asphaltum, have given excellent results. If used, these should be free from sulphur or other impurities.

After all, underground conditions are not nearly so severe on the steel as those above ground. Above ground the paint coatings are subjected to alternating conditions of high and low temperatures, various degrees of dryness and wetness, alternation exposures to light and darkness, abrasive action of winds, dust, etc., all of which are accelerative in their deterioration. Underground these conditions do not apply, and the coating is not exposed to any such severe service, consequently any first-class coating should show a high degree of endurance and insure ample protection. The fact that steel has been exposed 15 or more years in the anthracite region without renewal of the original preservative coating and without serious corrosion is a demonstration of the ease with which the life of steel may be indefinitely prolonged.

PERSONALS

Peter Haberstick, manager of the Elks Club, who planned the stage setting illustrative of a coal mine, and Arthur Langhan's florist, who did the decorating at the recent West Virginia Mining Institute meeting, in Wheeling, say that the members are jolly people and that they hope to see them again in Wheeling in 1913.

C. S. Herzig and W. Murdoch Wiley have resigned as president and vice-president, respectively, of the Constant-Herzig Co. C. S. Herzig has taken over the mining contracts and will continue the business heretofore carried on by the mining department of the company.

J. B. Tyrrell, Mining Engineer, of Toronto, has opened a branch office in Porcupine, in Northern Ontario.

Announcement is made by Charles G. Armstrong, the consulting engineer of New York City, that he has taken into partnership his son, Francis J. Armstrong, under the firm name of Charles G. Armstrong & Son. Francis J. Armstrong is a graduate of the Manual Training School of the Chicago University and of the Stevens Institute of Technology. He has been engaged with his father in consulting engineering work for the past year.

N. H. Darton, Geologist with the United States Geological Survey, has been appointed geologist of the United States Bureau of Mines, with headquarters at Washington, D. C. He states that he will continue to investigate the geological conditions under which explosive gases occur in coal beds.

Harry N. Taylor, President of the Wilmington Coal Co., has been elected president of the Illinois Coal Operators' Association.

W. A. Lathrope, President of the Lehigh Coal and Navigation Co., has been made a director in the Lehigh and Hudson Railroad.

Doctor Harold Osborn, of the Massachusetts Institute of Technology, was the first to receive the degree of Doctor of Engineering from the American Institute of Electrical Engineers.

Edward G. Locke has been appointed general manager of the Davis Coal and Coke Co., and the Western Maryland Railroad.

Richard Maize, who has been superintendent for the Pittsburg and Westmoreland Coal Co., at Hazel Kirk, has been appointed inspector for the First Bituminous Mining District of Pennsylvania, to temporarily replace Alexander McCanch who is ill.

THE MORAL OF STARKVILLE

Written for Mines and Minerals, by Sim Reynolds, Mine Superintendent

Questions Which All Having Responsible Positions at Mines Should Ask Themselves

During the night shift of October 8, 1910, it was the unenviable opportunity of the Starkville Mine, near Trinidad, Colo., to add to the long list of major mine explosions of late years, and, further, to give additional evidence that the number of combinations which can, and do, cause disaster in mines is not yet exhausted. Let us hope for our future's sake they are at least limited, and that the end will soon be reached.

This particular "accident" was a distinct surprise to a goodly number of people, although to one fully conversant with the results at Monongah it should not have been such. Both explosions were practically identical as to primary causes, differing slightly, of course, in detail. Evidently the surprise was greatest where it happened, among the managerial force of the Starkville Mine. This is certain; it was one of the few large explosions which was apparently totally unexpected. There have been disasters on a large scale heretofore that have been but confirmation of such rumor on the part of the employes and others, although not always arriving on schedule time. And among this class Pennsylvania and West Virginia have had a large share.

That at Starkville falls at once into a different category, and therein is the only feeble extenuation that we can see. To the writer the very idea of it at once conjures Cherry and Monongah. Neither was considered a dangerous mine, by which term we mean having within its operation and the winning of its coal bed possible death at one time for a large majority of its employes. Yet both were the scenes of manifold death and destruction of property. In spite of these obvious lessons, there are running today, as before these disasters happened, scores of just such "non-dangerous mines." Many of these latter have within them potential possibilities even graver than the holocausts mentioned. Many of them are today working under the exact duplicate of conditions at Starkville before the explosion. Many of them do use powder, dynamite, or other explosives of concentrated flame-producing power. Starkville even didn't have that, and, besides almost absolute freedom from gas, there was not even the usual dramatic setting of "a careless miner and a blown-out shot." The combination at the Colorado mine was contemptuously simple—merely a lot of black carbon settlings and an electric wire! It would seem as if our country were chosen of the gods on which to wreak undeserved vengeance when even this was chosen as a means of disaster, if—the same cause had not wrought the same result in France, in Belgium, in the little Staffordshire slaughter pits, and elsewhere, both since coal dust has attained to its modern dignity as an influence on mining mortality, and before men recognized its candidacy for a star role in this oft-recurring drama of the underground. But has it filled the mine official still operating under conditions similar to those that existed at Starkville with sufficient caution? I am afraid not. This happened at the other fellow's mine. His dust was undeniably inflammable, else the explosion would assuredly not have happened. But ours isn't! At least that's the way the continued methods seem to presuppose.

Fortunately in the Starkville case all the undeniable testimony did not die with the men, as is too often the case. From certain employes' evidence a vivid light is thrown on the utter disregard of danger characterizing that mine's operation previous to the blow-up. The superintendent knew the mine was very dusty, according to his own confession, but didn't consider it dangerously so until after it happened. He admits—now—that the mine was insufficiently watered. Doubtless he is also of the opinion shared by many other mining men that to allow the underlings having neither technical nor other knowledge of coal dust—except that it is a nuisance and black—to assume sole discretion regarding which part of the mine should be watered and which not, how much this part should get and how much that, was "going some" in the matter of managerial indifference. And all the mine superintendents and foremen do not live in Colorado nor at Starkville who would perforce have to admit guilt in this premise if cornered.

In view of recent events it seems to the casual observer that, scattered about this country, there are a considerable number of men in charge of mines unfitted by temperament for the positions they hold as guardians over human life. Neither is the indifferent temperament in a mine manager a good trait if one considers only the chances of property destruction, unless his employer's forethought has secured ample provision for anything that might turn up. Not because of insufficient practical or technical mining experience, mind you, for many of the most callously indifferent men have been raised in and about the mines. But there is lacking in their mentality that something fools define as cowardice, or fussiness, and wise men as philosophic wisdom. They lack that which is absolutely essential to the best management in all cases where human lives are the stake, an ever-present feeling of fear of what might happen; not largely, of course, but in that quantity of the golden mean which would insure their care regarding details as well as the large things; in short, a man who constantly labors under the impression that it is better policy, both from his own point of view, and from that pertaining to the company employing him, and for the not less vital ethical consideration involved in the lives in his care every day, to spend $10,000 to prevent an explosion than $50,000 in rehabilitation and law suits for damages. This of course does not preclude the possibility of his being efficient in other qualifications necessary according to circumstances and opportunity. And among the many mining men I have known they who have developed that instinct of wholesome caution were the bravest when it came to a pinch at the other fellow's mine. That's a fact regarding which I could fill many pages of Mines and Minerals with corroborative stories.

Of course I do not know the men actively engaged at all these mines which have blown up, and any expression made in this respect is general rather than specific. I refer to the mining industry as a whole. But what I decidedly want to convey to you fellows who are indifferent even now, after Monongah and Starkville, you men whose mines are dusty and have not much gas or none at all, but in which there are other means of communicating intense flame, is that a new era of management well besprinkled with plenty of water and a considerable quantity of caution and care of the little things, need not be defined by you wrongfully. Rather we would have you define it as essential precaution. You are doubtless a hustler or you wouldn't long hold your job; you are here and there and everywhere in a day. Doubtless you are fairly well educated, both generally and in mining. You have had all the practical experience necessary to make you proficient and an all-around mining man. You understand the possibilities that exist in all coal dust and gas, singly or individually, but—these things have always caused trouble at the other fellow's mine. You are the last to believe that your plant is prime for such an happening. Had this instinct of precaution been sufficiently developed, explosions would not have occurred. The coal dust accumulations of many years along the miles of roadway would have been thoroughly wetted and loaded out on Sundays and on idle days or nights. A hose would have washed down those trillions of carbon particles from their lodging places along the timber tops and the rib walls. To have obviated the necessity of having to take time to install new fans in event anything did happen, the ventilators would have been so situated that the worst explosion could not have destroyed them nor their operating apparatus. They would have been in operation in 10 or 15 minutes at most after the blow, pumping the fresh air so essential to rescue. Also, being so vital a part of the mine

machinery, they would have received their power direct, and not have been dependent on all kinds of contingencies along the main line of wiring. Had the superintendents been the logical men I assume them to be now, they could readily have convinced themselves and their companies that a few hundred dollars expended along those lines stood every possible chance of saving the companies many many thousands some unlucky day, and, should everything continue to run without accident of the character under discussion, the additional security and smooth-running qualities would amply repay the slight investment. That is logic that never fails to move any "tight wad" holding the purse of a coal or any other corporation and convinces him that each stitch put in the corporate cloth today stands to save nine tomorrow. If it does not, my advice is to hang on to your reasoning and find a new employer. Otherwise he's just as liable to leave you, as well as your men, wishing you had, some day you are knocking about in the mine. And if your own ideas calmly expressed fail to move things in your direction, gather, as your last card, the overwhelming mass of evidence along this line which has appeared in MINES AND MINERALS during the last 10 years; evidence which is as incontrovertible as that the earth is round, that such mines as yours do explode under the certain circumstances which it is your desire to forestall. If he still resists your effort to make the necessary changes it's up to you to make the next move, and meanwhile pity the blindness of some men whom fortune has given more money than brains. I absolutely refuse to believe it is the wilful, deliberate purpose of any mining man to toy with human life, even when it is of the lowest grade of labor. I cannot conceive of a man in his right senses deliberately placing himself before God, even if he manages to hoodwink and escape his state's law, as a predetermined slaughterer of his kind in cool calculation involving only dollars and cents. There is a vast difference between the burglar who is suddenly confronted with the man he is endeavoring to rob, and, fearing the other might shoot first, plugs him with a bit of lead, and the man who sits in a quiet office and does his killing. If the latter is obdurate he is blinded, let us hope, by the nearness of danger. To get a clear perspective of anything one must endeavor for a sufficiently long time to get away from it. And the effort is surely worth while if it removes from your life or from mine the possibilities of a life of regret and self-condemnation that no power on earth can remove from us once it shall be accomplished.

In mining, as in the broader affairs of men, there are more sins of omission than commission, but unfortunately they are just as potent in filling a graveyard and creating widespread poverty among the innocent. The fact that your mine gobs, your roadways, your timbers, like those at Starkville, have been covered with coal dust unremoved for upwards of a generation without incident does not preclude the possibility of it happening this month or next, this year or the year following. Yet that is a very common line of reasoning indulged in by many of us when we wish to delude ourselves in a false belief of safety. A very illogical method, I grant, not to say criminal, yet, again, pitifully commonplace. If you don't believe it after what has happened in the last decade from Mexico to British Columbia, from Pennsylvania to Utah, why you are beyond conviction, and this article is not for your kind.

And in closing let us examine a phase of the methods used at Starkville, not because of any suggestion we can make regarding the Colorado mine, not because of any criticism or condemnation for any of the officials concerned therewith, but because of the possibility that there is still at your mine, amenable to changing before anything really bad comes of it, just such a piece of misjudgment.

It is said the machinery driving the fan drew its power from the same lines as those furnishing power to the haulage motors. Here, in trying to kill two birds with one stone (a bit of economy, by the way, which can, and often does, result in more harm than good about mines) those in charge stood to have the men in the mine go to their death in several ways contingent on several kinds of accident liable at all large mines. Not only was the fan in each instance placed where any unusual force exerted on it from the interior could (and did) demolish it, but they trusted to everything going right along many miles of haulway to keep the ventilation going. A mine fire, small in itself, at any one of a thousand places in those vast ramifications could have been diverted by changing the current while efforts were made to remove the men from the interior, if all went well along the haulways. But, assuming it occurred, as it most likely would, along the main roads, and off went the ventilating power, the air in the mine at once would become stagnant, and the men in the workings perish. But, taking the same instance of possibility, and granting that previously there had been a little trouble and expense to carry the wires from the power house to those fans somewhere above or below ground, if in the latter case it were not along the haulways, or if so, so guarded as to be safe from ordinary short-circuiting and other accidents, and the last thing that could be done to safeguard the men's lives would have been done. Verily, as it was, in a mine of Starkville's character the management played against fate with long odds against them. And while they did not lose by fire, they lost in the other way. Obviously the officials there had not retained in their memories the lesson all learn in boyhood, that if one continues to play with fire sooner or later he is pretty sure to get burned. I'll warrant there's a better arrangement of the ventilating apparatus at the Starkville plant now, and a direct application of power. But why not before? Surely the management saw the possibilities of such an arrangement! Seems so obvious to the onlooker that one would not be surprised to hear of the trappers in a similar case making application to the state inspector for a change in methods or a change in heads, or refusing to work until the pernicious possibilities were removed. Surely men calling themselves superintendents, managers, foremen, or what not, could see these simple stumbling blocks which at any time might trip them, and at one blow undo all they had done in other directions. Surely their mining experience was sufficient to see beyond mere temporary necessity! But was it? Is yours? If they did why didn't they remove the difficulty? Why don't you remove yours?

What happened at Starkville tempts us to the magnanimity of believing they didn't, or this story I have just read of death in that Colorado mine would never have had to be written.

Do we need point the moral?

OUTBURSTS OF CARBON DIOXIDE IN FRENCH MINES

J. Loiret, of Clermond-Ferrand, read a paper before the International Mining Congress at Dusseldorf, on "Sudden Outbursts of Carbon Dioxide in Mines of the Central Plateau of France," and the dangers arising from this gas. Isolated cases had been known since 1856, but during the last 5 years the danger had much increased. The conditions which favored the outbursts were not understood, and outbursts could not be predicted. To guard against them, the use of the pick was forbidden, and blasting should be done by electricity from a safe distance. In a second paper M. Loiret referred to an interesting case in which the provision of a safety chamber, such as is used especially in Austria, in the collieries of the Kaiser Franz Nordbahn, had done good service. The chamber was provided in a cul de sac, which was entered through two doors, fixed about 9 feet apart; between these doors was the end of a special ventilator feed-pipe. It was the rule that the blasting should be directed from this chamber. The men did not observe this precaution, however, and were overtaken by a sudden rush of carbon dioxide. Two men fell down, so that the first door could not be closed; three others died, but five kept themselves alive by breathing the compressed air until they were rescued 10 hours later.

PRINCIPLES OF ELECTRIC BLASTING

By W. G. Hudson, M. D.

In Fig. 1 is shown an ordinary dry-cell battery, with two binding post connectors, *A B*. These are called, respectively, the positive + and negative − poles.

Elementary Electrical Principles as Applied to Electric Blasting

If the poles are connected with a piece of wire *C* an electric current will flow through it from *A* to *B*, and will continue to flow until the chemicals in the battery are exhausted.

The wire forms an unbroken circuit along which the current flows from the negative to the positive pole of the battery The current only flows when the circuit is complete; and a break in the wire stops the flow.

Non-conductors are those substances which do not carry the electric current. Conductors are those substances which carry it readily; poor conductors are those which carry it, but with difficulty. Strictly speaking, there are no perfect non-conductors, and no perfect conductors; but the terms are in common use, and are convenient and unobjectionable if it is borne in mind that they are relative. Metals are the best conductors; silver heads the list, followed in turn by copper, zinc, iron, platinum, lead, mercury, etc. Among the best non-conductors are glass, rubber, sulphur, silk, cotton, paraffin, tar, resinous materials, oils, etc. Water is a representative of poor

Fig. 1

Fig. 2

Fig. 3

conductors, but its conductivity is greatly increased when various salts, such as those likely to be derived from rocks in drilling, are dissolved in it. Acids also increase the conductivity of water.

The wire comprising the circuit can be much longer than shown in Fig. 1—even many miles in length—and still the current will follow it throughout its entire length, so long as some shorter or easier path between the two poles is not offered. If the wire is covered with some insulating material like silk, rubber, or cotton, so as to prevent the current from escaping from it and following some shorter or easier course, then the wire may be wound many times around other objects, or make any number of bends and twists, and still the current will follow it from one pole of the battery to the other, with almost as much ease as it did the short piece of wire.

Now, how is it known that a current is flowing through the wire in the manner described? It is known by its effects, and a few of these, which are of importance in understanding blasting by electricity, will answer for the present consideration.

First, if part of the ordinary thick copper wire used in Fig. 1, be replaced by a very fine piece of wire *G*, Fig. 2, the fine wire being preferably of iron, platinum, or German silver, then the difficulty which the current has in passing through this small piece of wire, or as electricians say "overcoming its resistance," will transform part of the current into heat. The fine wire will become red hot, and even melt if the current is strong. This is the principle made use of in firing electric fuses. Another familiar application is the incandescent electric light, where a fine carbon wire is forced to carry a large amount

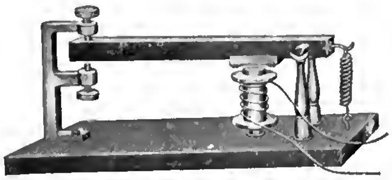

Fig. 4

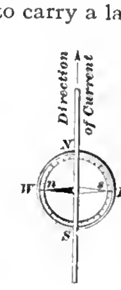

Fig. 5

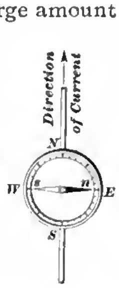

Fig. 6

of current, and becomes so intensely white hot (incandescent) that it gives out light.

Second, if wire insulated with cotton or silk be wound many times around a bar of ordinary soft iron as in Fig. 3, the ends of the wire being connected with a battery so that the current will flow through it, the iron bar will be found to become powerfully magnetic. As soon as the circuit is interrupted* at any point, whether by removing one or both wires from the battery, or breaking or cutting the wire anywhere throughout its length, nearly all the magnetism immediately departs from the iron. As soon as the circuit is closed, the magnetism returns, even though the opening and closing of the circuit is performed many times a second and the point of interruption is in a far distant part of the circuit. If another piece of iron† for the magnet to attract is balanced by a spring over the magnet, every time the circuit is closed it will be drawn toward the magnet, and when the circuit is opened the spring will draw it away. Such a piece of iron provided for the magnet to influence is called an armature. The telegraph sounder, shown in Fig. 4, works on this principle, the armature in its up and down movements causes a lever to strike resonant metal pegs, which give out the familiar "clicks" by the sound of which the operator reads the message. Many other electrical instruments also work on this same principle.

Third, that an electric current is flowing through the wire, *C*, Fig. 1, can be shown by crossing part of the wire over a compass needle, as shown in Fig. 5. Ordinarily, the needle of the compass will point north and south, and the wire above it should run in the same direction. But as soon as the connection with the battery is established the needle will be deflected, so that it will stand at right angles to the wire, or in other words point west and east. If the end of the wire that is connected with the positive pole of the battery be transformed to the negative pole, and vice versa (that is, if the "poles be changed") the needle will reverse its direction, so that the end which pointed east before will now point west.

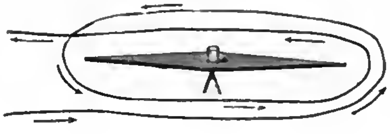

Fig. 7

The needle will also reverse its direction, if the wire be moved from its position above the needle to one below it, as shown in Fig. 6. In other words, the direction of the electric current affects the direction in which the magnetic

* Interrupting or breaking a circuit at any point is referred to by electricians as "opening" the circuit; reestablishing it so that the current can pass as "closing" the circuit.

† Soft iron readily loses nearly all its magnetism as soon as the current stops, and the softer the iron the more readily it becomes demagnetized; although it never loses all of it. Hard steel on the contrary retains a great deal of magnetism once it has been magnetized and on this principle depends a permanent magnet. The magnetism left in an electromagnet after the current has ceased is called "residual magnetism."

needle is deflected; and also deflects it one way when it passes above the needle, and in the opposite way when it passes below it. This fact enables us to greatly intensify the action of the current upon the magnetic needle, by putting a coil of insulated wire about a compass, as shown in Fig. 7. With such an arrangement all the strands of wire above the needle are carrying the current in one direction, and all those below in the opposite direction. They all, therefore, tend to deflect the needle in the same manner, and the effect is very greatly magnified, so much so, that such an instrument indicates the passage of currents that are too feeble to be detected by any other means. It is called a galvanometer.

Practical Magnets.—The electromagnet is much more powerful when, instead of winding the wire on a straight bar, as in Fig. 3, the bar is bent **U** shape, as shown at *A*, Fig. 8. For in this position both ends can be made to act at once upon the same piece of iron, and they can attract it with double, or more than double force. It is also found that the wire in the middle of the electromagnet does not have as much of an effect as that near the ends, and for this reason the wire is not generally wound on the middle part, but only on the ends, as shown at *B*, Fig. 8. Again, it is ordinarily advantageous, from the manufacturing standpoint, to make the iron core of a magnet in sections, afterwards fastening them together, as shown at *C*, Fig. 8. The section, as shown in Fig. 8 *D* at *H* can then be wound with the wire, just like thread is wound on a spool, securing great efficiency as well as ease in manufacture. Fig. 8 *D*, shows the section of a spool *I*.

Such electromagnets, as shown in Fig. 8 at *D*, when of large size and actuated by powerful currents, are of tremendous power, and will lift masses of iron weighing tons.

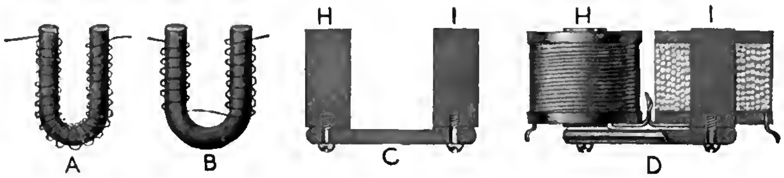

FIG. 8

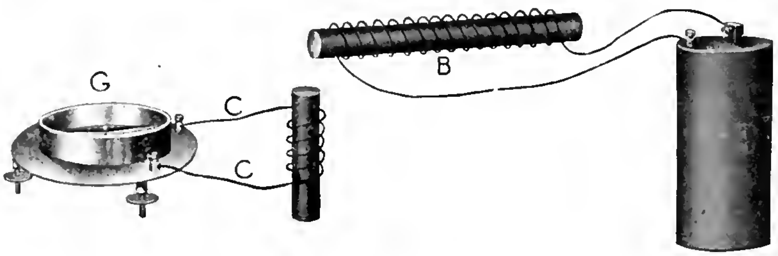

FIG. 9

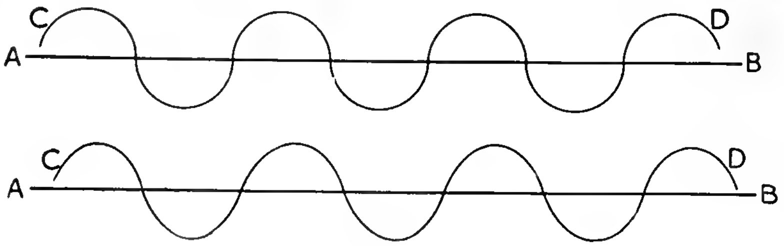

FIG. 10

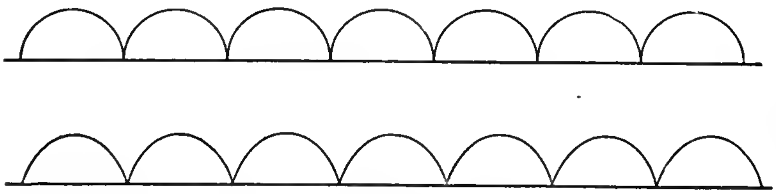

FIG. 11

If a piece of soft iron; i. e., an armature be placed between the poles of a conveniently-shaped magnet, as shown in Fig. 12, the piece of soft iron is also caused to become magnetic. North polarity is induced in the end near, or in contact with, the south pole, and vice versa. If the position of the armature is reversed, so that the end *A* is nearest the south, and *B* nearest the north pole of the magnet, then the armature reverses its polarity, so as to always present its south end to the north end of the controlling ("field") magnet. This it does, even though the reversal of ends is very rapid, such as would result from fixing a shaft into the armature, and rotating it rapidly in the direction shown by the arrows.

It has been shown how passing an electric current through wire wound upon a soft-iron bar is capable of causing it to become magnetic. The reverse of this proposition; namely, the induction of an electric current in the wire about an iron bar by causing the bar to become magnetic, is also true with certain limitations. Take such a bar wound with wire *C*, as in Fig. 9, and connect the ends with a galvanometer, the construction of which has been explained, to ascertain if a current passes. Now cause the end of the bar to approach the live electromagnet *B*. All the time it is approaching *B*, the galvanometer *G* shows that an electric current is passing. When the movement is stopped the current stops.

If the movement be reversed, that is, if the wire-bound bar be moved away from the magnet, the galvanometer will again show that a current is passing, but in the opposite direction.

The reason the current is induced in the wire *C* around the iron bar, is because the iron bar is caused to become magnetic as it approaches the live magnet *B* and loses this induced magnetism as it is withdrawn; and there is a natural law that any change in the magnetic condition of an iron core will induce an electric current in wire around it.

It may be argued that the result is not an electric current, but a series of electric pulsations. That is perfectly true; but if the pulsations are sufficiently frequent, through rapid rotation of the armature shaft, they produce similar enough effects to the steady flow of a battery current to be available for most purposes.

But the currents induced in the armature do more than pulsate. If the ends of the armature wire are connected with a galvanometer, and the armature slowly revolved so that the movements of the needle can be watched, the needle will be found to swing first to the east, then to the west, then east, then west again, changing direction with each half revolution of the armature. If the end of the galvanometer needle should be equipped with a pen, so that it could make a mark on a paper tape moved steadily beneath it by clockwork, the tracing that would be obtained by this experiment would look like Fig. 10.

In this illustration, the straight line *A-B* is the mark the pen would make, if the paper were moved forward with the needle at rest and pointing to zero, or north. The wavy line *C-D* is the mark made by the needle when such a current, continually reversing its direction, is sent through the apparatus. Such a current is called an alternating current.

But it is evident from what has already been said that such an alternating current would not do to energize the field magnet. In order to maintain the constant polarity of the field magnet, the current supplying it with energy must be in one direction, like the battery current—this is called a direct current. The alternating current induced in the armature is, therefore, rectified or changed into a direct current by means of the commutator, Fig. 13.

The commutator consists of a cylinder of hard fiber or rubber, covered with copper, and mounted on the same shaft which drives the armature. The copper is cut lengthwise into two sections A and B, Fig. 13. These are firmly attached to the surface of the hard fiber close together, but not touching; that is, they are insulated from each other by the fiber which carries them. One end of the armature wire is connected with section A, the other with section B.

The current is taken off of the commutator for use by C and D called brushes. Now, as the commutator revolves with

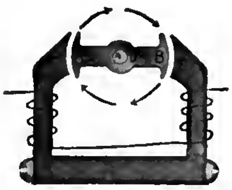

Fig. 12

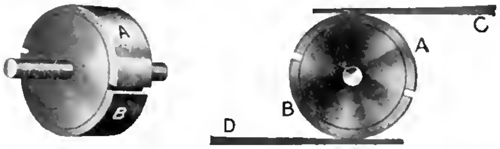

Fig. 13

the shaft, while the brushes remain stationary, the section A is in contact with brush C for half a revolution, then with brush D for the other half. The same thing happens to section B. Therefore, the effect of the commutator is to change the alternating armature current into a direct current, and the tracing which the recording galvanometer will make on the tape, when it receives the current from the dynamo equipped with the commutator, is shown in Fig. 11.

The alternating current would fire electric fuses as well as the direct current; but if it were not converted into a direct current as it is, we would either have to energize the field magnet with a battery, or use a permanent magnet. With the present arrangement, the rectified current is carried from the armature through the wire on the field magnet, which is thus energized by the current from its own armature. At the start, the very slight residual magnetism which is retained by the field magnet is sufficient to set up a feeble current in the armature; this in turn makes the field magnet stronger, and the stronger field magnet develops a stronger current in the armature; thus the machine "builds up," as it is called, until after a few revolutions it is working at its full power. This is noticed when one pushes down the rack bar of a "push-down" blasting machine. The first part of the stroke is easy, but after the armature has made a few revolutions, it pushes quite hard, because the magnet has become strong and pulls back on the armature, tending to resist the effort to turn it.

The dynamo just described, which is used in most American blasting machines, is one of the simplest and earliest forms of dynamo. Those used for generating powerful currents for electric lighting, etc., are more complicated, and more efficient electrically than those made on this simple design; that is, if the blasting machine dynamo were constructed on modern principles, it would take less power for the same output of current, or give greater output with the same amount of power, whichever way one chooses to look at it. But for the purpose to which a blasting machine is put, considerations of simplicity outweigh this kind of efficiency. Blasters would rather exert a little more muscle in operating the blasting machines than pay for the increased cost of repairs to a more modern dynamo, not to mention the increased first cost. Indeed, it is doubtful if a more satisfactory blasting machine could be reasonably asked for than the "push-down" machine, as it is now made. To show how the electrical principles so far explained are applied, the blasting machines shown in Figs. 14 and 15 are to be dissected. The field magnets F are shown enlarged in Fig. 16 by *8* and *9*. They are shown to be wound with insulated wire at each end and fastened in a way to form a **U**-shaped magnet. In both Figs. 14 and 15 is shown the brass end of the armature that revolves between the magnet ends F, but which is better shown by *16* in Fig. 16.

The brushes are shown in Figs. 14 and 15 bearing on the commutator, shown at *15*, Fig. 16. The ends of the armature wire are soldered to their respective commutator sections. In Fig. 16 the rack *1* attached to handle *36* is shown, the remaining numbers being *4* contact spring, *10* and *11* bearings, *81* connecting wire, *3* guide rod, *35* leather strap, *7* guide plate, and *45* shelf. These numbers represent repair parts and are not considered in this article. There is a pinion not shown which is on the armature shaft opposite the commutator, which is made to revolve as the rack is pushed down. This imparts a rotary movement to the armature.

There is one part of the blasting machine which has not yet been taken up, and that is the "shunt," sometimes called the "circuit breaker." This is the brass contrivance *s*, Figs. 14 and 15, placed in the bottom of the box. It is a brass spring which makes contact with the bridge above it at one end when in its normal position. The parts of the spring and bridge which come in contact are covered with platinum so that they will remain bright, and make a good electrical connection.

The function of this shunt is as follows: The spring *s*, Fig. 15, called the "contact spring" *4* is connected in Fig. 16 by means of a piece of heavy copper wire to one of the binding posts surmounted outside on top of the case with a wing-nut, representing one pole of the dynamo; the bridge is connected with the other binding post, representing the other pole of the dynamo, so that when the contact spring is up in contact with the bridge, a short easy circuit called a "shunt," of practically no resistance, is offered for the electric current to pass from one pole to the other—in the language of the electrician, the dynamo is "short-circuited." While the rack bar is being pushed down, the blasting machine is "building up," the current generated passing across the shunt, so that by the time the rack bar is near the bottom of the stroke the dynamo is

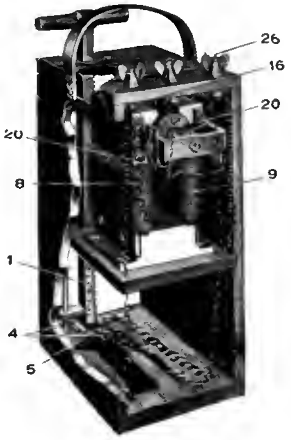

Fig. 14

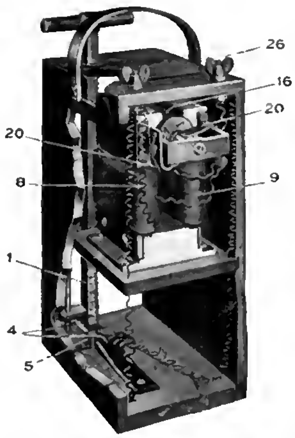

Fig. 15

working at its maximum. When the rack bar strikes the contact spring, however, separating it from the bridge, the short circuit is broken, and the current of the dynamo has now no other way to pass from one pole to the other except by flowing out through the electric fuse circuit, which it does just at the instant when it is at its maximum strength. The little piece of platinum wire within each electric fuse heats up almost instantly, causing them all to fire at practically the same time.

Were it not for the shunt, operating as just described, current from the dynamo would begin to flow through the

electric fuses, so soon as one started to push down the rack bar. It would be a very weak current at first, gradually increasing with the building up of the blasting machine. Such a current is not well adapted to fire a number of electric fuses simultaneously, because it is impossible to make all of exactly the same degree of sensitiveness, and with the gradually increasing current, the more sensitive electric fuses would fire first, breaking the circuit and causing the less sensitive ones to miss. By employing the shunt, on the other hand, no current is sent out from the blasting machine until there is ample power to fire even the least sensitive.

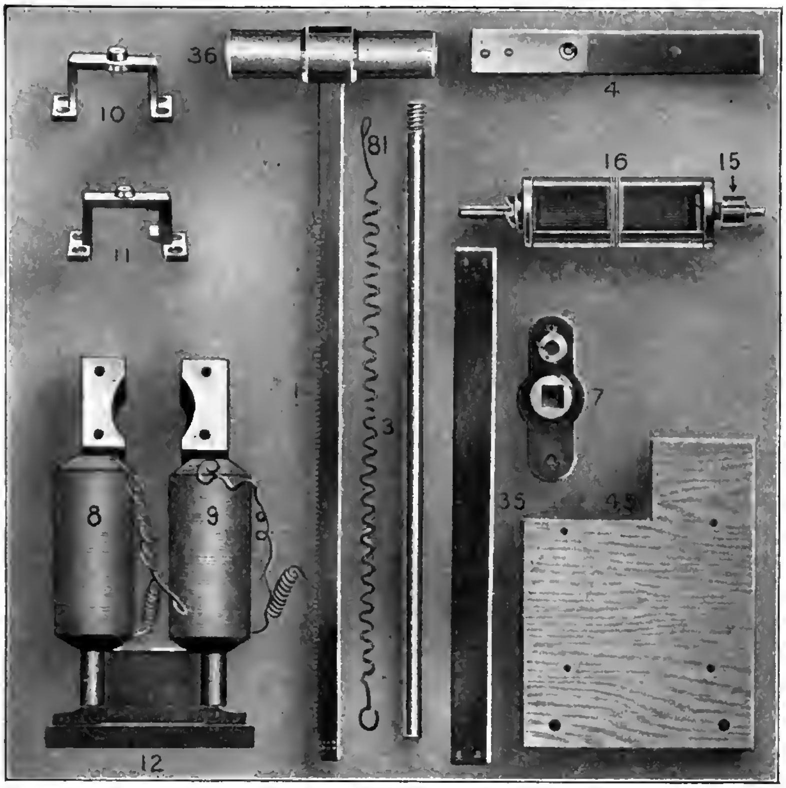

Fig. 16

The three-post blasting machine, Fig. 14, contains an ingenious device for increasing by nearly 50 per cent. the number of electric fuses that the two-post blasting machine would be able to fire. When it is desired to take advantage of the three-post feature of such a blasting machine, the electric fuse circuit is arranged as shown in Fig. 17. Three leading wires are used, which divide the blasting circuit into two separate circuits. The great increase in efficiency is brought about by equipping the contact spring with both an upper and a lower contact, and arranging it so that it will throw the full power of the dynamo first into one circuit and then into the other. While the two circuits do not really fire simultaneously, the interval between them is so extremely short that only one explosion is heard. If it were not very short the wires in one circuit would be broken by flying fragments of rock from those bore holes in which the charges detonated first.

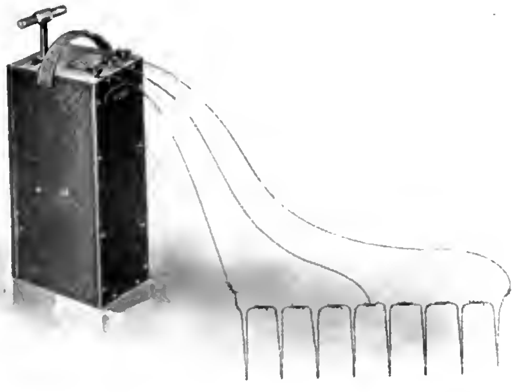

Fig. 17

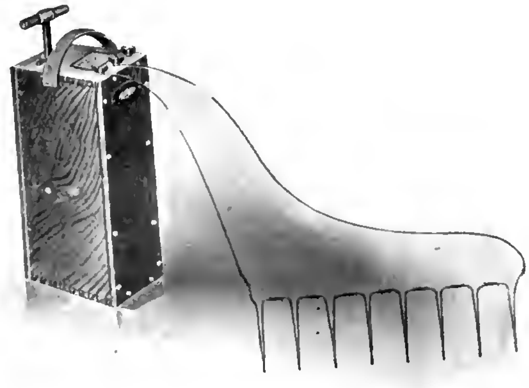

Fig. 18

By connecting to the middle binding post and either one of the outside ones, a three-post blasting machine may be used with two leading wires just like a two-post blasting machine, shown in Fig. 18, whenever the number of electric fuses to be fired does not exceed the capacity of a two-post blasting machine of that particular size. The great advantage in having a three-post blasting machine, is that when difficult conditions arise, which would ordinarily require a larger blasting machine, they can often be met in a very satisfactory manner, merely by laying another wire, and making use of the three-post feature.

⁂

[Eucalyptus trees are said to be quick growing and to thrive in localities and on soil where less hardy trees will not. It has been frequently suggested that these trees be planted in western mining sections where timber suitable for mining is scarce. The following complaint from the Forest Service is intended to correct the misstatements of boomers who are misusing Government reports to give their schemes plausibility.—Editor.]

The Department of Agriculture has been informed that certain of its publications dealing with eucalyptus have been misquoted by several companies interested in selling lands. For instance, Circular 97, of the Forest Service, has been misrepresented as saying that California will in a few years be the only source of hardwood supply in the United States. Such a statement has never been made in any of the Forest Service publications and is not considered a fact.

The Department experts believe that there is promise of considerable success in the cultivation of eucalyptus trees in many parts of California, but estimates of profit and of growth have been attributed to the Department which are unauthorized. There are many uncertainties connected with eucalyptus culture which the investor should take into account. In future any concern which attributes to the Forest Service unauthorized statements may expect the statements to be publicly disavowed.

COMMERCIAL CLASSIFICATION OF FUELS*

Fuels in their natural state may be classed as (1) gaseous, (2) liquid, and (3) solid. Under the third class, coal only will be considered in this paper.

The Qualities Necessary in Fuels According to the Purposes for Which they are to be Used

Coal is technically classified as anthracite, semibituminous, bituminous, and lignite.

In the commercial classification of fuels, coals are known as (1) steam, (2) by-product coking, (3) producer gas, (4) illuminating gas, (5) cement, and (6) domestic.

Steam coal constitutes more than 50 per cent. of all coals mined, and covers a wide range in quality. For steam production all kinds of coal are used, with the following range in analytical values:

Volatile matter, from 15 per cent. to 42 per cent.

Ash, from 4 per cent. to 18 per cent.

Sulphur, from .8 per cent. to 5 per cent.

British thermal units, from 9,000 to 14,800.

Anthracite is not included and will be eliminated from further consideration, as its use is confined principally to the large cities and densely populated districts along the eastern seaboard of the United States, where local conditions determine almost entirely the fuel to be used.

Steam coals may be subdivided into locomotive, steamship, and stationary power plant fuels.

Locomotive fuel is required to meet rapidly the maximum variations in demand for steam, and a coal which will deliver a considerable portion of its total heating value in the shortest possible time is the most satisfactory. This requirement is best met by gas coal, as it will give up about one-third of its total heat within 2 minutes after firing, due to the liberation and combustion of the volatile matter. The remaining fixed carbon maintains a constant temperature by its practically uniform rate of combustion.

That the manner of firing and the condition of the locomotive are the ruling factors in "smoky" or "smokeless" operation of locomotives with gas coal has been proved by some of the leading railroads. In such cases three-quarter gas coal is used with very satisfactory results, and almost smokeless combustion.

To avoid excessive smoke, low-volatile coals of high heating value are often used, but they do not burn as quickly as gas coals, a shortcoming compensated for by the reduction in smoke.

Aside from regions where low-volatile coal is the most available fuel and localities where strict smoke laws prevail, low-volatile coal is used by some railroads on certain passenger runs in order that the quantity of smoke may be more easily kept at a minimum.

While high-ash coal is not especially desirable in locomotive fuel it is used with very satisfactory results, due to the readiness with which the ashes can be removed from the firebox as well as to the increased grate surface with which recent locomotives are provided. For locomotive fuel, sulphur in coal need be given no serious consideration. The belief that locomotive coal must be lumpy or screened is gradually disappearing.

Owing to the strong draft in a locomotive firebox a large proportion of fine coal is objectionable, as considerable of it may be carried through the flues without combustion. The tendency to exaggerate the extent of such loss is due largely to prejudice against any but lumpy coals for locomotive use.

Steamship fuel is required to meet a steady demand for steam, as the boiler load remains practically constant once the vessel is under way. For such service a fuel high in heat units and having a practically uniform rate of delivery of its heat units is best adapted. Low-volatile coals are most desirable for steamship fuel, and nearly all vessels of the trans-Atlantic trade and of the United States navy have adopted such fuel.

Practically the entire tonnage of low-volatile coal reaches the market as run-of-mine, consequently the percentage of small coal is considerably in excess of that in a similar quantity of run-of-mine bituminous coals; but this is not objectionable in steamship operation, because, with the draft much less than in locomotive operation, the loss due to unburned coal is small.

On some freight vessels sailing the Great Lakes mechanical stokers have been installed that use slack of bituminous coals with satisfactory results, as far as can be learned.

The chemical analysis for steamship fuel would be within the range of percentage values given for locomotive fuel—specifications usually requiring ash under 10 per cent., sulphur about 2 per cent. or under, volatile matter approaching the lower limit, and British thermal units near the upper limits. Sulphur content is of no importance, and the requirement of 2 per cent. or under must be met to satisfy the purchaser rather than because of any detrimental effect the sulphur may have on the fuel value of the coal.

The load of large central power stations usually varies greatly, and to meet the peak loads the fuel must generate steam quickly. The advantages of meeting this demand by using a coal which will give up a large portion of its heat units in the least time after firing becomes more apparent as the boiler load and capacity approach an equality.

The selection of coal for large power plants in densely populated districts is influenced by the smoke laws operative in such localities, and to comply with the law low-volatile coals are given preference.

In boiler plants fired by mechanical stokers in the eastern United States, low-volatile run-of-mine coal is used, crushed so that no piece exceeds 3 inches in size.

In the central section the prevailing practice in large plants is stoker-fired boilers, using slack or screenings of bituminous coal. Fuel of this size avoids the necessity of crushing, and, for the greater portion of the time, affords practically smokeless operation. Bituminous slack is capable of meeting sudden changes in load more readily than low-volatile coal, and allows more uniform operation under widely varying plant loads.

Where freight is the larger part of fuel cost, the highest quality of coal is the best investment for the purchaser, as the cost of transporting coals of any quality for the same distance would be identical. For this reason principally, the eastern United States is the great market for the best grades of low-volatile coal. In the central section slack is the cheapest fuel obtainable.

If the use of low-volatile coal is advantageous in large boiler plants equipped with mechanical stokers, the peak loads are usually provided for by having ample boiler capacity. In small power plants with hand firing, the size of coal is considered of importance. In rare instances do such plants have the variations in load commonly found in large power stations. Taking into consideration steam fuels used in the various regions, it is found that they cover the entire range of chemical values, but in some small plants a coal low in ash is desirable on account of furnace-grate arrangement.

Smoke prevention is frequently of much importance. Care in manner of firing and selection of coal will usually permit of operation within the requirements of the smoke laws.

For by-product coking, requirements as to quality are far more strict than for steam coal, the range for sulphur being confined to rather narrow limits. In the by-product process coal is coked in such a manner that the gas, tar, and ammonia are recovered. Gas is sometimes the principal product and the ammonia, tar, and coke are the by-products.

A satisfactory by-product coal must be rich in gas, and meet certain requirements as to quantity of some of its constituent elements, the limits of which are determined largely by

* Abstracted from R. E. Rightmire's paper read at the Wheeling, W. Va., meeting of the West Virginia Mining Institute, December, 1910.

the purposes for which the coke is to be used. This means that gas coals are most desirable for such use. While many low volatile coals will yield a satisfactory coke, their yield of gas is low, and and bituminous coals other than gas coals are unsuited, because they are non-coking and their gas lacks the rich illuminant found in strictly "gas" coals.

Where illuminating gas is the principal feature and the coke is not intended for use in iron manufacture, limits of sulphur are not so closely drawn, although it is difficult to purify gas made from high-sulphur coal. Two per cent. or over of sulphur in coal has been used in such plants, the coke being used for steam and domestic purposes.

For by-product operation in connection with steel plants, sulphur limits in coal are ordinarily placed at 1.50 per cent. as a maximum, with an average value of about 1 per cent. to 1.25 per cent.

The standard range for coal for by-product use is 6 per cent. to 7.50 per cent. ash, which produces a coke ranging from 9 per cent. to 11 per cent. in ash. Ash is objectionable in coke for iron making, as its final appearance is in the form of slag, which requires heat for its production, representing so much loss of heating value and in part explaining why limits have been established.

In general, the range of analytical values for by-product coals would be represented by:

Volatile matter, from 28 per cent. to 38 per cent.

Ash, from 6 per cent. to 7.50 per cent.

Sulphur, from minimum to 1.50 per cent. for coke used for metallurgical purposes. From minimum to 2.50 per cent. for coke not intended for metallurgical purposes.

Fuel for producer gas covers a wide range in values, especially since gas engines are meeting with increased favor as prime movers.

Producer gas found favor by supplying the demand for cheaper fuel, and is used principally for metallurgical and power purposes, although it is applicable for kiln-burning of clay products, lime, cement, and firing steam boilers. The principal use of producer gas is in the manufacture of steel, which requires a coal ranging from a minimum to 1.5 per cent. in sulphur content.

All coals will produce about the same quantity of producer gas, but in metallurgical processes gas coal is preferred, for the reason that its gas burns with a long flame, giving more uniform distribution of heat at high temperature.

Other bituminous coal from which the demand could be supplied, and satisfactory temperatures obtained, have a prohibitive sulphur content. The selection of fuel for producer gas is limited by the use to be made of the gas and the type of producer.

Producers are classified according to their method of operation as, (1) suction, (2) pressure, and (3) down draft.

The suction producer has found application in small plants operated by gas engines, and the fuel has been limited almost exclusively to charcoal, anthracite, and coke, or fuels whose gas is free from tar, which is very objectionable in gas-engine operation.

Pressure producers are operated under a low pressure produced by a blast of steam and air. This is the type generally used for metallurgical purposes where the gas is used direct from the producers and tar is not objectionable.

For gas-engine use the gas is stored and the tar removed before passing to the engine, and lignite, peat, and bituminous coals, as well as charcoal, coke, and anthracite, may be satisfactorily used in this type of producer.

Tests with a pressure producer conducted by the United States Geological Survey at the various government testing plants have shown satisfactory results with fuels ranging widely in analytical values, as follows:

Moisture, 1.40 to 39.60 per cent.; volatile matter, from 9.70 to 42.50 per cent.; fixed carbon, from 23.80 to 73.70 per cent.; ash, from 2.70 to 23.40 per cent.; sulphur, from .30 to 7.40 per cent.

It is reported that bone coal containing 44 per cent. of ash produced a gas affording economical gas-engine operation, and that any coal of commercial value can be successfully used.

Down-draft producers made their appearance after the pressure producers. These fix the tar as a permanent gas, thus making use of all the volatile matter and preparing it for immediate gas-engine use.

Gas producers are utilizing more and more the inferior grades of fuel, and at present are operated with fuels covering the range from anthracite to charcoal and peat.

In illuminating gas manufacture, practically all plants specify a screened coal gas of low sulphur content.

Three-quarter-inch screened coal is specified for several reasons:

1. It can be gasified in less time than run-of-mine coal.
2. It is lower in sulphur than run-of-mine coal.
3. Charging of retorts by hand is readily accomplished.

Low sulphur is required that the gas may be purified to meet the requirements of the law.

The commonly accepted standard of analytical values for illuminating gas coal would be approximately represented by the following: Volatile matter, from 32 to 37 per cent.; ash, from 6 to 8 per cent.; sulphur, not to exceed 1.50 per cent.

The usual standard for yield of gas is an average of 10,000 cubic feet per ton of 2,000 pounds of coal, with an average candle power of 18.

Coal for cement burning is reduced to a powder before being used, hence slack coal is generally used because of its low price and the readiness with which it can be reduced. The essential requirements are that the fuel be: (1) Sufficiently high in volatile combustible matter to insure quick ignition; (2) sufficiently high in heating power.

While the maximum sulphur content of cement is definitely fixed, the sulphur in the coal has not been closely limited, as it does not enter into combination with the cement as long as proper kiln temperatures are maintained. As the impurities of some coals are approximately of the same composition as the cement, no strict limits have been placed on the amount of ash in such coals, but high ash percentages reduce the heating power, and, for this reason only, a low ash content is desired.

Gas coals have been found to give best results in cement burning, as they are high in volatile matter, which has a high heating value with long flame of quick ignition and maximum temperature at a short distance within the kiln.

If coal which ignites slowly is used, ignition takes place too far inside the kiln, giving the zone of maximum temperature at such a distance from the firing end that difficulties are encountered in securing proper clinkering of the cement, besides increasing loss of heat due to the waste gases leaving the kiln at a high temperature. While gas coals are considered the best for cement burning, other high-volatile bituminous coals are used satisfactorily.

Domestic coal must meet consumers' requirements as to size, and is prepared as lump, egg, and nut. Coal firm in structure and suffering the minimum amount of breakage in handling will meet domestic requirements most satisfactorily. It should be non-coking or free burning, so that its heat is given off readily. The ash should be small in quantity and free from clinker.

Export bituminous coal must be in large sizes and of firm, tough structure, that it may reach its destination in large sizes with minimum amount of breakage. This coal is usually passed over 1½-inch screens before shipment from mines.

With the low volatile or semibituminous coals which produce a large amount of fine coal in mining, size of coal for domestic purposes is obtained by screening. For export these coals are usually shipped as run of mine.

In general, the preparation of coal for market by the

removal of slate, bone, and sulphur balls, is of importance to the producer as well as the purchaser. It is of importance to the producer in extending his market by maintaining the reputation of the coal he produces at a high standard, and to the purchaser that he may receive the greatest fuel value for the money expended.

Sulphur balls produce about one-third as much heat in burning as the same weight of coal, and on this basis alone are not so objectionable as other impurities, which have no heating value whatever. They are objectionable on account of difficulty in handling the clinker they produce.

The impurities without heating value go to increase the amount of ash, and represent so much worthless material at the same price and freight rate as the coal. As transportation is usually the greater portion of cost of coal to the consumer, the importance of removing as much free impurities as possible is readily apparent.

The selection of coal to be used for any particular purpose is dependent upon, cost to the consumer, limitations imposed by smoke laws, and fuel value. The fuel value is greatly influenced by the readiness with which clinker is formed from the ash, the greater the freedom from clinker the greater is the recoverable "fuel value."

THE BELLEVUE EXPLOSION, ALBERTA

*Written for Mines and Minerals, by James Ashworth**

On the evening of the 31st of October last, the writer was called on to visit the Bellevue Mine, belonging to the West Canadian Collieries, Ltd., where an explosion had occurred about noon on that day. This mine has been developed by a main gangway driven in on the coal seam from the tipple level. The rooms driven up the pitch of the seam, which is from 60 degrees to vertical, have cross-cuts at various distances between them Before the coal reaches the surface an anticline throws it down to a syncline, from whence it again rises, and thus, by cross-cutting into the mountain above the anticline, the seam is again worked from a surface opening. This part of the seam has a separate ventilating current of air. The coal from this No. 2 working is brought in cars to the top of No. 45 chute, down which it is carried to the main gangway and again loaded into cars and taken by an air locomotive to the tipple. Nos. 81 and 82 chutes are the upcast proper, but there are two other openings through which some air is allowed to escape via No. 45, and one where the mine has caved to the surface. No. 109 is also in course of being driven through the rock cover to the surface. For ventilation there is a Sirocco fan 78 inches diameter by 72 inches wide, driven by an electric motor. This fan furnishes the mine with about 60,000 cubic feet of air per minute at 2-inch water gauge. A short time ago the mine was worked with open lights, but now all the miners use the Wolf double-gauze safety lamp.

Difficulties in Bringing a Large number of Men through a Poisonous Atmosphere

After the miners had quit work on Saturday, the 29th of October, the fan was stopped for about 2 hours, and on the Sunday from about 7:30 A. M. to 4:30 P. M. The explosion occurred at noon on Monday, when no one was in the mine. No effects were apparent at the mine entry, but a door on the fan was blown open without doing any serious damage, and was quickly reinstated. The only people who can be said to have seen the effect of the explosion were a party of electricians who were putting up an electric power line on the surface between the generating station and the upper mine on the mountain (No. 2). These men were scared out of their wits by a loud noise, and the issuing of what they thought was smoke and dust from the caved-in portion of the mine, and also by the same appearance accompanied by more force from No. 81 chute, the upcast, and from No. 45 chute. They at once rushed down to Bellevue and gave the alarm. The effect of the explosion was also felt by a dairyman, whose milk ranch is not far from the position of No. 36 chute. As soon as the officials could be assembled, an examination of the mine was made and a great deal of damage was found inside, chutes, brattices, and timbers being blown out. It was at first thought that there was a fire in one of the chutes but this was not the case and, as the main doors in the gangway were fortunately undamaged, men were sent to the top of No. 45 chute to cover it over so that the force of the ventilation could be concentrated on No. 81. All the outlets to the surface were examined, and the writer came to the conclusion that there was little or no fire underground, and that the disaster was not an explosion of firedamp so much as a huge caving of rock. On examining the mine it was found that there had been a perfect hurricane of "sludge" on the main gangway extending outwards from the neighborhood of 72 chute, and inwards from about the same point. The ends of the loaded cars were thickly coated with about 2 inches deep of sludge, the timbers likewise, and at several points inbye the props were coated on both sides with a conical streak of mud, showing great force inbye and an equal force outbye, caused by the reflex action of the compressed air. No fire was found in the mine, but some coal in No. 82 chute was decidedly warm. Further investigation showed that there had been a very large fall of rock where the pillars were being extracted, in the neighborhood of 71 and 75 chutes. There was no evidence of flame anywhere on the main gangway, which, as previously remarked, was soaking wet.

The damage to the mine was not so great as to seriously interfere with its reopening, and it was just getting back to its normal condition when about 7 P. M., on the 9th of December, the engineer of the power house found both the high- and low-pressure air lines had been broken, whereupon he stopped the high-pressure engines thinking that a joint had blown out. No damage was done to the fan. A horse driver on the surface tramway connecting No. 2 mine with the top of No. 45 chute of No. 1 mine was the first to report that he had seen smoke and dust thrown out of the chute, and was told that he was spinning a yarn. Probably if it had not been for this incident the fact of a disaster having occurred would not have been known in Bellevue sooner than when the few men who escaped alive had reached the mouth of the entry.

The writer believes that it was due to Mr. Brown, of the Hillcrest mines, that phones and wires were put into use to summon the trained men of the district, with the Draeger apparatus from the British Columbian Government station at Hosmer, also from the Crows Nest Pass Coal Co.'s mines at Fernie. All the men who could quickly be collected together were transported to Bellevue by special train from Fernie, calling at Hosmer and Michel. This party was composed of Mr. Strachan, British Columbian Inspector of Mines; Messrs. Wilson, Fuller, and Alderson, of the Hosmer mines; Mr. Norman Fraser, of the C. N. P. C. Co.'s mines at Michel; a miner named Birmingham, who had had experience with the Draeger apparatus in Nova Scotia, Messrs. A. J. Carter and W. Mackie (who had been in the Bellevue Mine the previous afternoon as late as 4:30 to 5 o'clock) and the writer. This party arrived at Bellevue shortly after 2 A. M. Later another train, the "Flyer," was stopped at Bellevue and landed a further contingent of Draeger and other experienced men amongst whom were Mr. Evan Evans, another British Columbia Inspector of Mines, who brought the Half-Hour Draeger outfit from the C. N. P. C. Co.'s Coal Creek mines, and Messrs. Spruston, Matusky, Huby, Mathers, and Musgrove. Later in the day, Mr. Williams, of Lille, and Quigley with others from Hillcrest, rendered assistance, also Messrs. Whiteside, Davidson, and others from Coleman. By the first train in the morning Mr. Shanks, of the C. N. P. C. Co.'s mines, at Coal Creek, arrived with all the company's Draeger apparatus and a band of willing and experienced officials. The

* General Manager Crow's Nest Pass Coal Co., Ltd.

latter apparatus was, however, too late to be of service. Before the arrival of the rescue party 6 men had come out of the mine alive and the bodies of 4 dead men had been recovered. Two of these men had been killed by violence in the neighborhood of No. 54 chute, and two had been suffocated by afterdamp. One man who escaped alive was up in No. 45 chute bucking coal when the disaster occurred. The driver of the air locomotive standing near No. 54 chute was inbye, and before he heard any noise he saw what he thought was a white cloud approaching and he was immediately knocked down by a hurricane of sludge. The loaded cars alongside of which he was passing at the time must have protected him from the direct force, and thus have saved his life.

The first rescue party under Mr. John Powell, the superintendent of the mine, and who had taken charge only 8 days previously, found a few men on the road alive, and also 21 dead all in one bunch arranged around a high-pressure air locomotive charging station, near No. 84 chute. About this time the rescue party arrived on the scene and commenced work. Messrs. Strachan and Alderson first went in with a full 2-hour helmet outfit, but after going inbye about 500 feet had to return, as Alderson said something was wrong with his helmet. On a second try they found a group of men ranged around the inside high-pressure air charging station at No. 124 chute. The problem now was how to bring these men out from No. 124

Surface Plant, Bellevue Mine, B. C.

chute to No. 84 chute, a distance of about 2,000 feet. It was agreed that Strachan should go out and take one man with him by the aid of Alderson's Draeger outfit, and thus Alderson was left inside with the men and without any rescue apparatus. Mr. Strachan then started in again with his 2-hour apparatus and carried another complete apparatus for Alderson. Alderson then put on the apparatus, and Mr. Strachan stripped off his own and put it on another man, whom Mr. Alderson then took out to No. 84. Alderson again started in in his outfit, and carrying another full suit for Mr. Strachan's use, the load was, however, too much for him, and he dropped it on the way. On reaching Mr. Strachan he had his chin valve open and said he thought his potash cartridge was played out and consequently he was himself very exhausted. He then took off his apparatus and remained inside with the men to be rescued, and who were still in good form, having the high-pressure air to keep them alive. Mr. Strachan then put on the apparatus and came out without experiencing any difficulty. This appears to show that Alderson must have hurried in, and made a greater demand on the apparatus for air than it was capable of supplying The Draeger men had in the meantime been sent out of the mine to bring in two sets of half-hour apparatus, and Messrs. Evans and Huby also went out for a further supply of 2-hour oxygen cylinders and potash cartridges. About this time Birmingham had returned with two $\frac{1}{2}$-hour apparatuses, and another Draeger man, Matusky, put on a 2-hour apparatus, and went in carrying a $\frac{1}{2}$-hour apparatus in his hand. When he arrived at the place where the men were grouped together, he was alarmed to find that all of them had collapsed, from some reason that was not apparent to him. One man, the fire boss, was standing, and could just speak, but was incapable of assisting Matusky in putting the $\frac{1}{2}$-hour Draeger apparatus on him. Matusky then left the $\frac{1}{2}$-hour set with the man and hastened out to report the serious state of affairs. A messenger was then despatched to the outside to bring in additional help, and a conference was held to determine what should be done to save the men at No. 124 chute. It was decided to make a dash and pull out the men without waiting for the extra oxygen or for a rope, which had also been sent for. This "forlorn hope" party then formed themselves into a string about 10 feet apart. Mr. Spruston led the way and carefully tested the air as he advanced, and the only gas he detected on his lamp was about a $\frac{3}{8}$ to $\frac{1}{2}$-inch cap of firedamp before he reached the unconscious men. None of this party appear to have perceived the effect of any gas until they commenced to exert themselves, and hence the whole of them were affected at about the same moment. It then became a *sauve qui peut*, some reaching No. 84 chute dizzy and almost unconscious, and others falling by the way. Another messenger then rushed out of the mine and announced that every one of the rescue party was lost, and the Draeger men in particular. Doctor Mackenzie, who formed one of the "forlorn hope," in his eagerness to be of service carried in the pulmotor apparatus, and probably fell at the same time, at No. 114 chute. Messrs. Evans and Huby and others who arrived on the scene about this time were the means of bringing out and reviving by artificial respiration the whole of the men found at No. 124, excepting only Alderson and another man, who were found much later side by side and too late to revive them. The last man to be rescued alive was the doctor, who along with two others was pulled out by men attached to a rope which had been brought in by the fresh band of rescuers. At least 10 men of the "forlorn hope" party were rendered helpless by a mixture of firedamp and carbon monoxide gas. That it was this latter insidious gas which rendered the work of this party so dangerous is clearly proved by the certificate of the doctor, who certified that the two men taken out dead had died from poisoning by this gas.

This experience with the Draeger apparatus is a practical proof of the great danger which is inseparable from attempts to do work which is outside its scope, and such experiences bring out the practical fact, that though it may be of inestimable value as the assistant to old-fashioned methods of life saving, such as the renewal of brattices, doors, stoppings, etc., as the party advances, it does not entitle a large rescue party to run the risk of being cut off by gas driven into the roads behind them through a mistaken notion that the use of the Draeger or other rescue apparatus entitles the rescuers to neglect the plain common-sense precautions of mine-rescue operations.

The public at large, if the editorials in the public press correctly represent their opinions, expect too much from the Draeger apparatus. Thus it it has been stated in connection with the Bellevue disaster that if such apparatus had been immediately available every man would have been gotten out alive. No statement could be more misleading, and this was clearly demonstrated by the disaster which overtook the rescue party, and which cost the life of one brave man, and that of one of the men whom he was attempting to save.

There is a great difference of opinion amongst mine officials as to which size of apparatus is the most useful, and the experience at Bellevue shows most distinctly (in the writer's opinion) that the $\frac{1}{2}$-hour apparatus is far more useful than the 2-hour—in the first place it is lighter; viz., about 14 pounds, as compared with about 42 pounds; secondly, the wearer is not muffled up in a helmet, he is cooler, has the full use of his eyes, and there is no complication arising from a proper fit of the

helmet to his face, and no chin valve to close. It is also quickly adjusted.

The Bellevue case afforded a demonstration of the fact that any of the Draeger apparatus can be used for bringing a man out through a considerable length of poisonous atmosphere, even when he has never seen or used the apparatus previously. That the great weight of the 2-hour apparatus is a serious drawback was exemplified in the case of Alderson, who failed on his second journey to carry in a full outfit in addition to the one he was himself wearing. Another lesson worth noting is that the apparatus ought never to be put on in a vitiated atmosphere excepting in cases of absolute necessity.

The ½-hour apparatus is handier than the 2-hour when a man is renewing stoppings, etc., and most important of all it compels the wearer to keep in closer touch with the main rescue party.

The pulmotor and oxygen trunk are most important adjuncts to a rescue party, and although the former is recommended for use on the surface, the writer would, after the Bellevue experience, recommend that it be taken as near to the rescue party as the state of the air will admit, and that the oxygen trunk be even closer to the active rescuers, and in fact actually part of their outfit. It is just the "stitch in time which saves nine," and the trunk may easily be that one stitch.

In conclusion, the writer would suggest that every one with rescue experience should fully discuss in MINES AND MINERALS the very important points in rescue work which he has to some extent adversely criticised.

VALUE OF ALASKA'S COAL LANDS

In the hearings before the joint committee that investigated the Interior Department and the Forest Service, A. H. Brooks, of the United States Geological Survey, testified that the accessible coal of the best Alaskan fields—the Bering River and Matanuska—was worth half a cent a ton in the ground. To some persons this meant that the coal lands of Alaska had no value whatever, but the value stated by Mr. Brooks is higher than that of most coal lands in the Eastern States, notwithstanding their nearness to lines of transportation and to markets. In fact, good bituminous coal in some well-developed eastern fields has recently sold for one-thirteenth of a cent a ton in the ground.

Priced at the rate given the best Alaska coal lands are worth from $50 to $500 an acre, values far above the average price of bituminous coal lands in the United States.—*United States Geological Survey.*

THREE-WIRE MINE SERVICE

Written for Mines and Minerals, by J. M. Hunt

Method of Reducing Cost for Copper Wire in Mines Operated by 250 Volt Direct Current

Every coal operator when developing a new property which will use electricity for its source of power, is brought face to face with the problem relative to the system best suited to his wants.

This question in the case of the larger operator is taken care of by his consulting engineer, and so will not be discussed in this article, which purports only to suggest a method that may be followed by the smaller operators who are planning development, and to those who already have the 250-volt system and find that the cost of sufficient wire for satisfactory transmission is mounting so high as to become almost prohibitive.

The alternating-current system, with its main generating station and auxiliary substations is, in general, only to be considered for large operations having several openings, with a considerable distance of outside as well as inside transmission.

The 500-volt system is a temptation to most of the smaller operators, owing to the efficiency with which it may be transmitted, but when considering 500 volts one is inclined to go very slow before settling on it as the best, due partly to the fact that there has, in the past, been some agitation in an attempt to outlaw it on account of the danger to life, and partly to the fact that the inside-connected machinery has not proved as durable as has that working on 250 volts, due probably to the moisture generally encountered in mines. So that in most cases the operator has settled on the 250-volt system with its resulting enormous line losses.

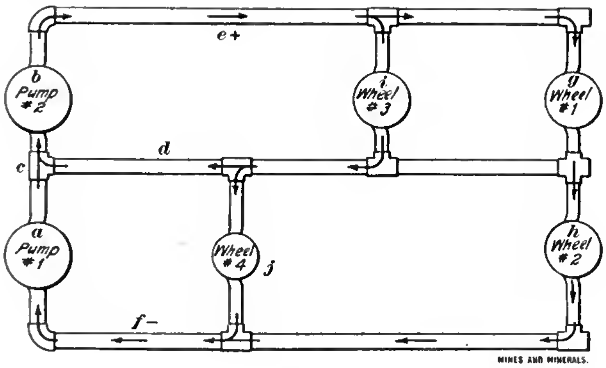

Fig. 1

The Edison three-wire system is in use in West Virginia only to a very limited extent, and that with the special three-wire generator. The writer knows of no such system where the three-wire results are obtained by running two 250-volt generators in series. Is it because it has proved itself to be unsatisfactory? No, for it was long in use before the three-wire generator was developed. In fact the satisfactory operation of two generators in series for lighting plants gave birth to the three-wire generator. Then what is the reason? Is it not that the average operator of small plants has felt that the size of his operation did not justify him in employing an engineer to work out such a small detail as his power equipment? He found that his neighbor's 250-volt plant was giving good results, and rather than get himself mixed up with anything that he had never seen in operation and which sounded so complicated as the Edison three-wire system, he would copy this neighbor.

Now that he has copied him and development has advanced so that he is getting anywhere from 40 to 75 per cent. line loss, and he finds that sufficient copper to cut this down to anything like a legitimate loss will cost him a miniature fortune, he is wondering if he did not make a mistake, and if so, where is the way out.

The writer will endeavor in this article to make the principles of the three-wire system a little plainer than perhaps it has been heretofore, and maybe show the operator that he did not make such a gross mistake as he had before feared.

The action of electricity has often been made more comprehensible to those who are not well posted by comparing it with that of water. It will perhaps serve better here to demonstrate the theory of the three-wire system than any other comparison we could make.

Let two pumps, *a* and *b*, Fig. 1, represent two generators. Assume each pump capable of delivering a 6-inch stream of water, which represents the current, at a pressure of 250 pounds, which would represent the voltage. Then there would be a pressure between the discharge and the suction of one pump amounting to 250 pounds. Should the suction of both pumps be connected to one pipe and the discharge of both to another, there would still be 250 pounds pressure between the discharge and the suction, but a stream equal to two 6-inch pipes. Should, however, the discharge of the pump *a* be connected to the suction of the pump *b* there would be a pressure of 500 pounds between the discharge of *b* and the suction of *a* throwing a 6-inch stream. If a T connection *c* was placed at the point where the two pumps are joined and from this point bring out a third pipe, it would then be connected to the discharge of *a* and the suction of *b*. The pressure between this pipe *d* and the suction of pump *a* would be 250 pounds, and the pressure from the discharge of *b* to this central pipe would be 250 pounds.

Assume that the discharge *e* of the pump *b* is the positive line, and the suction *f* of pump *a* is the negative line of an electric circuit and the central pipe *d* the positive-negative, or neutral.

Suppose that a waterwheel *g* which requires a certain stream of water at a pressure of 250 pounds is connected between the positive pipe and the neutral, the wheel would run, drawing its power from the positive pipe and delivering to the neutral. The circuit being from the discharge of pump *b* through the wheel, back through the neutral pipe to the suction of pump *b*, where the pressure is again raised to 250 pounds, drawing no water from the pump *a*. Should a second waterwheel *h* be installed of equal capacity to *g*, with its intake connected to the neutral pipe *d* directly opposite the discharge of wheel *g*, there would be a circuit from the discharge of pump *b* through wheel *g* to the neutral pipe *d*, thence through wheel *h* to the negative pipe *f* and on to the suction of pump *a*, where the pressure would again be raised to 500 pounds through the two pumps. There would be no current in the neutral, as there could not be a current flowing both ways at the same time in one pipe. Connecting a third wheel *i* of a certain capacity, to the positive and neutral, and a fourth wheel *j* of a smaller capacity and not directly opposite, from the neutral to the negative line, the circuit would then be the same as before for *g* and *h* wheels, but for *i* and *j* wheels would be from the positive through *i* wheel to the neutral, on through the neutral to the opening for the *j* wheel where it would split, only that amount necessary to run *j* would pass through the intake and the wheel to the negative, and so on to pump *a*, the balance passing through the neutral back to the suction of the pump *b*. Wheels could be added at will up to the capacity of the two pumps, and only that amount would pass through the neutral pipe which was in excess of the amount used by one of the outside pipes over the other, the direction of flow depending on which carried the heaviest connected load. The result on the pumps being that the pump which was connected to this pipe would be carrying the heaviest load. To get the full benefit then of the 500 pounds, it is necessary to see that the two outside lines are practically balanced and as little as possible returning through the neutral.

The action of electricity to all practical purposes is the same as that of water, as described above.

To see what will be gained by a change to the three-wire system, start with the following formula for determining the amount of copper necessary for the transmission of electric current:

$$\text{Circular mils} = \frac{\text{Dist. in feet} \times \text{Watts} \times 21.60}{\text{per cent. loss} \times \text{voltage squared}}$$

Then since in any given problem the distance is a constant, the load is a constant, 21.60 is a constant, and the desired loss is a constant. Circular mils $= \frac{\text{a constant}}{\text{voltage squared}}$. In the case of 500 volts and 250 volts the ratio would be

$$\frac{\text{a constant}}{\text{500 squared}} \div \frac{\text{a constant}}{\text{250 squared}} = \frac{1}{4},$$

or 500 volts requires wire only one-quarter the size that is required by 250 volts to transmit a given power a given distance with a given line loss.

Two 250-volt generators running in series develop 500 volts across the outside wires, with 250 volts from either to the neutral. Therefore, the size of the wire required for a 250–500-volt three-wire system, working under perfect conditions, need be only one-quarter the size required for a 250-volt system simple, and equal to that used in a 500-volt simple. But as most 500-volt and 250-volt systems are operated with a rail return, and the three-wire system must have a copper return, the length of the wire will be double that required for the ground return. The weight of the copper will therefore be one-half that required for the 250-volt system and double that required for the 500-volt system simple.

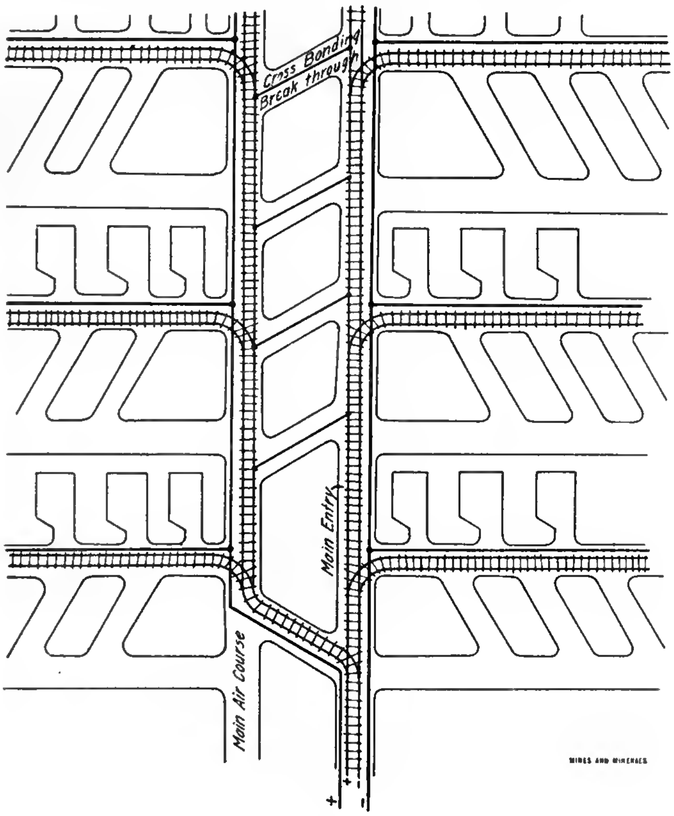

FIG. 2

It should be understood, however, that the necessity for bonding the rail is not done away with, as the rail serves as the neutral wire between the two generators.

In Fig. 2 is shown a sketch of the general plan for wiring a mine with this system. Details, of course, must be worked out on the ground as conditions demand. These would differ considerably in mines operating only a few mining machines and two or three locomotives, from those operating several mining machines and locomotives. In the smaller mines it could not be reasonably expected that the working in alternate cross-entries off the air-course, nor off the main entry, would be done at the same time, thus giving a fairly well-balanced load. The chances would, however, be good that the workings off the main air-course would equal those off the main entry, or very nearly.

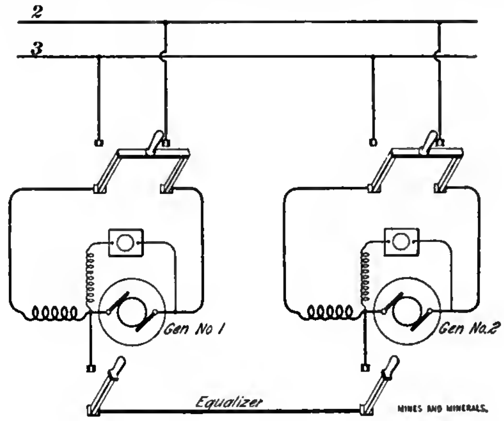

FIG. 3

Therefore, in order to balance the load, which is necessary to get the full benefit of the 500 volts, the one wire should be brought out the main air-course feeding the cross-entries off of it, while the other should be hung in the main entry, taking care of the workings off of it, with the air-course track bonded to the main entry track at each breakthrough. As there is a wire necessary in these entries with the 250-volt system, nothing need be added for the change, except the cross-bonding in the breakthroughs, sectional insulators at each point where the main-entry line is connected to the air-course line, and a different connection in the power plant.

In the larger mines, where the chances are that alternate entries would be worked together, both positive and negative wires should be strung in the air-course and the main entry, and probably in the more important cross-entries, depending of course on the amount of power required, taps being taken from the positive and negative wires, respectively, to feed alternate cross-entries, bonding the track at every available point.

It could not be claimed that under mine conditions the full advantage of the 500-volt transmission could be gained, but the

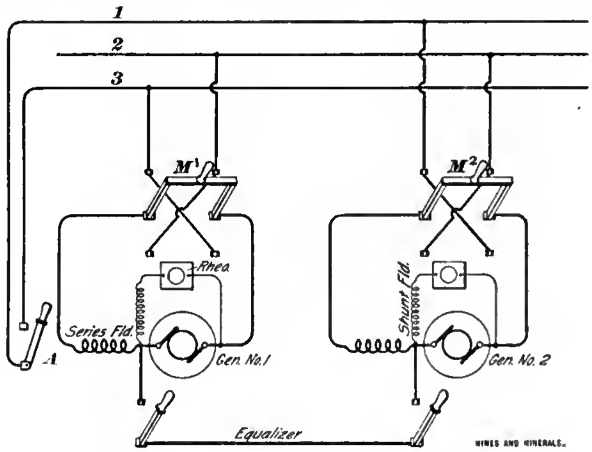

FIG. 4

fact remains that under no conditions could the line loss exceed that of the 250-volts simple, and it could under more or less favorable conditions be made to approach that of the 500-volt system, or one-quarter that of the 250-volt system, with no more danger to life and no change in the connected machinery.

The changes that would be necessary in the power plant would not be extensive, and after once made could be changed

at any time to the old system by simply throwing a switch, in case the system proved unsatisfactory.

Fig. 3 shows a sketch of a standard double-pole switchboard for a 250-volt plant? Comparing this with Fig. 4, which would be the connection for a three-wire board, it will be seen that all that would be necessary to make the change, would be another set of terminals for each switch, thus making double-pole double-throw switches, the cross-connections between the dead terminals, one extra bus-bar and connections to switches, and the short-circuiting switch between the positive and negative bus-bars. With this connection, by throwing in switch A, one generator switch, and leaving the other out, either machine can be made to feed both lines, giving 250 volts simple, and allow for the overhaulage of the other machine. With switch A still in, the equalizer switches in, M^1 up and M^2 up, the two machines may be run in parallel, giving 250 volts simple. With switch A out, the equalizer switches out, M^1 up and M^2 down, or vice versa, the two machines will run in parallel, giving the three-wire 250–500-volt results. With double-throw feeder switches any line may be connected to either bus-bar to equalize the load.

Going farther, should there be three generators in the power plant, two could be run in parallel with the third in series with these two. In which case that line to which both generators were connected should feed all outside machinery and that inside machinery which is close to the generating station, as that part of the load that is out of balance comes back on the neutral wire with a line loss equal to the 250-volt system, for which reason load enough to take care of the third generator should be connected as close as possible, as from the formula it will be seen that the line loss is directly proportional to the distance of transmission.

COAL MINING NOTES

The No. 2 colliery of the Kingston Coal Co., at Kingston, Pa., during the year 1910, mined and shipped 1,020,405.14 tons. This being the first instance in the history of the anthracite region for one breaker to prepare for shipment over 1,000,000 tons. The total shipment of the Kingston Coal Co. for 1910, was 2,131,672.07 tons.

Announcement was made that the holding company of the railroad anthracite producers, known as the Temple Coal and Iron Co., would be dissolved by court order. This seems to be premature as the company will await dissolution until a decision is rendered by the Supreme Court on appeal.

In the January issue of Mines and Minerals it was stated that the United States Department of Justice contended that the "Contract labor law" of Alabama was unconstitutional, even though the Alabama court decided differently. The United States Supreme Court has decided that the law was unconstitutional, and thus wipes out Alabama's, Kentucky's, and Tennessee's legalized grafting, so far as mining is concerned.

What can be said of a coal mine operated under the following conditions; the word system not being permissible? The rooms are driven in pairs with 100-foot pillars between each pair. The pillars between the rooms are drawn "as far as possible" by slabbing as soon as the limit is reached. Sometimes a foot is removed in this way and sometimes nothing. No attempt at all is made to recover the 100-foot pillars and the entry is abandoned when driven "far enough." Perhaps 25 per cent. of the coal in the ground is recovered and perhaps not, but who cares. It is "cheap, government" land of which we have an "inexhaustible supply." Also as there are some 91,000,000 stockholders in the corporation owning the land, the United States Government, who is going to stand up for their rights?

The coroner's verdict in the inquest which sat upon the accident of November 8, at Delagua, Colo., has been rendered and comes as something of a surprise. The jury says that "at the time of the explosion, the mine contained no coal dust of a dangerous character, and such as did exist had been thoroughly sprinkled 2 days before the explosion." How can non-existent dust be sprinkled, or is this to be taken to mean that at one time there was no dust in the mine, or that there was coal dust but it was not dangerous? However, the jury fully exonerated the company from all blame, and in this we believe they acted rightly when all the facts in the case are considered.

In Northern Colorado, where the lignite coal not infrequently carries as high as 20 per cent. of moisture and from 10 to 20 per cent. of ash, "gob fires" are of universal occurrence. In the southeastern part of the state, where the bituminous coal averages some 2 per cent. in moisture and 8 per cent. in ash, gob fires are practically unknown. In both fields the sulphur is well under 1 per cent. No satisfactory theory has been presented to account for the prevalence of fires in the one field and not in the other. A solution of this problem would be of interest.

S. K. Smith writes an interesting article for the *Black Diamond*, in which he concludes that there are from three to four times too many mines in actual operation. Mr. Beebe indorses Mr. Smith's conclusions but cannot agree with his deductions as to the natural remedy. If, he says, big companies were more uniformly profitable or satisfactory, and if consolidations reduced the cost of doing business, or even tended toward the solution of the economic problem involved, he might agree with consolidation of mines as a panacea.

The Interstate Commerce Commission has rendered a decision in the case of the Anaconda Mining Co., of Montana, against the Erie and other eastern roads in which discrimination was charged in maintaining two rates on coke from the ovens in West Virginia and Pennsylvania to Chicago. These rates are $2.65 per net ton "on coke," and $2.35 per net ton "on coke for use in blast furnaces for smelting iron from ores." The commission holds "the rate of $2.65 per net ton applying on coke was, and is, a low rate for the services performed, and that maintenance of a lower rate on coke for use in blast furnaces for smelting iron from the ores, while improper, did not subject the complainants to undue discrimination and is not the basis for awards of damages in these cases." The decision continues that "smelters of copper and iron do not compete in any proper or ordinary sense of the term, and the complainants have suffered no damage."

In consequence, the smelters of the Northern Rocky Mountain region will be compelled to pay 30 cents above the minimum rate for their coke or adopt the local product. The justice of this decision can hardly be questioned if coke destined for points beyond Chicago is, as is ordinarily the case, loaded in box cars, while that intended for use in the blast furnaces in and around Chicago is loaded in open-topped "racks." The proportion of live to dead load is so much greater when racks are used that the railroads can well afford to make a lower rate. Likewise there is usually a return load of iron ore immediately available for the "racks" which can be dropped at Pittsburg, only 75 miles from the Connellsville region, whereas the "boxes" may have to be hauled "light" several hundred miles from the smelter before a return load is obtainable. All these factors of live weight, return load and the like enter into rate making. On the other hand, for coke loaded in the same class or type of car we cannot see but what the rates should be the same. Eastern shippers of coal have been familiar for many years with the three rates on "gas coal for steam purposes," "gas coal for use in gas works," "and gas coal intended for points beyond the Capes," that is, for export.

Shell cameos, onyx, agate, and other semiprecious stones, cut, but not set, and suitable to be made into jewelry, are dutiable under paragraph 435, tariff act of 1897, as precious stones, cut.

EQUALIZATION OF FUELS*

H. K. Meyers

At the present there is much discussion on the question of purchasing coal on analysis and it has met with a large amount of objection on the part of the shipper, principally for the reason that he has been severely penalized.

Methods for Determining the Comparative Values of Fuels of Various Analyses

In general, the only equity in the specifications in the past has been in the number of British thermal units furnished. The other penalties have been arbitary and fail to provide for premiums in the event of supplying coal of a higher grade than agreed.

Most every producer of coal desires an analysis which shows up well on paper, regardless of its truthfulness, and until such time as the operator is willing to accept a general average of analyses as the standard, he is apt to be penalized when he sells on what might be termed the modern basis of purchasing fuel. When the producer learns the heat value of his coal thoroughly, there is no reason why he cannot dispose of his output more advantageously and satisfactorily.

Practically all raw products except coal are sold at a price based on the intrinsic value of their constituent parts.

Gold, silver, copper, lead, zinc, and iron ores bring a price in the market based on their metallic content, and are subject to penalties for impurities and deleterious matter associated with them beyond a fixed percentage.

The basis of settlement is their actual marketable wealth and there is no reason why coal should not be sold on the same basis.

After the various ores are delivered and settlement made, based on analyses, the responsibility of the shipper ceases; but if the purchaser sees fit to operate his smelter so that a large amount of valuable metal goes into the slag, it is of no consequence to the shipper. In order that the smelter may receive the maximum returns from the ores bought, he must have the proper apparatus suitable for the purpose, and in the event of having a fixed inflexible smelting plant, one in which a variety of ores cannot be used satisfactorily, he must confine his purchases to ores suited to his methods. If he purchased ores without a special analyses and looked only to the value of the resulting product, he would place the blame on the grade of ore furnished regardless of bis inefficient help and methods.

This would be an impossible condition in purchasing ores, yet it is practically the condition existing today in the sale of coal.

Probably 95 per cent. of the coal sold at the present time is not analyzed. The variety of boilers and fireboxes under and in which the coal is burned is many times the variety of smelters, and the persons doing the firing are not all gifted with brains.

When the boiler fails to produce steam satisfactorily or the engine fails to do the work required, the trouble is blamed on the fuel. From the complaints registered, one would think that the coal in a mine has a wide range of heating value, although it really is quite constant.

When troubles of the above nature arise, the purchaser immediately demands an adjustment, which is invariably allowed because the producer does not know his product sufficiently well to confirm its value.

Had this fuel been sold on a guaranteed analysis, such objections would not arise, for the analytical determination of the chemist (from whose rulings there is recourse through check analyses) would at once locate the cause. Under the new method it is as important for the purchaser to know the fire and engine-room conditions as for the operator to know the analysis of the coal he is shipping.

There is no doubt but that the purchaser of coal is entitled to the delivery of a certain amount of heat-producing substance per ton, and since the range of calorific powers of the various coals is wide, there should be some general equitable method of equalizing them. The purchaser is interested in obtaining the maximum of energy at the minimum of cost.

Where coal is purchased on analysis, it is customary to base settlements on dry coal; but this is erroneous, because some coals that are high in moisture in their natural state, when dried will compare well with their low moisture competitors. The purchaser of such coals must burn a certain amount of real fuel in evaporating this excess moisture.

The only equitable way of comparing a variety of fuels is by using the analyses obtained at the point of consumption or where they might be termed "commercial coals."

The ideal fuel would be one without moisture, ash or sulphur, and in making the following calculations, all fuels are figured back to the ideal, charging up to the fuel under consideration, the actual cost of the contained impurities.

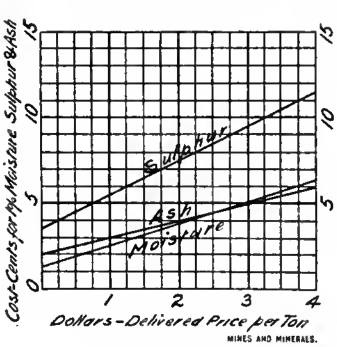

FIG. 1

In making the basic calculations, it was considered that the handling of the ash was an item of expense in addition to its cost, that a certain quantity of water had a first cost and that it required fuel to drive it off, that the sulphur in forming clinker picked up its equivalent in weight of good fuel although it was figured that one-half of its weight was volatile. The item of reduced output due to firing boilers with the impurities was not considered.

With the above conditions, the chart, Fig. 1, was calculated and can be used for comparison of coals, oil, gas, etc. In applying this chart, the delivered price should be used and probably the better method would be to determine the cost per million of British thermal units.

COST IN CENTS, FOR 1 PER CENT. MOISTURE, SULPHUR, AND ASH—VARIOUS PRICED COAL

	Delivered price per ton, in dollars	1.00	2.00	3.00	4.00	Remarks
Moisture	First cost	1.00	2.00	3.00	4.00	1% fuel evaporates 4% water
	Fuel for evaporation	.25	.50	.75	1.00	
	Firing	1.25	1.25	1.25	1.25	
	Total	2.50	3.75	5.00	6.25	
Sulphur	First cost	1.00	2.00	3.00	4.00	1%S. wastes 1% coal ½ S. is volatile
	Fuel wasted	1.00	2.00	3.00	4.00	
	Firing	2.00	2.00	2.00	2.00	
	Removing ash	1.50	1.50	1.50	1.50	
	Total	5.50	7.50	9.50	11.50	
Ash	First cost	1.00	2.00	3.00	4.00	Firing coal, $1 per ton. Removing ash, $1 per ton of ash
	Firing	1.00	1.00	1.00	1.00	
	Removing ash	1.00	1.00	1.00	1.00	
	Total	3.00	4.00	5.00	6.00	

In making comparisons, there must be added to the quoted price delivered the various cash values which the impurities represent, based on the price quoted.

The resulting sums for each coal considered must be divided by the number of British thermal units per ton, guaranteed and expressed in millions and decimals thereof.

The various quotients show the cost per million British thermal units and the lowest. everything considered, would be the one to purchase.

Suppose, for example, a coal whose proximate analysis gave the following: Moisture, 1.5 per cent.; ash, 6 per cent.; sulphur 1 per cent.

* Read before the Winter Meeting of the Coal Mining Institute of America.

Guaranteed British thermal units 14,000 per pound of commercial coal and the delivered price $3 per ton net.

From the chart are obtained the cost of the impurities in cents per ton:

	Cents
1.5 per cent. moisture	7.5
6.0 per cent. ash	30.0
1.0 per cent. sulphur	9.5
Total	47.0

If to this is added the quoted price per ton, the equalized price $3.47 is obtained, and since the coal was guaranteed to contain 14,000 British thermal units per pound, one net ton would contain $2,000 \times 14,000$, or 28,000,000 British thermal units and the cost per million British thermal units would be $\frac{1}{28}$ of $3.47, or 12.4 cents.

In the event the shipper guarantees the above analysis and upon delivery it is found that the coal contains 2 per cent. moisture, 7 per cent. ash, and 1.5 per cent. sulphur, it is only necessary to compute by the same method the equalized price and determine the cost per million British thermal units, the difference being a penalty.

This same chart gives the new equalized price of $3.59 and since the coal contained only 13,500 British thermal units per pound or 27,000,000 per ton, the actual cost per million would be $\frac{1}{27}$ of $3.59, or 13.3 cents.

This is in excess of the agreed price, the difference between 12.4 cents and 13.3 cents, or .9 cent per million British thermal units, the penalty.

Since the coal delivered contained a total of 27,000,000 British thermal units per ton the penalty would be .9 cent $\times 27 = 24.3$ cents per ton and the settlement price would be $2.757. The 24.3 cents penalty would have appeared as a premium if the various percentages of impurities had been less than the guaranteed analysis by the same amounts.

It might seem that this penalty is heavy; however, a glance shows that the total impurities are 2 per cent. in excess and the heat units 3½ per cent. less than the amount guaranteed, making a total of 5.5 per cent. that represents a first cost of 16.5 cents without taking into consideration the extra cost of handling the impurities and the resulting ash. This deduction is not extravagant. It will be observed that the method advocated places every coal on its exact level and shows its comparative intrinsic value.

At equal prices per ton, the operator having the best coal had, and always will have, a decided advantage, but if he is sure that his high-grade fuel is going to be recognized (and it must be in the event of purchasing being done by analysis), he will strive to obtain the maximum price through proper preparation for market. Some operators claim that it will increase the cost of fuel to the consumer, but this is not a logical conclusion although it will be the means of increasing the price per ton of the high-grade coals.

Such a method really makes actual fuel have a constant price and the consumer has ample protection in buying, but he has no recourse for troubles due to inefficiency of plant, as is too often the case under present conditions.

By using this method, after the contract is given, a chart can be constructed based on the actual contract price from which can be readily determined the penalties and premiums.

Every operator should thoroughly sample his mine and his shipments and then make his bid in accordance with the average analyses, and if allotted the contract he will doubtless find that the results are more satisfactory than under present prevailing methods.

Several years ago, the writer sampled a mine and a contract was based thereon. Over 100,000 tons of coal was shipped on this contract covering a period of 12 months and at the end the premiums and penalties practically balanced. At times there may be differences either way, possibly due to climatic changes, but they will offset each other.

In the acceptance of bids, the purchaser should note the various guarantees, and in the event of a bidder showing no general knowledge of the fuel offered he should discard his quotation and save future trouble.

Fuels of widely different natures may show the same calorific intensity and yet they are not equally valuable to the purchaser. Boiler conditions may be such that there is a maximum grate area which requires low-volatile coal whereas with small grate area, high-volatile coal must be used in order that maximum economy may be obtained.

In the New England States, they have been burning Cumberland coal many years, and one will find large grate areas under all the boilers. If they were to purchase Pittsburg coal there would be no trouble with the steaming, but the quantity consumed would be extravagantly large.

If the method described was to be used in some of the western markets where their fuels carry a large percentage of moisture, it would be found that a consumer could frequently afford to pay a higher freight rate on a low moisture and otherwise superior fuel.

The probability is that most of the fault found with coal comes from the fire room. It is much easier for the fireman to blame the fuel than to clean his boiler.

If the coal is sold on analysis, this series of troubles is sidetracked and there is no responsibility placed on the shipper, real or imaginary, after delivery has been made.

OIL OPERATIONS IN TAMPICO

By Consul Clarence A. Miller, Tampico

During the last few years the vicinity of Tampico, Mexico, has been explored with the result that the gulf coast of Mexico has possibilities of becoming an oil field. Several oil companies, including the largest and most powerful, have been engaged in the work of exploring and developing.

Until recently the only success obtained in the immediate vicinity of Tampico was that of the Mexican Petroleum and Development Co. in what is known as the Ebano field, about 35 miles from Tampico. The Pearson interests developed some wells in the Veracruz district, and had some little success in the Tuxpam region. During the last few months the Huasteca Oil Co. met with some success in the Juan Casianos field, and recently the Mexican Fuel Oil Co. brought in a well at Topila. During July, 1910, the East Coast Oil Co., representing the Harriman interests, were successful with a well at Topila and another at Panuco.

The companies operating in this section are: The Mexican Petroleum Co. of California; the Huasteca Petroleum Co., owned by the Doheny interests, and an allied company of the Mexican Petroleum Co. of California; the East Coast Oil Co., which has as yet no corporate existence, but which represents the Southern Pacific or Harriman interests; the Mexican Fuel Co., a Waters-Pierce Oil Co. concern; the Mexican Fuel Oil Co., incorporated under the laws of West Virginia; the Dos Banderos Oil and Gas Co., an Arizona corporation; the American International Fuel and Petroleum Co., which was organized under Delaware statutes; a California corporation, the Tampico Petroleum Co.; the Standard Oil Co. of Mexico, with home offices in London; the Standard Oil Co. of England, with the same official personnel as the preceding company; the Hidalgo Petroleum Co., composed of California parties; the Tampico Oil Co., Ltd., an English organization. The operations of S. Pearsons Sons & Co. have been very extensive.

The Electra Petroleum Co. is being formed, under English law, to develop leased land near Juan Casianos. A company is organizing in California for work on a hacienda 20 miles up the Panuco River from Tampico, and a Salt Lake City company, which has a fruit farm near Caracol, has oil-drilling machinery on the way for sinking a well about 15 miles from Tampico.

Trade Notices

The Western Electric Co. has now disposed of the greater part of its Chicago surplus real estate, which consisted of its Polk Street and Clinton Street properties. Nearly $4,000,000 which was received for the property will be added to its already large working capital and will render financing unnecessary in 1911. Recently the company appropriated $1,000,000 for new buildings at Hawthorne, and doubtless before the present lease expires on the 500,000 square feet of the Clinton Street property which the company still occupies, it will be necessary to erect further new buildings at Hawthorne to carry out the policy of concentration now in effect. Western Electric is employing 24,000 men.—*Wall Street Journal.*

The Jeffrey Mfg. Co., of Columbus, Ohio, whose manufactured articles originally consisted of elevating and conveying machinery, have during their present period of activity added this, that, and the other thing, to their line until a coal mine can be completely equipped from their plant.

Owing to the greatly increased business, the H. W. Johns-Manville Co. announces the removal of its offices, now located at 85 Shelden Street, Houghton, Mich., to more commodious and convenient quarters at 96 Shelden Street, where they will be better prepared to serve their patrons. As in the past, Mr. S. T. Harris, who has been associated with the company for a number of years, will be in charge of the offices at the new address.

B. F. Sturtevant Co., Hyde Park, Mass., has issued bulletin 187 "Economical Fire Room Methods," by F. R. Low, in which the value of the Sturtevant economizer is shown by the tests made at Wood Worsted Mills, Lawrence, Mass. The tests were conducted by A. D. Little and E. G. Bailey, of Boston, Mass.

The Western Electric Co. has just issued bulletin No. 1,116, describing magneto-telephone sets and accessories. This bulletin has been compiled for the purpose of bringing to the attention of telephone companies and telephone users in general the features of Western Electric standard magneto wall and desk sets, together with accessories. It contains 40 pages and is excellently illustrated.

A new booklet "Graphite Products for the Railroads," has just been issued by the Joseph Dixon Crucible Co., of Jersey City, N. J. This, as its name implies, covers the Dixon line of products that are widely used in railroad service.

The Jeffrey Mfg. Co. has opened a new office in the Fourth National Bank Building, Atlanta, Ga., with D. C. Rose, formerly with the Dodge Mfg. Co., as manager. A stock of Jeffrey chains and catalogs will be on hand. This is the tenth Jeffrey branch office in the United States, although there are over 100 Jeffrey agencies in the United States, as well as in the leading commercial centers of the world.

The engineering firm of Dodge, Day & Zimmermann, of Philadelphia, Pa., have added to their organization Walter Loring Webb and James M. Kennedy. Both gentlemen are well known in the engineering world. Mr. Webb is the author of several engineering textbooks, including "The American Civil Engineers' Pocket Book," "Economies of Railroad Construction" and "Problems in the Use and Adjustment of Engineering Instruments."

The Dorr Cyanide Machinery Co. has supplied the Pennsylvania Steel Co. with six classifiers to be used for dewatering magnetic concentrates from the wet-concentration process. This is of interest as showing the additional uses being found for the machine.

The Westinghouse Co. has electrified the Ernestine Mining Co., located about 100 miles from Silver City, N. Mex. Prior to 1905 two companies failed with enormous financial loss in their efforts to operate these mines, although now it is one of the best individual properties in the state.

The Link-Belt Co. is constructing a large washery for the Berwind-White Co., at Berwind, W. Va.

Edgar Allen & Co., Ltd., Imperial Steel Works, Sheffield, England, whose chief American office and warehouse is at 434 West Randolph Street, Chicago, announce that agency arrangements have just been completed with Roehm & Davison, Detroit, Mich.; J. L. Osgood, Erie County Bank Building, Buffalo, N. Y.; John J. Greer & Co., Inc., 207 West Pratt Street, Baltimore, Md., and that stocks of Allen's high-speed and carbon tool steels will be carried at the warehouses of these firms.

COAL MINING INSTITUTE OF AMERICA

The winter meeting of the Coal Mining Institute of America was held in Pittsburg, Pa., December 15 and 16, 1910. According to the secretary, the membership has increased 167 during the half year just closed.

President H. H. Stoek, of the University of Illinois, found it impossible to attend, his address and letter of greeting being read by the secretary. President Stoek also indicated a desire to retire from the office, and at the election which was held during the opening session, Samuel A. Taylor, of Pittsburg, was chosen for the position. The other officers elected were as follows: Vice-Presidents, A. W. Calloway, Punxsutawney, Pa.; J. W. Paul, Pittsburg, Pa., and Elias Phillips, DuBois, Pa.; Secretary-Treasurer, C. L. Fay, Wilkes-Barre, Pa.; Editor of Proceedings, W. E. Fohl, Pittsburg, Pa.; Executive Committee, F. W. Cunningham, Charleroi, Pa.; J. B. Hanford, Morgantown, W. Va.; H. H. Stoek, Urbana, Ill.; Austin King, Scottdale, Pa.

The papers presented were as follows: A Standard Shaft Bottom with Especial Reference to Safety and Economy in a Gaseous Mine, by W. E. Fohl, Pittsburg, Pa.; Mine Fires, by A. G. Morse, Pittsburg, Pa.; Recent Developments in Anthracite Mining Practice, by Charles Enzian, Wilkes-Barre, Pa.; The Best Methods of Removing Coal Pillars, by F. W. Cunningham, Charleroi, Pa.

Mr. Cunningham in his paper gave practical ideas of how pillars should be removed and this led to the discussion of the conservation of coal. Until recently it has been customary to leave the upper bench of the Pittsburg bed in the mine. This "rooster coal," as it is termed locally, protects the mines from roof falls, and is an inferior coal, carrying 12 per cent. ash, and clinkering, making it advisable to separate it from the most excellent lower bench of the Pittsburg bed. The conditions of course were not understood by members of the United States Geological Survey, who have been saying that millions of tons of this coal have been wasted, thus using their mistaken idea to bolster up conservation.

Samuel A. Taylor, said that this coal, which is 60 inches thick, is now being mined in the Panhandle and especially about Bulger.

At the dinner in the Flemish room of the Fort Pitt Hotel, Major Charles Lynch, U. S. A., of the American Red Cross Society, spoke on The Red Cross in Mining Work.

The sentiment of all the talks at the banquet was First Aid to the Injured; and First Aid to Those Not Injured. Among the other speakers of the evening were Jesse K. Johnston, of Charleroi; Dr. W. R. Crane, dean of the Mining Department of Pennsylvania State College; Professor Wadsworth, of the Mining Department of the University of Pittsburg; Lee Ott, of Thomas, W. Va., and A. P. Cameron, of Irwin, Pa.

On the second day the following papers were read: Recent Developments in the Use of Steel Mine Supports, by R. B. Woodworth; Equalization of Fuels, by H. K. Myers, Lecturer on Mining, Carnegie Technical Schools.

In the afternoon the members visited the Westinghouse Electric Co.'s plant.

COAL MINE TRANSPORTATION

Written for Mines and Minerals, by E. B. W.

Next to ventilation, the transportation system is the most important branch of coal mining. When the haulage system is balanced so that there are no delays the entire operation moves as harmoniously as a sewing machine, a condition which appeals to miners and management and even to the mules. The mine may be supplied with the necessary number of men to meet the market demand for coal; it may be equipped with approved modern machinery; the tipple may possess the latest improved tipping and unloading apparatus; nevertheless all these advantages will prove negligible if the transportation system fails to move the coal. From this statement it becomes evident that all branches of coal mining are interdependent, but particularly are they dependent on the physical condition of the tracks and the rolling stock.

Necessity of Proper Road Bed to Obtain Economy in Locomotive Running

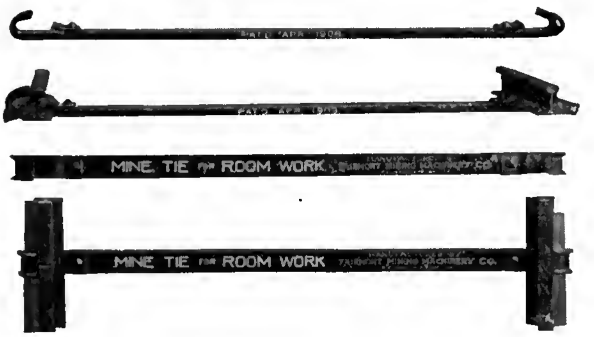

Fig. 1. Steel Tie

To a large extent the cost of car repairs depends on the condition of the mine tracks. Under favorable conditions the car upkeep item will vary from 2 to 4 cents per ton hauled, this, however, is but one item. It is a true statement that the cost of mine haulage is governed by the number of cars of coal moved in a certain time with a given number of men, mules, and locomotives, yet under favorable conditions the minimum cost of haulage varies from 7 to 10 cents per ton. Owing to this expense every mine manager endeavors to economize in this particular department; sometimes with success, but more frequently without, because the subject is not thoroughly analyzed. The first problem involved in economical mine haulage requires for its solution that the tracks be kept in the best possible condition, even to room roads, in fact any neglect of this important matter will be reflected to every department of the operation. Little has been written on the mine roads, and that little is general. Possibly this is due to the assumption that mine roads involve merely manual labor, and if it is so, then it is time for the management to wake up.

The method most frequently adopted to keep the tonnage up to the prescribed mark as the haul increases is to use larger locomotives and haul a greater number of cars than when the haul was shorter. This heavier traffic requires heavier rails, and also that the roadbed be kept in as good condition as a surface railroad. Where 30-pound rails were used a few years ago on the main haulage roads, now 60-pound rails with angle fish-plates are laid on from 6- to 8-inch face hardwood ties spaced 18 inches from center to center. The length of the ties depends on the track gauge, although in every case the ties should extend beyond the track 15 inches, in order to furnish plenty of bite and keep the track in alinement. Under the rails, and particularly at the ends, the ties should be well tamped to prevent spring as the trains pass over them. If this is not done, there will soon be low joints, the spikes will come up, after which will follow track spreading and derailment of cars. Surface-railroad trackmen carefully drain the roadbed in order to preserve the ties and prevent the track springing in wet weather; in fact, where gravel is not available iron-furnace cinders and crushed stone are adopted for ballast. If this practice has been found from experinece to be necessary for surface roads, how much more necessary it is on main haulage roads in mines, where usually mine-track ballast consists of slate and ashes, both of which are sure to go to dust in a short time. Whenever a mine road is thus ballasted and poorly drained, low joints, springy and decayed ties will shortly appear.

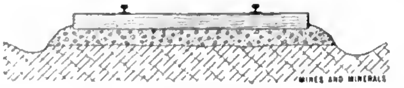

Fig. 2. Road Bed

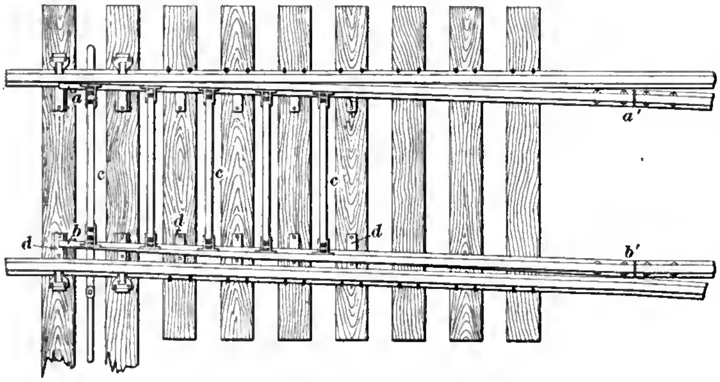
On cross-entries where 20-pound rails were the heaviest used a few years ago, now 40-pound steel rails are adopted at large operations, and wherever motors travel the ties are given at least 6-inch face and 2-foot centers. Close attention is paid to the curves, partings and room necks on these roads, as it is more thoroughly acknowledged that a stiff well-kept track is easier on live and rolling stock, than a crooked, uneven, dirty, wet road. Usually engineers furnish centers for driving the headings, curves, and room necks, and the management watches to see that the work laid out is done properly by the miners, as a uniform mine on the map looks well, besides the men doing the work are usually contract miners. This remark is not intended for sarcasm but to call attention to the fact that more science and skill is required to lay the curve, turnout and room-neck rails to center than in mechanically furnishing centers with an instrument or making the excavations. If a careful and intelligent oversight of the track laying in these particular places is neglected there will be wear and tear on the rolling stock that might have been avoided.

Only a few years ago, wooden rails, or 16-pound iron rails, furnished the tracks in rooms, now they are almost universally discarded for 20-pound rails laid on small-faced ties and more recently on the steel ties shown in Fig. 1. Too little attention has been given in the past to room tracks, and in some collieries any piece of sapling, green or dry, that could be blazed was thought good enough for room ties and often these were laid with 3- or 4-foot centers. The result of this negligence was that the rails spread, the car wheels fell between the tracks, time was lost and and nine times out of ten the car was wrenched in some part, which hastened it to the repair shop. Good roadbeds are essential to a well-managed mine, for it is difficult, and likewise expensive, to haul a large coal tonnage over poorly-laid tracks. Assuming that the management furnishes good track material, if it is not properly laid on solid roadbeds, the fact will be reflected in the cost of haulage and car repairs. It will be seen therefore that track laying is not entirely mechanical labor, but requires a skill which should be intrusted to experienced men. If good mine roads are advocated on the basis set forth in this article, the writer is apt to be declared impracticable, the suggestions unnecessary and theoretical. Doctor Peters, some years ago, covered this ground thoroughly when he stated that the practical man has infinitely more theories than the theoretical man, but the trouble with them is that they are all wrong. When mines are in their infancy the haulage problem is simple compared to what it will be 10 years later. This very fact makes it essential that the roads over which there is heavy traffic should be kept in alinement, laid on a uniform grade and drained. Sometimes switches are the cause of accident, and it is seldom that they and the frogs are made properly. In order to obtain a good rail frog it is necessary to make it at the plant, and this calls into action the science of the engineer, the boss-track man, and the blacksmith. Split switches should be installed on all main-haulage roads, as well as rail frogs, and it may be further added that there is no economy practiced by cutting down the lead. Whenever

possible, posts should be eliminated from haulways, and if this be not possible then the post should be countersunk, and if the coal spalls, the post should be cemented in place or a concrete post substituted. The main haulage is a permanent road that is to exist probably so long as the mine, therefore all things in connection with it should be permanent. Countersunk posts will not be hit by cars if they jump the track; will not be knocked down in case of an explosion; and lastly, will not injure employes. Haulways should be made at least $2\frac{1}{2}$ feet wider on each side than the top of the car. Then the brakeman will not be knocked from the car when called on to set brakes.

Hauling is done in two different stages in drift mines, and usually four stages in shaft mines, if the pushing or getting cars to the room face be neglected. The gathering is usually done



F gi 3. Split Switch

by mules and drivers, and it is an old saying that the mine boss can control every one but the mule drivers. If all drivers feel inclined, mules will be kept in order and cars delivered on time at the partings; however, if one driver has a grouch the other drivers will be kept waiting on his movements. This may be partly corrected by sending the drivers from the parting in rotation, thus varying the length of haul, and if it does not, the driver should be consulted relative to his ailment. If the driver is sick he should be relieved from duty; if he has a plausible grievance it should be adjusted at once or another run given him, but if he is soldiering a discharge is due him.

The second stage in mine transportation is mechanical, and consists in hauling the cars that have been made into trains on the gathering parting to the shaft bottom or to the tipple. Since the introduction of compressed air and electric motors, rope haulage has been gradually discarded in the United States, and in the consideration of successful motor haulage several propositions appear for discussion.

1. The electric locomotive is capable of hauling so many tons of coal and cars on the mine track, when that is in good solid condition, and when the cars are in good repair and well lubricated. Any one of these factors may entirely upset calculations and instead of a 20-car trip the locomotive may be able to haul only 18 or 19 cars.

2. The second proposition assumes that everything is such that the first proposition may be eliminated from consideration, then time becomes an element and this is dependent on the speed of the locomotive, but more particularly on the drivers having a full trip of cars at the gathering station. While delays at the tipple are not chargeable to the transportation system, nevertheless they are reflected in dollars and cents on the cost of haulage sheet. In order to prevent the motor being delayed at some place along the road, a number of empty mine cars should be held in reserve. The usual delays at the tipple are not so serious as to cripple the system, and then only temporarily, while mine-car loading and waste time cannot be made up. The cost of gathering cars by mules is one of the expensive items in the haulage problem; however, the system is so flexible that if there is additional expense involved for room tracks, mechanical haulage will not appeal greatly to coal operators. Here the steel room ties shown in Fig. 1 feature to advantage both as an improvement on room ties and as a stiffener for tracks. When these are properly laid, gathering locomotives will be found superceding the mule.

The Baldwin Locomotive Works has recently built a special electric locomotive for the Lehigh Valley Coal Co. which is equipped with both traction and gathering reels. The locomotive is shown in Fig. 4.

The frames are of plate steel, placed outside the wheels, and strengthened by angle irons riveted to their outside edges. The front and back bumpers are of angle irons so that the frame combines strength with lightness, and allows more weight to be put into the motors than would be possible if heavier frames were used.

The locomotive is propelled by two Westinghouse motors, wound for 220 volts, that are suspended between the axles. The traction reel which is driven from the rear motor, is placed in a vertical position and carries 400 feet of $\frac{5}{8}$-inch wire rope. By means of clutches, it is possible to drive both the locomotive and reel together, or either may be operated independently.

The gathering reel is mounted in a horizontal position, above the frames of the locomotive. It is operated by an independent motor, and carries 400 feet of double conductor cable, which may be guided over either end.

The application of these two reels enables this locomotive to enter sidings where rails are unbonded and no trolley wires are provided, or to haul cars from the room face while standing with brakes set on the main tracks.

The principal dimensions of this locomotive are as follows: Gauge, 4 feet; wheelbase, 4 feet 8 inches; drivers, diameter, 30 inches; journals, 4 in. × 6 in.; width, 5 feet 9 inches; height, 3 feet $7\frac{1}{2}$ inches; length, 11 feet 8 inches; weight, 15,000 pounds.

TRANSPORTATION IN ALASKA

The continuation of the present prosperity of the mining industry in Alaska is dependent on the cheapening of operating costs by the improvements in means of transportation. The present industrial advancement of inland Alaska is small compared with that which will take place when railway communica-

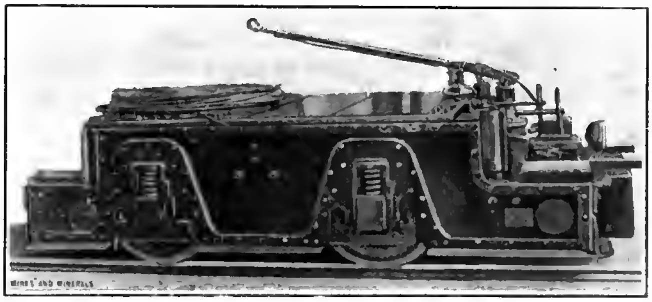


Fig. 4. Baldwin Electric Locomotive

tion with tide water has been established. As it is, the coal, which will furnish the export tonnage necessary to support railways built for opening the coal fields, is of first importance to the entire territory. Alaska has now about 370 miles of railways distributed among nine different systems. Construction work is proceeding on two lines and some progress has been made on a number of other transportation enterprises.

Interest in railway construction now largely centers in the Copper River basin and the Bering River coal field, Kenai Peninsula, and the Susitna and Matanuska basins, and the Yukon-Tanana region.—*United States Geological Survey.*

COMPENSATION FOR INJURY

Written for Mines and Minerals, by Raymond P. Tarr

Classification of Injuries in State of Washington. Plans and Costs of Compensation

There is no question of more real merit before the American people today than that which concerns the maimed and fatally injured. It is an unsettled question because an adequate treatment of such is a tremendous problem. There are various degrees of hazard in the different industries, the business rush is everywhere, and in many cases the complex labor problem increases the hazard. No solution is possible until both capital and labor take hold of the situation whereby each may assume its respective obligations. There certainly should be some satisfactory method of reimbursement for disaster, primarily for the sake of humanity, secondly, in order to bring capital and labor more closely together, and thirdly, in order to obtain conditions which will minimize disaster. Since some industries are more hazardous than others, the compensation could not be alike for all. Since in a discussion of this subject loss of life and injury to limb must be measured in money, one can determine by careful study the actual cost to any particular industry, and thus be prepared with facts upon which to base conclusions that will be fair to that particular industry.

All accidents in any industry can be classified according to responsibility under one of the four following causes:

1. Company negligence.
2. Carelessness of the fellow servant.
3. Carelessness of the individual.
4. Hazard of the industry.

The following resume of the fatal and non-fatal accidents in the coal mines of Washington for the 20-year period ending December 31, 1908, classified as above mentioned, is hereby given for the purpose of showing the causes and effects in this particular industry for this particular state. On account of the length of the period, and also because during the first 10 years the precautions and the mining methods were below par, these results represent a fair average for the country as a whole. Following the resume is a computation which has been made in order to show how much relief would have cost had some sort of mutual insurance plan governed the mining casualties in Washington during the past 20 years. The conclusion is an argument for prevention of accidents and compensation for injury as based upon the results as revealed in this article, and from observations made in various sections of the country.

Mine Explosions.—May 10, 1892, 45 men were killed at Roslyn, in Mine No. 1. This ranks as the worst mine disaster the coal industry has suffered in Washington. Gas was known to exist in the mine and the ventilation was kept in good order. The opinion of Mine Inspector Edmunds was, that "it took place in the cross-cut that was being driven from the airway to the slope, an accumulation of gas having taken place in the manway and cross-cut; that when the hole was drilled through, as it was evident that it had been driven into the roof, cutting the coal at the top as it entered the roof, the gas found its way through this little crack and was ignited by the naked lamps of the men on the slope side, the man that was working in the airway, working toward the slope, had a safety lamp, the others having naked lamps."

Dust greatly augmented the force and intensity of the explosion, which was greatest on the east side of the mine. The miners on the west side were victims of the deadly afterdamp. Since the coroner's jury rendered a verdict "that this explosion was due to improper ventilation," these lives are chargeable to company negligence, although it is known that positive orders had been given not to break through the cross-cut. Inasmuch as the official record stands company negligence, this disaster is so rated here.

The financial loss which results from an explosion is so great that no practical management can afford to poorly ventilate a mine. Miners still employed at Roslyn who were witnesses of that catastrophe emphatically agree that the disaster was due to the carelessness of those at work in the cross-cut. [Mine explosions may be reduced, but they can never be absolutely eradicated. A careful investigation will show that there is as strong desire and effort on the part of mine managers in the United States to reduce these disasters as can be found anywhere else in the world.]

April 9, 1895, an explosion of firedamp at Blue Cañon resulted in the death of 25 men. It seems that this disaster was due to gross carelessness. The report of Inspector Edmunds was that "a hole had been driven into the bottom rock, at the face of the gangway, and it had been charged with giant powder and fired. The hole had been driven in a very improper place. Instead of drilling it in the direction of the gangway, and making it a lifting shot, it was located on the top of the rock, or across the strata, and pointing into the solid, thus making a line of great resistance. The explosive failed to perform the work intended for it, merely making a small cavity on the face of the rock." Such a shot would cause a great concussion, similar to a blown-out shot.

It was stated that the mine was free from gas that morning when the fire boss made his examination, but it is probable that the gas was present when the shot was fired, or a quantity of it was liberated from the strata with the blast, and the heat produced by the stored-up energy of the giant powder, when it failed to perform work in removing rock, must have ignited a pocket or blower of gas. According to the testimony of the men working on opposite shifts, and some of the officials of the company, rumbling noises were heard the day previous under the floor of the gangway.

It was evident that there was not a large quantity of firedamp present, as but few of the bodies were burned. The men in the working places came down and were suffocated by the afterdamp. These 25 deaths are chargeable to the error of the fellow servant.

December 9, 1899, 31 lives were lost in the Carbonado No. 7 mine explosion. This mine gives off considerable firedamp, but is, and always has been, exceptionally well ventilated. It was the unanimous opinion of the State Board of Coal Mine Examiners that "the origin of the explosion occurred by the ignition of a small quantity of gas in some manner unknown, the force due to this raising the dust was undoubtedly the principal factor in the explosion." These 31 lives are chargeable to the hazard of the industry.

April 26, 1907, seven men lost their lives in the Black Diamond Morgan's Slope mine explosion, which, according to the finding of the coroner's jury, "was caused by the concussion and fire produced by an explosion of a pocket of gas, which was brought down by an unavoidable cave, and was ignited by some unknown miner." The disaster was therefore due to unforseen causes, and consequently attributable to the hazard of the industry.

Dust Explosions.—At Coal Creek, October 9, 1894, an explosion of dust ignited by a charge of giant powder caused the deaths of four persons. But for the fact that the floor of the gangway had been well watered the day before, the disaster would undoubtedly have been very much greater. No firedamp has ever been found in this mine. These four lives were lost on account of the carelessness of the individual who fired the hole, and chargeable therefore to fellow servant.

October 1, 1901, 11 lives were lost at the Lawson Mine by an explosion of dust. Investigation proved that a heavy shot had been fired on the bottom, and that about 4 inches of a drill hole was found near the top rock. The finding of the coroner's jury was that "an explosion was caused by two shots being fired one after the other, the second shot igniting the dust created by the first shot." Evidence of poor work on the part of the

individual who tamped these holes would place the responsibility under the head of carelessness of the fellow servant.

December 7, 1904, at Burnett, 17 lives were lost as a result of a blown-out shot which ignited the dust and produced a disastrous explosion in one of the chutes. Twelve men were killed outright, and five were suffocated by afterdamp. The finding of the coroner's jury was that "the men were killed as a result of the explosion of coal dust, caused by heavy shooting." The finding therefore places the responsibility against the fellow servant.

Mine Fires.—In some of the mines of the state the coal is susceptible to spontaneous combustion, and in these mines have occurred disastrous mine fires. The most disastrous mine fire occurred at Franklin, August 24, 1894, when 37 men lost their lives through suffocation by smoke. These men might have escaped, but they had gone to the seat of the fire in the effort to extinguish it, when some incompetent or excited individual stopped the fan and thus cut off the air supply. The men were soon compelled to retreat toward the bottom of the slope. While going through the rock tunnel to the airway, smoke was encountered, which would not have been there had the fan been continued in operation.

Had the exact location of the fire been known the fan might not have been stopped. It is probable that he who was responsible for the execution of this act may have witnessed the stopping of the fan at some previous fire, and have believed that such a precaution was necessary in the case of every mine fire. Since it has not been determined whether the stopping of the fan was due to an incompetent official, or to an excited individual miner, it is but fair to place the responsibility equally under two causes, company negligence and carelessness of the individual.

The second serious mine fire occurred at Franklin, October 14, 1895, when four men lost their lives. A gas blower had been ignited, which in turn ignited the timbers. The men had reached the surface in safety, but the four who had gone below to extinguish the fire, and who had gone in spite of strenuous warnings, perished in the smoke and flame. These four lives are chargeable to the carelessness of the individual.

August 21, 1900, five men perished in a mine fire at Issaquah, which started from a surface brush fire. All but five of the miners escaped after the warning had been given the men to come out. Hazard of the industry is clearly the cause under which these fatalities should be considered.

Individual Gas Explosions.—Seventeen men have been killed in minor gas explosions. Of this number, nine were killed on account of their own carelessness, three by the carelessness of others, and three were due to the hazard of the industry. (Two, causes unknown.)

Powder Explosions.—By this cause four men have been killed through their own carelessness, and two on account of the carelessness of others.

Suffocations.—Seventeen men have been suffocated. In most cases these deaths have been due to the men returning to their working places too soon after firing shots. Of this number, 14 fatalities were due to individual carelessness, two to the hazard of the industry, and one to company negligence.

Fall of Rock.—Out of the 135 fatalities caused by falls of rock or coal, it is positively known that 31 had spurned the advice against continuing at work until the timbers already at hand had been put in place to support the overhanging and dangerous masses, which later fell with fatal results. Thirty-one are thus charged to the carelessness of the individual, 10 to the fellow servant, 91 to hazard of the industry, and three to company negligence.

Runaway Cars or Trips.—Nine trips have wholly or partly broken loose with fatal results, because cables, couplings, or drawbars have broken, been improperly attached, and in some cases defective. Undoubtedly, some of these defects were not reported by the miner, or possibly even not repaired by the company man to whom defects may have been reported. For these reasons it is but fair to distribute the responsibility equally between carelessness of the individual, company negligence, and hazard. Of those killed by cars (besides the nine mentioned), whether by collisions, falling off or under trips, or by being run down, the deaths of 13 are attributed to the carelessness of the individual, 15 to the fellow servant, 15 to the hazard of the industry, and three to company negligence.

Other Accidents.—A large number of causes, such as coal falling off cars, falling timbers, falls, unspragged cars, etc., etc., have killed a large number of men. Under these minor causes 12 men have been killed on account of their own negligence, four through the carelessness of others, and 37 fatalities were due to the hazard of the industry.

Note.—Twenty deaths (two by explosion) from various responsibilities have been charged in proportion to those known, five to the carelessness of the individual, eight to the hazard of the industry, four to fellow servant, and two to company negligence.

Summary of Accidents.—Causes: Explosions, 163; fall of rock, 135; cars and trips, 55; fires, 46; all others, 69.

Responsibilities: Hazard, 195 = 42 per cent.; carelessness, 109 = 23 per cent.; fellow servant, 91 = 19 per cent.; company negligence, 73 = 16 per cent.

During the past 20 years 59 per cent. of all fatalities in Washington were caused by falls of rock and by mine explosions. These same causes produced 59 per cent. of all the deaths in all the coal mines of the United States during the year 1906.

Summary of Outside Fatal Accidents.—Killed by machinery, 9; trips of cars, 4; boiler explosions, 3; falls, etc., 11.

Responsibilities: Hazard, 19; carelessness, 4; fellow servant, 1; company negligence, 3.

Causes of Outside Fatalities.—Six men have been caught in machinery while attending to their duties, and their deaths are here considered chargeable to the hazard of the industry. Two were killed on account of the breaking of machinery and the charge is placed against company negligence in these particular cases. Four men have fallen under trips, the deaths of whom should be placed under the cause of hazard.

The Cost of Fatalities.—Taking the foregoing casualties into account as reliable data, computation has been made on a basis of $2,000 as compensation for each fatality where a widow was left, and in those cases where children have been bereft, $500 for each; and in addition $500 in each case where no widow was left; and since 495 men have lost their lives, leaving 182 widows and 498 fatherless children, a fund of $769,500 would have been necessary to thus compensate those left without means.

Note.—For 4 years the widows and orphans were computed according to the law of averages. This was necessary owing to the condition of the records.

The Cost and Extent of Injuries.—The total number of nonfatal accidents which have been recorded is 1,359. These produced 1,261 inside and 98 outside injuries. Allowing a fair compensation for the various injuries, taken into account according to the following scale they would have cost as follows:

Injury	Number	Compensation	Total
Broken leg	270	$ 300	$81,000
Severe	328	150	49,200
Broken arm	120	150	18,000
Slight	304	20	6,080
Severe burn	173	100	17,300
Slight burn	134	20	2,680
Fractured skull	7	1,000	7,000
Injured spine	4	5,000	20,000
Arm amputated	4	1,500	6,000
Leg amputated	4	2,000	8,000
Hand amputated	8	1,000	8,000
Both eyes out	2	5,000	10,000
One eye out	1	1,000	1,000
Total	1,359		$234,260

How the Burden Might Have Been Carried and What It Would Cost to Carry It at the Same Rate Now.—The grand total

of tons mined was 40,651,289 for the 20-year period, and of men employed 76,628. According to the figures above, the total cost of injury would have amounted to $1,003,760. These figures show an average cost per ton of $.0247, and of $13.10 per man per annum to compensate in this manner. If the state had carried one-half the burden of the hazard, its share would have amounted to 21 per cent., and had the company paid for the remainder of the hazard and the company negligence charge, its share would have been 37 per cent. This would have left to the men 42 per cent., comprising the responsibilities resulting from negligence on the part of individual and fellow servant. For convenience and fairness let us reckon on the following basis, charging to the state, 25 per cent.; to the men, 35 per cent.; to the company, 40 per cent. Accordingly, the results are:

	Cost Per Ton	Cost Per Man Per Annum
To the state per annum	$.006175	$2.75
To the company per annum	.009880	5.50
To the individual per annum	.008645	4.85

Prevention of Accidents.—Prevention of accidents is largely dependent upon the kind of precautionary laws in force, the degree to which they are enforced, and also upon the spirit with which such laws are received, while compensation for accidents must be based upon reliable data, in order to not only afford relief, but also to promote responsibility and thereby react as a great agent for the prevention of accidents. Casualties in this country are greater in proportion to the number of men employed than in like industries in most any other country one might select. Not only this, but in coal mining at least, the ratio of casualties is rapidly on the increase. In spite of these facts we cannot treat the problem as it may be treated in any other country, because the conditions are so different. It is for this reason that we must here deal with carefully prepared facts and figures.

The rigid enforcement of laws framed to insure the safety of the individual and to protect the lives of all others employed, seems the only policy that can help reduce the number and kind of accidents in every sort of hazardous industry. The time is also ripe for men to depart from the false notion that it is unfair (scabby) and useless to complain of fellow workingmen whose actions are wrong. This is a false notion which has assumed such proportions in present-day America, that its results are too frequently disaster and death.

Accordingly, as the laws are made and enforced and the respective responsibilities appreciated, the annual levies will decrease. While the preceeding results show the average of the past, they should be considered as excessive for the future, because there is reason to believe that in the very near future the recommendations resulting from the labors of all investigators will aid in a material reduction in the number and kind of disasters. The recklessness practiced in the use of powder, which causes many mine explosions, and the consequent falls of rock which result as after effects of these explosions, will be the greatest errors to overcome. Since these two causes are practically one, and since they produce the majority of injuries, and because a remedy is easy, the prediction for a reduction is well founded. The belief of those who have studied the question is that the reduction should amount to between 50 per cent. and 75 per cent.

Any contemplated bill aimed to prevent disaster should possess a feature encouraging more care on the part of all concerned, and no feature in any bill could be of much greater value than such a one as would under-rate the amounts to be collected for compensation, because the entire working force would then be made to realize that great precaution is necessary in order to fully recompense for injury. Thus a proper and necessary incentive would be created to help reduce both disaster and levies for compensation. None can afford to be so pessimistic as to not expect such reductions, and those who cannot assume such an attitude have no business seeking employment or engaging in business in any hazardous pursuit. Assuming the reductions to be 30 per cent (and they should go much lower), the amounts necessary to cover requirements according to the foregoing reckoning would become reduced as shown in the following table.

	Cost Per Ton	Cost Per Man Per Annum
To state per annum	$.004322	$1.92
To company per annum	.006916	3.85
To individuals per annum	.006055	3.40

Mr. Richard Newsam, president and mining engineer of the State Mining Board of Illinois, in his article, "Timely Remarks," sincerely but positively states: "We have laws that would help in our state, but we also have some that could be greatly benefited if they were changed. Yet what is the use of making laws if no notice is taken of them?" Naturally, the inference from Mr. Newsam's remarks is fewer but better laws and all enforced. After 55 years of practical mining experience Mr. Newsam states that "he believes 75 per cent. of the lives can be saved that are now being lost in Illinois mining operations, that the only one who can stop the great loss of life in our coal mines today is the miner himself, by living up to the laws, and thinking more of his own life and of the lives of others." There are undoubtedly thousands of others who would testify precisely as Mr. Newsam has done. The sort of logic which these men present must be heard and obeyed, there must be more thought, more duty, more education, more consideration for others, a few good laws, every one alive. These are the requisites to solve not only this, but also every civic problem.

Compensation.—To secure legislation simply to assure compensation for those who are dependent upon those killed, and for those who become injured in hazardous pursuits, is a possibility which may afford relief for those affected, but this is only half the problem. The enactment must be framed to help reduce the number and kind of accidents as well. A cooperative insurance plan might be better than a workingmen's compensation benefit or an employer's liability act. Most men concede that it is well to carry certain kinds of insurance. Thinking men know that it is their duty to assume such responsibility. Since the majority of workingmen possess both intelligence and a high sense of duty, would it not be possible to frame for his benefit some sort of insurance act for his particular industry, which will satisfy both his sense of duty and his intelligence, one equable both to employer and to employe.

In 1907 a carefully prepared bill failed to pass the Illinois legislature. The bill had many meritorious features for the benefit of the workingman. The failure to pass was largely due to the fact that such insurance had to be carried in some casualty company, organized under the laws of the state or admitted to do business in that state. An insurance plan which provides for a minimum of profit ought, when sufficiently improved, to satisfy and become effective. Insurance companies must make a profit, and they can prosper without soliciting business from laboring men. The latter should be able to obtain insurance by some more economical method than that offered by insurance companies.

If a bill were framed making it lawful (after the Illinois bill), viz.: "For any employer to make a contract in writing with any employe, whereby the parties may agree that the employe shall become insured against accident occurring in the course of employment, which results in personal injury or death in accordance with the provisions of this act, and that in consideration of such insurance, the employer shall be relieved from the consequences of acts or omissions, by reason of which he should without such agreement, become liable toward such

employe"; the state might well afford the additional expense for the necessary officials to collect, maintain, and disburse these casualty funds, and also pay one-half the compensation due to hazard responsibilities. For the reasons given it might be a better law if it were provided for the men to enter the agreement as contributors to the insurance plan.

According to our present system, there is financial relief from but one of the four causes mentioned; namely, when an accident is declared by jury as due to company negligence, and under this process but a small portion of this money is actually received by those most dependent upon the awards. Whenever compensation is obtained by law, the disbursement of funds would require a vast amount of consideration. They should be payable in monthly instalments, according to the needs, and extend over as long a time as possible. This would be particularly necessary in cases of large sums due beneficiaries who could easily become victims of fraud or robbery.

The state is a great beneficiary from tax levies in mining operations and it would be a much greater beneficiary with proper compensation laws enacted, whereby legal processes which arise from damage suits were eliminated. It cannot but help working to the benefit of all concerned when the provisions are made for the employer and employe to contribute to a general fund for compensation to the injured. Some great economical change must be brought about in order to make workingmen better satisfied, better protected, more certain to follow their chosen line of work, and what is more important, to develop in them a larger sense of responsibility. If these results are obtained, both the employer and the employe will have the adequate protection to which both are entitled, but greatest of all the benefits will be the results which will come as the individual fully appreciates the feeling of assurance while he proceeds with his daily labors.

MINE CAR CAGING MACHINE

Written for Mines and Minerals

When mine cars are moving smoothly during working periods in mines every one seems satisfied and works with plenty of ginger, but if there is a hitch in any part of the transportation department it is reflected and usually magnified along the entire system. If a car is off the track and trips are delayed, the entire system is immediately disorganized, the miners inside are disappointed at the output, and those men at the surface as well, because hindered in their work.

In order that cars may be kept on the move and delays in hoisting reduced to a minimum, there must be suitable arrangements at the top and bottom landings for running the cars off and on the cage. This "caging" occupies so much time, that in England and on the Continent two- and three-decked cages, requiring expensive landings at the top and bottom of the shafts, are employed. Where there are such landings, of course a greater quantity of mineral can be hoisted at a time, which increases the output. However, in the United States, the output is usually as large from a single shaft with a one-decked cage, owing to the use of larger cars and quicker caging, thus permitting more trips. The caging problem has been studied carefully, and in order to avoid delays at the landing several men are employed. Experienced mining men state that it is economical to expend $1,000 for a positive-acting piece of machinery that will do away with the labor of one man. In the apparatus shown in Fig. 1, which is known as the automatic safety mine-car caging machine, there is a system of levers attached to a shaft situated parallel with and inside the track rails. At the end of this shaft there is a crank lever *A* arranged so as to open or close the horns *B* and *C* in such a manner that they will lock the car wheels and stop the cars.

When the cage reaches the bottom landing its weight coming on the crank lever *A* revolves the shaft sufficiently to work the levers actuating the horns *B* and cause them to open; at the same time the levers attached to horns *C* are moved so as to cause the latter to stand upright, and also the weight *D* attached to the end of a lever arm. This allows the car to run by gravity on the cage, but prevents the second car moving forward past horns *C*. When the cage is raised the weight *D* rotates the central shaft, thereby opening the horns *C*, closing

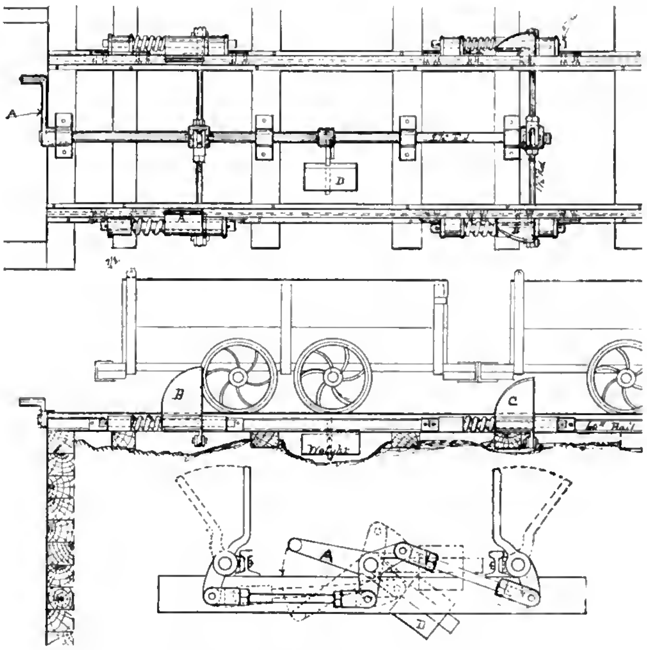

Fig. 1. Automatic Caging Device

the horns *B*, and raising the crank *A* to its original position. The next car to go on the cage then moves forward and is stopped by *B*. A system of hand levers may also be applied to the apparatus if it is desired to use it at intermediate landings. The writer is indebted to the Mining Safety Device Co., of Bowerston, Ohio, for the use of the accompanying cut showing the method of operation of this valuable and interesting adjunct to caging.

EUROPEAN LAWS REGARDING BREATHING APPARATUS

In Austria the law requires a pneumataphore to be kept in order and readiness for every 100 miners employed. The government permits the coal owners the choice of four approved types of breathing apparatus, but the mining office may authorize the use of any new appliance approved in future.

In the different states and districts of Germany the regulations vary according to the natural conditions of the mines, but as evidence of the stringency of the law it may be mentioned that no fewer than 700 sets of breathing appliances are kept ready for use in the Dortmund district alone, and in the Breslau district no mine has less than 2 sets, the government mining engineer being empowered to order any number he deems fit.

In France, all mines employing more than 100 persons underground upon one shift must be furnished with breathing apparatus, the number ranging from 2 to 6 per mine, according to size, gassy nature. number of workers, etc., and double brigades of not less than 8 trained men must be kept for every set of rescue appliances. Some interesting experiments in the utility of safety chambers have been conducted recently in France, and as a result some of the leading colliery companies are putting "blind" galleries, supplied with compressed air, water, food, etc., and signal arrangements, in their pits.

In Holland a number of mine workers must be trained to rescue work, and sets of apparatus must equal 1 for every 50 miners employed.—*United States Consular Report.*

ANSWERS TO EXAMINATION QUESTIONS

Answered for Mines and Minerals, by J. T. Beard

PRELIMINARY QUESTIONS

Mine Foremen's Examination Held at Fairmont, W. Va., November 16, 17, 1910

A.—Give place of birth. B.—Are you a resident of West Virginia and a citizen of the United States? C.—Have you testimonials of character? If not give names and addresses of three reputable persons as reference. D.—State the number of years of experience you have had in or about coal mines; and how many of these have been spent in West Virginia. Give the names of the companies for whom you have worked, the mines, and the kind of work performed in each case, in this or other countries.

E.—What quantity of air is required by law in gaseous and non-gaseous mines? Where is such quantity to be circulated? How often, where, and by whom shall this air be measured and recorded?

Ans.—In mines generating firedamp, the minimum circulation required by law is 150 cubic feet of air per minute for each person employed in the mine (Sec. 12); in non-gaseous mines, 100 cubic feet per minute per person (Sec. 11); the same to be circulated around the main and cross-headings and working places; and measured at least twice a month at the inlet, the outlet, and at or near the faces of the advanced headings by the mine foreman, who shall record such measurements in a book kept for such purpose (Sec. 15).

F.—What are the requirements of law in regard to the methods of conducting the ventilating current to the working faces by means of doors, stoppings, overcasts, etc.?

Ans.—See Sec. 12, West Virginia mining law.

G.—To what scale must a mine map be drawn to conform to law? What information should be placed on the map? How are often are mine maps to be extended? Where should they be kept? What useful information should a mine foreman be able to obtain from the map when the mine is approaching old abandoned workings that may contain water or gas, and what precautions should be taken at such times?

Ans.—A scale of 100 or 200 feet to an inch, to be stated on the map. Map must show all shafts, slopes, entries, and airways, with arrows to indicate the direction of air-currents; also, all headings, rooms, pillars, and abandoned places; also, the general inclination of the strata, and all property lines or outcrops of coal within 1,000 feet of any portion of the mine workings. The map must be extended twice a year and not more than 7 months apart. The original map or a true copy of same must be kept at the mine office, and another copy at the office of the district mine inspector. When approaching abandoned workings, a reference to the map should show the exact relation of the workings to each other and their distance apart; but as a precaution, drill holes should be bored 12 feet in advance of the face of the heading (Sec. 15) and flank holes on each side, to insure the supposed thickness of barrier pillar and avoid accident.

H.—What are the legal requirements in regard to traveling-ways and means of entrance and exit from mines? Answer fully.

Ans.—See Secs. 8, 9, 10, and 15 of the West Virginia mining laws.

I.—State what the law requires in regard to safety appliances at shaft mines with reference to cages, ropes, signals, lights, brakes, safety catches, machinery, and methods of inspection.

Ans.—See Secs. 9 and 15 of the mining law.

J.—What dangers are connected with the use of powder for blasting coal in mines? What precautions should be used to overcome these dangers? Where should explosives for use in mines be stored? How much powder is permitted for use of each person per day, and how must it be carried when taken into the mine?

Ans.—Aside from the danger of accidental explosion in the handling of the powder or the charging of holes in blasting, there is the more common danger of a possible windy or blown-out shot occurring, which may stir up a sufficient quantity of fine dust to cause a serious explosion. The danger is more common in the use of black powder in presence of gas or dust or both, owing to the flame produced in its explosion. The precautions that should be observed are: Avoid excessive use of powder; use proper judgment in placing all shots; fire but one shot at a time in any working place, and never fire a shot in a close place where the air is laden with dust and the smoke of other shots; test the place for gas before firing. In many mines the only safe plan is to have all shots examined and fired by competent men, after the workmen have left the mine. Explosives should be stored on the surface in a specially constructed magazine, located at a safe distance from the shaft and other buildings. Only sufficient powder for reasonable use in one shift may be taken into the mine by any person, and this must be carried in a metallic canister that will hold not to exceed 5 pounds (Sec. 11).

K.—State what persons and of what age can be employed in coal mines in Virginia. What is the duty of the mine foreman when an employe disobeys an order resulting in loss of life or injury to persons or property?

Ans.—Males only, who are 14 years of age or over (Sec. 17). In case of accident causing serious personal injury the mine foreman, in the absence of the superintendent, must notify promptly the mine inspector of the district, and in case of loss of life, he must also notify the coroner of the county, or a justice of the peace (Sec. 20).

MINE FOREMEN'S EXAMINATION

Ques. 1.—What qualifications must a mine foreman possess, and what duties must he perform to meet the legal requirements in West Virginia?

Ans.—The necessary qualifications are: Ability and skill in handling men; sound judgment in the planning and direction of work; a firm and resolute character; patience, forbearance, and consideration for others; a thorough knowledge of all work in hand and machinery employed, together with a practical experience in the operation of mines. The legal duties of a mine foreman are given in Sec. 15 of the West Virginia mining law.

Ques. 2.—Name the chief causes of accidents in coal mines, and the methods you as a mine foreman would adopt to avoid the liability to such accidents. Answer fully.

Ans.—The common causes of mine accidents are: Falls of roof and coal; mine cars; explosion of gas or dust; explosion of powder; falling down shafts or slopes; overcome by gas; kicked by mules; and other minor causes. Require a strict compliance with the state mining law and the mine regulations and exact suitable penalties for violation of these rules. Keep on hand an ample stock of all needed timber and other supplies and arrange for their prompt delivery to the men as ordered. Employ good fire bosses to examine the mine thoroughly before each shift and maintain efficient ventilation in all working places. Appoint competent men to examine and, if necessary, to fire all shots. See that miners timber their places promptly as required, and use proper caution in mining their coal.

Ques. 3.—The distance between two pairs of cross-entries is 600 feet; from the main-entry pillar to the boundary is 1,000 feet; the thickness of the seam is 6 feet. How many tons of 2,000 pounds each may be gotten from this block of coal, assuming that a cubic yard of the coal weighs 1 ton, and allowing 25 per cent. to be left for pillars?

Ans.— $\frac{600 \times 1{,}000 \times 6}{27}(1 - .25) = 100{,}000$ tons.

Ques. 4.—To what use is electricity applied in the operation of a coal mine? What are the advantages and disadvantages of using electricity for power or other purposes? State the conditions under which you would recommend the use of elec-

tricity for power in mines. What dangers are attendant on its use, and what precautions should be taken to insure safety to those employed in the mine?

Ans.—Electricity is used to haul coal, operate drills and coal-cutting machines, and in some cases pumps and fans. It is also used for signaling, lighting, telephoning, and for firing blasts. For power and other purposes, electricity furnishes an elastic system that is readily installed and easily changed or extended to suit the variable conditions of mining; its adoption, however, requires the installation and maintenance of expensive machines and the employment of one or more electricians to superintend and operate them; and exposes the mine employes to danger. Electricity may be recommended for power purposes in large mines having long haulage over fairly level roads, and where the coal is drilled and blasted or mining machines are employed. The dangers and precautions to be taken in the use of electricity to insure safety are explained in answer to Ques. 14, page 53, Mines and Minerals, August, 1910.

Ques. 5.—What are the causes of mine fires? Explain how a fire may occur in a mine spontaneously, and what means you would employ to prevent this; or if started how you would extinguish it with safety to the men employed.

Ans.—The common causes of mine fires are given in answer to Ques. 11, page 734, Mines and Minerals, July, 1910. Spontaneous ignition of carbonaceous matter is the result of the absorption of oxygen by the carbon, and the generation of chemical heat in the disintegration of pyrites (sulphide of iron) in presence of moisture. The oxygen absorbed is brought into direct contact with the volatile hydrocarbons of the coal and combustion follows. The best means of preventing this danger is to remove as far as possible its cause, by loading out all fine coal and slack from the mine, and by reducing the heat by the thorough ventilation of the mine. See also Ques. 6, page 52, Mines and Minerals, August, 1910. The method to be employed for the extinction of a mine fire depends on the character and extent of the fire. A gob fire of small proportions may be loaded out before it spreads. Gas feeders in the floor sometimes become ignited and draw the flame back under the gob where it is difficult to reach. These may at times be extinguished by a small stick of dynamite exploded on the floor close to the place. Fires that have gained some headway must be approached from the fresh-air side to avoid the workmen being overcome by the gases produced. The general plan of procedure is to reduce the air supply as far as practicable, and apply water, or carbon dioxide from a chemical engine, or other means to extinguish the fire. When this fails, the fire must be sealed off by building air-tight stoppings in all openings leading thereto, and allowing these to remain till the fire is apparently extinct. Carbon dioxide gas is sometimes injected into the enclosed space behind the stoppings. As a last resort the mine or a portion of it is flooded.

Ques. 6.—Specify the conditions that must be fulfilled in order to secure good ventilation in a mine employing a large number of men. Why is the ventilation of a mine necessary?

Ans.—This question is fully answered in reply to Ques. 4, page 279, December, 1910; and Ques. 3, page 381, January, 1911, Mines and Minerals.

Ques. 7.—How would you determine the quantity of air passing in a mine at any given time? Where the airway is 12 feet 6 inches wide and 5 feet 6 inches high, and the velocity of the air is 375 feet per minute, what is the area of the airway and the quantity of air passing per minute?

Ans.—The quantity of air passing per minute in an airway is determined by measuring the sectional area of the airway, at a chosen point, and multiplying this area (square feet) by the observed reading of the anemometer (feet per minute), as more fully explained in reply to Ques. 8, page 319, Mines and Minerals, December, 1909. The area of the given airway here is $12.5 \times 5.5 = 68.75$ square feet. The quantity of air passing is then $68.75 \times 375 = 25,781.25$, say 25,800 cubic feet per minute.

Ques. 8.—State to what extent the air-current in a mine can be split in the efficient ventilation of the working places. What advantages are obtained by splitting air-currents over a single continuous current in ventilating a mine? Compare the advantages and disadvantages of the different means of producing ventilation in mines, with respect to their effectiveness, safety, and economy.

Ans.—The first two parts of this question are fully answered in the reply to Ques. 6, page 279, Mines and Minerals, December, 1910. The most reliable means of ventilation in mining operations is the centrifugal fan, which, when properly designed to meet actual conditions, will yield the largest volume of air at least expenditure. In fan ventilation the circulation is under better control, and can be readily increased or decreased by regulating the speed of the fan. The mine furnace is an efficient means of ventilation in deep shafts, but is not as easily controlled, requires more constant attendance, and consumes more coal for the same air volume and water gauge produced. In furnace ventilation there is greater danger of fire; it is not efficient in shallow mines, and cannot be used with safety in mines generating firedamp. In mines not generating gas in dangerous quantities, should a dust explosion occur, it might be difficult or impossible to reach the furnace and restore circulation in the mine; while a fan located on the surface is always within reach, and if damaged by an explosion can be repaired. The furnace represents, however, a much smaller investment than a fan. The steam jet is only useful in sinking shafts. The wind cowl or any form of natural ventilation is wholly unreliable.

Ques. 9.—How would you determine the size of pillars and widths of rooms and entries necessary to properly work out the coal, prevent squeezes, and keep the mine in good working condition?

Ans.—This question is fully answered in reply to Ques. 5, page 318, Mines and Minerals, December, 1909. See also Ques. 2, page 574, April, 1910.

Ques. 10.—Make a sketch showing how you would draw back pillars from a section of a mine that has been driven to the

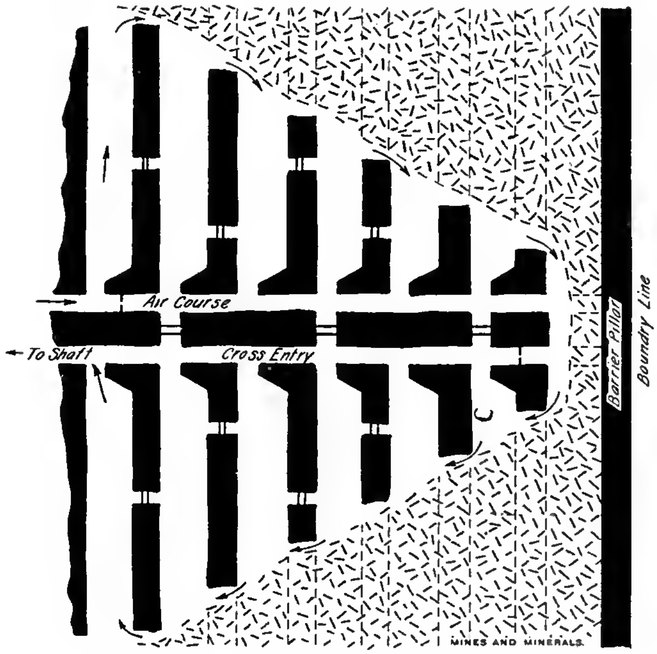

Fig. 1

boundary, in order to obtain the largest percentage of coal with the greatest degree of safety to the miners, in respect to falls of roof or accumulation of gas.

Ans.—When the entries have reached the edge of the barrier pillar to be left at the boundary, and the rooms have all

been driven up to their limit, work is started on the extreme end of the inside room pillars and proceeds in order outby, the work on each pillar following in succession so as to preserve a regular line of pillar work, as shown in Fig. 1. As the room pillars are finished the entry pillars and stumps are drawn. Care must be taken to keep the work in line and leave no timber standing.

Ques. 11.—What precautions are necessary to prevent squeezes in coal mines, and what conditions govern the mode of procedure? What dangers attend a squeeze and how may these dangers be minimized?

Ans.—To avoid squeeze in coal mining it is necessary to lay out and prosecute the work in a systematic manner, according to a definite plan in which the width of entries and rooms, and the widths of the main entry, cross-entry, and room pillars are all made to correspond to the depth of the seam below the surface, the character of the roof, floor, and coal, thickness and inclination of the seam, and the method adopted for the extraction of the coal. All of these conditions govern the manner of conducting the work. It is important also to avoid a large standing area. Pillars should generally be drawn as quickly as the adjoining rooms reach the limit. As pillars are drawn back care must be taken to secure a steady roof settlement by withdrawing all timber. At times it is necessary, in order to relieve the entry pillars of undue roof pressure, to break the roof by a shot placed in the mouth of the room. The effect of fault lines must also be carefully observed; and, on account of such fault lines, it may become necessary to change the direction of driving, so as to cross the fault on an angle. The dangers arising from squeezes are the crushing and loss of pillar coal, and often the closing off of large areas of valuable coal that must then be reached from other directions or abandoned wholly; sudden and extensive falls of roof, and increased danger of mining coal in adjoining workings. To reduce these effects as far as possible, every effort must be made to arrest the squeeze by rapid drawing of pillars adjoining the affected portions; and withdrawing all standing timber and causing roof falls in nearby abandoned places. Where pillars are weak in entries and workings desired to be held, timber cogs should be built and packed solid with waste. Often a squeeze can be diverted and broken entirely by causing heavy roof falls behind or at one side of the trouble.

Ques. 12.—Show by a sketch and explanation how you would stand props or timbers in a mine having a draw slate 16 inches thick overlying a seam 4½ feet high, with a bottom of 12 inches of soft fireclay.

Ans.—If practicable, this coal should be worked by driving up narrow stalls (Fig. 2), say 12 or 14 feet wide and supporting

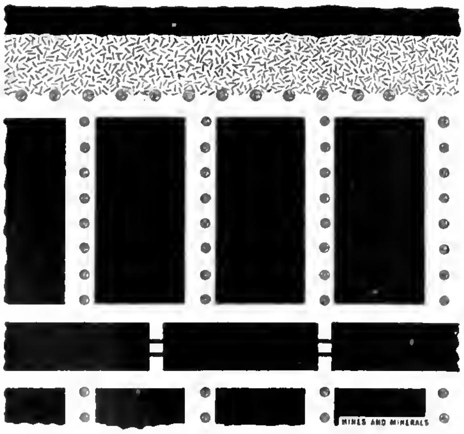

Fig. 2

the draw slate by a line of posts at the side of the road in each stall. The pillars separating the stalls may be any suitable width from 10 to 20 yards, depending on conditions relative to depth of cover, strength of coal, slate, and roof strata above slate. One or more lines of posts should be kept behind the line of pillar work to support the draw slate over the miners. These posts are removed as the pillars are drawn back and the slate allowed to fall. If the fireclay is very soft it may be necessary to set the posts on foot-boards or sills.

Ques. 13.—Explain the principle of action of a pump. What is the height that a pump can lift water and do effective work? Describe the various ways by which coal mines are drained and compare their efficiency and economy.

Ans.—The movement or stroke of the piston or plunger of a pump creates a more or less perfect vacuum in the suction pipe, and the atmospheric pressure acting on the surface of the water in the sump presses it up through the suction pipe into the pump barrel. On the return stroke of the piston, the suction valve being now closed and the discharge valve opened, the water is forced out of the pump barrel into the discharge pipe. This action, in a double-acting pump, is repeated each stroke of the piston, alternately, in each end of the cylinder or barrel. The height a pump will draw water is dependent on the pressure of the atmosphere; it may be taken, in feet, ordinarily, as from .8 to .9 of the height of the barometer reading in inches. For example, if the barometer reads 30 inches, the suction lift of a pump, at that place, may be safely taken as from 24 to 27 feet, depending on the condition of the pump. The means in most common use for unwatering or draining coal mines are pumps, siphons, water buckets, and various forms of displacement pumps actuated by steam or compressed air; as for example the pulsometer, air lift, pneumatic, and steam jet, or injectors. Improved forms of steam, electrical, air, or belt-driven pumps of the piston, plunger, or centrifugal type are in common use and are the most generally efficient and economical for unwatering shafts. Water buckets of special design have been used in many cases owing to their simplicity and effectiveness. Siphons are applicable only in special cases for draining water by a pipe line over a small rise or elevation. They are simple and very economical when properly installed. The pulsometer is a simple and effective means of unwatering a shaft, especially when sinking. The air lift can only be used when it is possible to submerge the pipe to a depth greater than the point of discharge above the surface of the water in the shaft.

Ques. 14.—State how you would lay a good haulage road in a main entry where 12-ton motors are used; the loaded cars weighing 3½ tons, and the track having a 1-per-cent. grade in favor of the loads. Give weight of rails per yard, size of spikes, number and size of ties used, and estimate the cost of 5,000 feet of the track, assuming that the rails cost $26 per ton, ties 10 cents each, spikes $3.75 per keg of 200 pounds, labor for trackmen $2.50 per day, and helpers $1.75 per day.

Ans.—The rails for a 12-ton motor haulage should not be lighter than 40 pounds per yard, which would require $(2\times 5{,}000\times 40)\div(3\times 2{,}240)=59.5$ tons at a cost of $26\times 59.5=\$1{,}547$. For 40-pound rails, use $3\frac{1}{2}'' \times \frac{7}{16}''$ spikes, 12 kegs, at $3.75 per keg = $45; and 4″ × 6″ cross-ties, spaced 2 feet, center to center, 2,500 at 10 cents each = $250. There will be required also, using 24-foot rails, 832 angle or fish-plates, 6,240 pounds, at 1½ cents per pound = $93.60, and 8 kegs bolts, nuts, and washers at $5 per keg = $40; making the total track material $1,975.60. The laying and surfacing of 5,000 feet of track in mine entries, under ordinary conditions, including the handling of the material in the shaft and its distribution in the entry will require, approximately 120 days labor for helpers at $1.75 per day = $210; 50 days, trackmen, at $2.50 per day = $125; and 6 days, drivers, at $2 per day = $12; total for labor $347. The total cost of the track laid is therefore $2,322.60, making no allowance for special grading which might be required at some points in the entry.

The volumetric capacity of a fan is the ratio of the actual volume of air produced to the cubical contents of the fan multiplied by the number of revolutions.

AN ANTHRACITE CRYPTOGRAM

Written for Mines and Minerals

The diamond, which is pure carbon, crystallizes in the isometric system which is similar to the anthracite shown in crystal form in Fig. 1. Graphite, another well-known kind of carbon, crystallizes in the hexagonal system, and consequently, has a different form from that shown in Fig. 1.

Minerals that have definite chemical compositions crystallize from solutions, and since coal is not a definite chemical compound, it has never before to the writer's knowledge been found in crystal form.

All the minerals termed carbonates have a definite chemical composition and contain carbon as a necessary constituent, nevertheless coal varies in chemical composition in different beds and even in the same bed and this adds further interest to the natural cryptogram in Fig. 1; from these facts the following deductions are made:

(*a*) Coal is not a mineral because of its not being a definite chemical compound. (*b*) Coal does not crystallize, because it has not been taken in solution as a chemical compound.

(*c*) Coal before hardening was plastic and was folded and contorted when in that condition; and it is probable that in the anthracite field it was made plastic and afterwards metamorphosed by dynamic earth movements.

(*d*) The anthracite shown in crystal form is an impression made by pyrite in soft plastic material that was afterwards hardened by metamorphism.

Fig. 1. An Anthracite Cryptogram

(*e*) While the anthracite has the isometric form of pyrite, as shown in Fig. 1, it is not a pseudomorph form, for the reason that there has been no interchange of materials; in other words, the pyrite was imbedded in the coal which was in a plastic state.

(*f*) Metamorphosed carbon grades from the free burning variety of Northeastern Pennsylvania anthracite, through the difficultly burning graphitic anthracite of Rhode Island, to graphite.

WEST VIRGINIA MINING ASSOCIATION

The West Virginia Mining Association held its annual meeting at the Willard Hotel, Washington, D. C., December 16, and more than 100 members were in attendance. President W. N. Page presided over the deliberations, and in his annual address, made the statement that, at that time not one life had been lost in West Virginia by a mine explosion for 23 months.

G. H. Caperton, treasurer of the association, read his annual report, which showed that there was on hand a cash balance of $401.44. During the life of the association, 3 years, the receipts have been $13,661, while the expenditures have amounted to $13,259.56.

It was recommended that an additional district be added in the association.

W. D. Ord, M. T. Davis, and Earl Smith, were named as the committee on resolutions.

E. W. Parker, G. O. Smith, and M. R. Campbell, of the Geological Survey, made short addresses, as did also David White, of Charlestown, and Dr. I. C. White, of Morgantown. J. W. Herron, of the C. & O. Railroad, spoke on "Car Allotment," and John Laing, Neill Robinson, and Frank Haas, read interesting papers. Thomas Nelson Page, author of "Santa Claus' Partner," "Two Little Confederates," etc., gave an interesting 10-minute talk. The meeting was both successful and profitable.

COAL-DUST EXPLOSION IN A CEMENT MILL

A most unusual coal-dust explosion by which 8 men were so badly burned that they lived but a short time, while another is not expected to recover, happened at the cement mill of the Portland Cement Co., at Portland, Colo., on January 3. Before the coal is used in burning the cement, it is very finely pulverized, a large quantity of the finely divided dust naturally escaping from the grinders and settling over the walls and floors as in a coal mine. This dust is cleaned up every 2 weeks. While engaged in this work on the day mentioned the dust was either drawn into the boilers and exploded with great violence, or was ignited by coming in contact with a sparking electric motor in the kiln room. The former explanation appears the more reasonable, allying this accident with the explosion in the Washburn Mills, in Minneapolis, Minn., in 1873.

UNITED STATES COAL PRODUCTION FOR 1910

It is estimated by E. W. Parker that between 475 and 485 million tons of coal were mined in 1910.

The following approximate number of short tons were produced by the coal-mining states:

Pennsylvania anthracite	72,468,464*
Pennsylvania bituminous	136,100,000‡
West Virginia	60,000,000*
Ohio	31,500,000*
Alabama	15,000,000*
Tennessee	6,234,922†
Kentucky	9,550,640*
Michigan	2,000,000‡
Colorado	12,089,447†
New Mexico	3,684,627†
Utah	2,526,093†
Montana	3,053,940*
Washington	4,500,000*
Alaska, California, and Oregon	100,000*
Arkansas	2,000,000‡
Wyoming	6,750,000

*E. W. Parker. †State Mine Inspector. ‡Estimated. The coal-mining industry, in Illinois, Kansas, Arkansas, Oklahoma, and Missouri was demoralized by strikes.

Mines and Minerals

ESTABLISHED 1881

PUBLISHED MONTHLY AT SCRANTON, PA.

WESTERN EDITORIAL OFFICE: 728 Equitable Building, Denver, Colo.
CHICAGO OFFICE: 309-311 Michigan Ave.

Entered at the Post Office at Scranton, Pa., as second-class matter

Address all business communications to MINES AND MINERALS, Scranton, Pa.

CABLE ADDRESS, "RETSOF, SCRANTON"

SUBSCRIPTION RATES

Single Copies........25 cents
Yearly Subscriptions, including postage:
To United States, Mexico, Cuba, Porto Rico, Hawaii, and Philippines $2.00
To Canada........2.50
To all other countries........3.00

Remittances should be made by P. O. Order, Express Money Order, Bank Check or Draft, or Registered Letter.

The date after your name on the wrapper is that of the month to which your subscription has been paid. If you do not want to continue your subscription after that time, kindly notify us

Notice to discontinue or change of address should be sent to the Scranton office.

When notifying us of a change of address always gives your FORMER as well as your present address.

COLORADO COAL-MINE COMMISSION

GOVERNOR SHAFROTH, of Colorado, has selected as commissioners to inquire into the recent coal-mine disasters of that state, and to suggest remedies to be incorporated in the laws, Dr. Victor C. Alderson, President of the Colorado School of Mines; John B. Ekeley, Professor of Chemistry at the University of Colorado; Mr. R. D. George, State Geologist; Mr. James Dalrymple, Chief Inspector of Coal Mines.

Without reflecting on the personality of the members of the commission, we are inclined to think that Governor Shafroth would have secured very much better results with a somewhat different commission, or even with the same commission augmented by an equal number of practical mining men. By this we mean, men who are, or have been, engaged in the production of coal, either as mining engineers of high repute or as mine managers, and there should be at least one or two intelligent, practical miners on the commission. Such a commission would, naturally, be rather large, but this is about the only thing the Governor can do, after appointing his regular commission. If, in making the original appointments, the Governor had nominated Doctor Alderson, for instance, as chairman, a mining engineer of education and broad practical experience in coal mining, the chief mine inspector of coal mines and a broad-gauged intelligent miner, the commission for a small one would have been ideal, because a mining engineer would not only be competent to pass on questions of mining methods, but he would be fully as familiar in a practical way with the questions bearing on chemistry and geology as either of the two gentlemen the Governor did nominate. It is to be hoped that even if Governor Shafroth does not himself see the advantage of following the suggestion contained in this editorial, that the gentlemen comprising the present commission will recommend that practical mining men, such as we have referred to, be given representation on the commission.

The preliminary report of this commission has been published in the daily papers of Denver, and we were somewhat inclined to criticise it, but as the report was merely a preliminary one and not definitely codified in the shape of a proposed law, we refrain from such criticism, and will reserve our judgment until the proposed law is codified. At that time we expect to take it up, section by section, commend all of it that we conscientiously can, and, of course, criticise all such portions of it as may be deemed impractical or inimical to the best interests of the mining industry. We include in the statement "the best interests of the mining industry," the interests of every one engaged in coal mining from the humblest trapper to the stockholder.

One statement in the preliminary report of the commission to which we do take exception is that, "a coal mine is, with the possible exception of a powder mill, the most dangerous of all places in which to work."

If the gentlemen of the commission will take the trouble to go over the reports of the mine inspectors of the various coal-mining states and get out the number of fatalities and injuries per thousand men actually engaged in mining and compare it with similar reports pertaining to railroads, they will find that the ratio of death per thousand is from two to three times as great and that the ratio of injuries from four to five times as great in railroading as in coal mining. Furthermore, except in abnormal years, the commission will find that less than 10 per cent. of the deaths due to fatal accidents in mines were caused by gas or dust explosions, and that nearly 60 per cent. were due to falls of roof and coal, with about 15 per cent. due to accidents from cars. They will also find, particularly in the matter of accidents from falls of roof and coal, and accidents from cars, that over 75 per cent. of such accidents were due to absolute carelessness on the part of the victims. All men practically engaged in mining know that these statements are approximately true. Men who are engaged in educational work pertaining to mining, no matter how eminent they may be, are not as familiar with the actual details of mining as they should be to enable them, without the advice of a practical miner, to codify a set of laws which would tend to the production of coal with the utmost safety to the employe, and the property of the employer, without making the cost of production prohibitive.

MINING ENGINEERS AS CITIZENS

WHY IS the mining engineer so indifferent to his duties and privileges as a citizen, is a question asked frequently and answered in many ways. Mining engineers as a rule are not indifferent citizens, even though nomadic and living on the fringe of civilization, they mold public opinion to a larger extent in their particular bailiwick than is supposed. They do not touch politics for office, but use their influence for the good of the country generally and their own business particularly, without public notice. Their work demands all their attention, which prevents their attaining prominence in the business world, in politics, or in letters, and being ethical in their ideas of publicity they are seldom heard of outside their own profession. When mining engineers meet in convention they talk mining; in part of their spare moments they talk, read, or think mining; but the remainder of their lives is not shadowy or unsubstantial, for the mining engineer has an economical end to his business second to none, either mercantile or banking. His mental development is not that of a specialist on some particular branch, as some seem to think. If this were so his vision would be narrowed and strabismic, and he would fall into a groove where he might become an expert on a mining specialty, but never a mining engineer. The mental development of the specialist is not that of the mining engineer, for the latter must be informed on civil and constructive engineering, and, in addition, must be a fair chemist, mineralogist, geologist, economist, and also be endowed with executive ability. Almost any intelligent man can run a mine after it has been put in condition and systematized by a mining engineer, provided he has the mining engineer to consult with occasionally; but not every one can put a mine in condition, establish an economical system of mining, and the proper method of keeping cost sheets.

Probably no class of men work harder and to better advantage for their country than mining engineers; therefore, if their names do not appear in print as frequently as lawyers, they are far from being negligible as public citizens.

GOVERNMENT OIL LAND SUIT

ON DECEMBER 10 a suit was filed in the United States District Court, at Los Angeles, Cal., by United States District Attorney A. A. McCormick in the name of Attorney General Geo. W. Wickersham, against the Southern Pacific Co.; Southern Pacific Railroad Co., Homer S. King, trustee; James K. Wilson, trustee; Central Trust Co. of New York; Equitable Trust Co., of New York, and Kern Trading and Oil Co., to recover title to 6,109 acres of land in the Midway district, now claimed to be unlawfully held by the defendants.

This is the long-expected suit about which so much was heard at the Los Angeles convention of the American Mining Congress in the latter part of September last. It is based upon the construction to be placed upon the act of Congress of July 27, 1866, and a subsequent resolution dated June 28, 1870. Under the terms of the above, the railroad company, in order to encourage its construction, was allowed to patent every alternate odd-numbered section on each side of its right of way, but in this original grant mineral lands, either known to be such at the time or subsequently proved to be mineral bearing, were specifically excluded, and it is this clause which is said to render the patents invalid. It is further claimed that maps on file in the Surveyor-General's office, and dated 1902, show that at that time these lands were classified as mineral bearing, while the formal patents were not granted to the Southern Pacific or its trustees until 1904.

Not only are misrepresentation, fraud, and deceit charged, but the bill recites that the Government's own officials were negligent in granting patents to lands to the railroad company without any investigation whatsoever, relying entirely upon the statements of the defendant corporation as to the character of the lands.

The Kern Trading and Oil Co. is a subsidiary of the Southern Pacific Railroad, and in the bill of complaint is stated to have been organized as a dummy for the purpose of furthering the railroad's alleged "fraudulent, dishonest, and unlawful purpose of witholding this land from its rightful owner," the United States.

The outcome of this suit will naturally be awaited with much interest, as upon its successful issue will depend other suits involving title to many hundreds of thousands of acres of land now said to be unlawfully in the hands of corporations and individuals. In the case at issue the lands, being oil bearing, are said to be worth $10,000,000, and other lands now in possession of the railroad and aggregating $50,000,000 are also at stake. An interesting point is the bearing the alleged neglect of the Government's own officials will have upon the case. Is the Government responsible for their negligence or not?

Justly or unjustly, the people of Southern California seem to feel that this suit will never be brought to conclusion, pointing to the affiliations of the Attorney General and the Secretary of the Interior, the strong "pull" of the Southern Pacific, and the well-known flaccidity and lack of back bone on the part of the administration. Perhaps Washington has waked up at last, and after the rebuke of November 8 may now be willing to carry out the plainly expressed wishes of the people. Let us hope so.

Book Review

A Gold Mine in Tennessee Clays. Tennessee Geological Survey, Press Bulletin No. 8, G. H. Ashley, State Geologist, Nashville, Tenn.

American Red-Cross Abridged Textbook on First Aid. This pocket edition is prepared for general readers, students, boy scouts, schools, etc. There has already been published an "industrial edition" adapted to the special needs of miners, railway employes, workers in iron and large manufacturing establishments. This edition will be issued also in Italian, Slovak, Polish, and Lithuanian. This manual of instruction is by Major Charles Lynch, Medical Corps of the United States Army; 183 pages, 55 illustrations. P. Blakiston's Son & Co., Philadelphia, Pa., publishers, price 30 cents.

Gurley's Manual, 45th edition, 516 pages with index. This book is illustrative of American engineers' and surveyors' instruments. It furnishes instruction in the adjustment and use of field instruments in as simple a manner as is consistent with the subject. No attempt is made to be technical or deal with surveying as a study. All instruments used in surveying and mapping are illustrated. Gurley's Manual is in nearly every engineer's office and can be had if not, for 50 cents, from W. and L. E. Gurley, Troy, N. Y., or Seattle, Wash.

Rock Drills, by Eustace M. Weston, Associate School of Mines, Ballarat; Reef Lecturer on Mining, Transvaal University College; 367 8mo pages with index; 193 illustrations; 16 chapters as follows: Historical; Standard Piston Drills; Hammer Drills; Electric Drills; Operating Rock Drills; Piston Drills Designed to Use Air Expansively; Philosophy of the Process of Drilling Rock; Repair and Maintenance of Rock Drills; Drill Steel and Drill Bits; Explosives and Their Use; Theory of Blasting With High Explosives; Examples of Rock Drill Practice, Africa and Australia; of America; Rock Drill Tests and Contests; Notes on the Use of Compressed Air. Mr. Weston has covered the ground thoroughly with the exception of tunnel driving, but for this neglect he makes up in other ways. In the chapter on the Repair and Maintenance of Rock Drills there is an important element lacking; namely, the care of rock drills. A large part of the cost of repairs in rock drills comes from the maltreatment they receive in handling, setting up, pointing, and during running, and not from natural wear alone. The book is published by McGraw-Hill Book Co., New York City, and sold at $4 net.

Practical Stamp Milling and Amalgamation, by H. W. MacFarren, 166 pages and index; no illustrations; postpaid $2. Publishers, Mining and Scientific Press, San Francisco, Cal.; Mining Magazine, 819 Salisbury House, London. There are other books on stamp milling and volumes written about this simplest of crushing machines. "No machine can compare with it in amalgamating or in preparing an ore for concentration, except where the friable nature of the material requires stage crushing." "So thoroughly can it be depended upon that it has passed into an axiom that a standard stamp mill has never caused the closing of a property by failing to do good work where work was possible, and that it has replaced every other kind of crushing machine." "The height of drop of the stamps in a battery, and the other adjustments, are made for each ore according to its hardness and fineness." "The subject of battery foundations is important, and the seal of approval has been placed on concrete mortar blocks; but while realizing that a good concrete block may be perfect, it must be admitted that in a large number of cases they have been unsatisfactory from defective construction, while the wooden block has given satisfaction in practically every instance." "The concrete block gives a cleaner looking mill, and does not decay." "By its solidity and non-cushioning effect, it increases the capacity of a battery sometimes as much as 33⅓ per cent." "Mortars are made of cast iron and approximately 6 or more times heavier than the weight of the stamp to be used in them." "It is generally cheaper to use steel shoes and dies than iron ones despite its increased cost, on account of the smaller consumption of steel per ton of ore crushed, and the less time lost in renewals and setting of the tappets." "The life of steel shoes and dies may roughly be estimated at 4 months or less." "No die should be permitted to stand higher or lower than another, or it will cause its stamp to 'pound' or to 'cushion' through having too thin or too thick a bed of pulp over it." "In putting on a new set of shoes, the stems are first cleaned of the grease below the tappets by passing a long strip of burlap or cloth wet with kerosene or gasoline about the stem and alternately pulling each end of the cloth until the stem is clean." "This is necessary as it would be impossible to make two slippery greasy metal surfaces hold together."

The reader will understand from the above quotations taken at random from the book that the author is practical; that his statements are facts and that these are followed up with the reasons why. The book is the product of experience enriched by observation; and written without adjectives. Did the reader ever try to fill a fountain pen that had accumulated a lot of bubbles; if so, he found it disparaging. Bubbles in a fountain pen barrel are like adjectives in a book. Mr. MacFarren has written a most valuable book, devoid of theoretical discussions and academic distinctions but replete with the details of practical stamp milling. It might be truthfully said that it was the ink and not the bubbles that made the author's fountain pen write.

Books to be Reviewed. Elementary Crystallography, being Part 1 of General Mineralogy, by W. S. Bayley, Ph. D. McGraw-Hill Book Co., New York City.

More Recent Cyanide Practice, edited by H. Foster Bain; Mining and Scientific Press, San Francisco; price $2. This book supplements "Recent Cyanide Practice," published by the same firm.

Manual for Assayers and Chemists, by W. H. Seamon. Published by John Wiley & Sons, New York. Price $2.50.

Books Received

United States Geological Survey Publications, Washington, D. C. Thirty-First Annual Report of the Director of the United States Geological Survey to the Secretary of the Interior for the Fiscal Year Ended June 30, 1910. Bulletin 430,

Geological Notes, by G. Henriksen, Inspector of Mines, Bergen, Norway.

COMMON CASTING COPPER

A very useful alloy for soldering irons, copper hammers, and all copper castings, where high conductivity is not essential, is given by the *Foundry*, as copper 96 pounds, zinc 4 pounds. This formula will always be found satisfactory, as the zinc is sufficiently high to ensure solidity, whether ingot or scrap copper is used. The color of the metal is sufficiently red to pass for copper, and the castings can be relied upon to show up clean, bright, sound, and free from abnormal shrinkage. The copper should be melted in a clean crucible, and, when first charged, two tablespoonfuls of salt are added. The chlorine gas from this protects the copper from excessive oxidation until it settles down in a liquid state, when it should be covered with charcoal, hardwood chips, tan bark, or any organic substance that forms charcoal. The zinc should be added after the copper is melted. The mixture is then thoroughly stirred and the metal is allowed to superheat a few minutes before being cast. If the color of the metal is not sufficiently red, the zinc with careful melting, may be reduced to 2 per cent.

It is believed that the refuse from the mines is capable of yielding profit in the way of gas and briquets. It is argued that if coal men gave the same attention to the problem of by-products as do manufacturers, the rewards would go a long way toward meeting their fixed expenses, and that the labor problem would diminish in importance.—*Fuel.*

RESTORING DREDGED GROUND

Written for Mines and Minerals, by A. S. Atkinson

Australian Gold Dredging Method Which Leaves the Ground in Condition for Agriculture

In view of the constantly increasing use of the modern big gold dredges, and the constantly recurring question of the damage they do to the land which might otherwise be used for agricultural purposes, the efforts being made in Australia to restore dredged ground to a condition which permits of agricultural use should be of more than general interest. The big bucket dredges have come to stay, and their operation in many parts of the world is the most economical of any method yet invented for recovering the precious metal. Even in Alaska and the Klondike, where the cost of getting the dredges there and set up is enormous, the work of the gold dredges has advanced rapidly. It costs something like $120,000 to get one of these dredges in Nome ready for operation, and yet in spite of this first heavy initial cost they are proving extremely profitable.

In California the gold dredges have been in operation so long that their operation has caused more or less friction between the mining companies and the agriculturists. The same is true in parts of Australia. It may be said that in some respects the question is more acute there than in our own country. In the state of Victoria, Australia, the gold dredge has been in operation on such a stupendous scale that it has threatened large areas of agricultural land, and the conflict of interests began early and reached an acute stage some time ago.

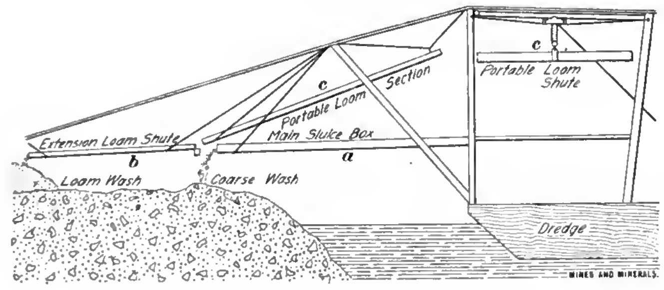

Fig. 1. Handling Loam and Gravel

From official figures, 2 years ago there were 133 dredging plants in operation in the state of Victoria, but only 45 of these were of the bucket type. The rest were pump hydraulic sluices, or the four-jet elevators. The bucket type of dredges are mammoth affairs, three of them capable of treating more than 9,000 cubic yards of soil a week, and four of 8,000 yards capacity. Altogether these 133 dredging plants treated in 1907 over 20,000,000 cubic yards of soil, and obtained nearly 98,000 ounces of gold. About 2,500 men were employed in operating the plants.

Naturally, this wholesale dredging turned up considerable soil,and the fear that a good deal of valuable agricultural and grazing land would thereby be permanently injured led to the adoption of plans for restoring the land thus dredged, so it could be utilized for farming purposes. The development of this work has been a feature of the past year's dredging and a good deal of progress has been made. It is not claimed that entire success has been reached, or that the land is just as good after the dredging as before, but it is quite evident that it is not rendered worthless by the miners.

The method of restoring the soil consists in nearly every instance of some system of classifying and separating the dredged material. By depositing the fine sand on top the dredged area is partially restored to its former productiveness.

In suitable ground where the material is of a loose, friable, sandy nature, the tendency in bucket dredging has been to discard screens and elevators. In their place riffle-bottomed sluice boxes are used. Sand launders are used so that the silt and coarse wash are automatically separated, and with the proper distribution of the material the soil is not entirely destroyed. The sand launders are laid with cocoa matting placed under sheet iron with ¼ to 1-inch openings. This method is an improvement upon the old, so far as extracting and saving the gold is concerned. It is more economical in initial cost and maintenance, and about one twenty-fifth of the gold is saved in these sand launders.

Where the gravel contains much clay this method is not so simple and easy of adoption, for the balls of clay are not always broken up and they carry a good deal of the gold away into the tailing. In order to overcome this difficulty a number of devices have been tried experimentally. One of these consists of a revolving screen that works around a fixed axle, and inside iron chains are hooked up loosely, and attached to the bar are spikes or teeth. The balls of clay are caught between these teeth and the loose chains, so that they are broken up completely. The object of the loose chains is to agitate and stir up the material, and the fixed teeth of iron then act as a sort of rake to break up all coarse particles not separated by the agitation of the chains. As the screen revolves this action of chains and teeth goes on steadily and thoroughly digests all coarse clay substances that may enter it.

In order to solve the question of restoring dredged ground it was found that preliminary work must be undertaken to suit different kinds of soil. The first step was to classify and separate the different materials, and then the problem of distributing them so that the lighter soil could be deposited on the top could be worked out. In Australia, as elsewhere, stripping in advance has been found necessary to keep the surface soil separate and from entering the dredge. In the sand-box arrangements described, the fine silt is apt to be carried down into the underlying coarse gravel in spite of all that can be done, and thus it becomes lost to all future agricultural purposes. Stripping the surface soil in advance, with as little water as possible, the rich top soil can be separated.

At three different places in the state of Victoria excellent results have been obtained through some of the various devices in restoring dredged land. These are at the plants on Crooked River, on Livingston Creek, and at Eurobin, on Owens River, where several dredges are at work. At the latter place the dredges work the gravel and surface soil separately. The first operation is to strip the top soil and deposit it some distance off, and then the gravel is dredged and deposited nearer the dredge. The dredges on Owens River are replacing from 80 to 85 per cent. of the surface loam on top of the dredged gravel, so that the land, after all operations have ceased, is nearly as good for agricultural and grazing purposes as beforehand.

An idea of the working of this type of dredge, which has become general in parts of Australia where resurfacing of dredged land is considered imperative, may be gained from Fig. 1. The main sluice box *a* of this dredge is 4 feet wide and 18 inches deep. Its length from the drop-chute bars to the end of the delivery is 56½ feet, and an opening 5 feet long extends from the lower end of the main sluice box to the upper end of the extension loam launder *b*. When ordinary dredging is in operation the special loam chute is not in use. This extension loam launder is of the same width as the main launder at its upper end, but it gradually tapers down to less than half the width and half the depth. The upper end of the launder is movable, and can be raised or lowered as needed, so that when ordinary dredging is going on it is out of the way. It can be quickly lowered, however, into position when needed, and without much interruption of work.

This movable section *c* of the loam launder is made of iron plate bent into a semicircular form, and along the upper edges there are light iron flanges to fit on top of the upright sides of the main sluice box. This section when dropped into position extends along the top of the main sluice and bridges the 5-foot

space between the end of the sluice and the special extension loam launder. The resoiling material thus passes along this movable part into the extension launder and is deposited some distance from the gravel heap.

The movable sections of the launder are controlled by a continuous wire rope which is operated by a winch on the dredge framework. The device is so simple that it takes only 3 minutes to drop or lower the loam launder. Thus when the dredge is moved forward the top soil can be rapidly stripped and deposited some distance off, and then when the gravel bed is reached an interruption of only 3 minutes is required to change from top soil dredging to gravel dredging. Advance stripping thus proceeds steadily for a few hours each morning, and then the gravel dredging is begun. In fact, it has been found that 2 or 3 hours of advance stripping with this type of dredge prepares enough ground for ordinary gravel dredging that occupies the balance of the 24 hours. On an average it has been found that in advance stripping the top soil is removed at the rate of about 85 cubic yards per hour, against 60 cubic yards for gravel dredging.

In order to make advance stripping successful in this way a certain amount of water is needed to wash the loam along the launder. But the amount of water is far less than that required to keep the sluice box clear of ordinary gravel. Probably 10 per cent. of the amount of water required for ordinary gravel dredging will answer for advance stripping. The saving of this top soil from being washed away by the water and thus being lost in the gravel bed is a matter that requires a little additional forethought and preparation. Usually this is done by building small dams of brush, timber, or stone, so that the liquid part of the loam cannot rush back into the pit. There is bound to be a certain amount of waste in this way, but some dredging companies in Australia have had constructed sheet-iron spiles which are driven a foot into the soil around the loam beds to form protecting dams. These pieces of sheet iron are moved from place to place after the water in the soil has had a chance to percolate through the ground. Some sort of a movable dam of this nature is found to be more economical than stone or brush dams. Material for the latter is not always to be found when needed. A set of sheet irons for dam building will last indefinitely, and they can be set up as easily as a stone dam. The sheet irons are slightly curved so that a semicircular dam can be formed around any loam heap, with corner pieces turned at a sharp angle.

This process of saving the top soil for restoring the land to its previous fertile condition has, in addition to solving the problem of resurfacing, actually improved the economical output of the gold dredges. It has been found that more gold can be saved by separately stripping and conveying the overburden through the loam launder than by sending both gravel and overburden together through the sluice box. The result of this is that surface-restoration methods in gold dredging is becoming popular and general in many parts of Australia. There is no longer any conflict between the farmers and the miners in this respect, especially where the most advanced methods of dredging are pursued.

WET ASSAY OF GOLD

In the October issue of Mines and Minerals in the article on "Wet Assay of Gold" the exact ingredients of the solution were not given, and we are again indebted to Doctor Jerome Davis, of Raymond, Cal., for the correction. The solution is composed of potassium iodide and iodine, not potassium iodide and potassium. The solution is made as follows: Potassium iodide, 4 ounces; resublimed iodine, 2 ounces; distilled water, 94 ounces.

He further states that in this reaction the gold, while it forms a button, when the mercury is boiled out is in its primitive shape, that is crystalline. These crystals are needle shaped and are very distinct. While gold crystals are sometimes found native it is seldom that they are obtained artificially and at the same time give the yellow color of gold. Doctor Davis sends a number of these crystals whose shapes under a microscope are plainly seen. He further states that the crystalline form of gold is common in some of the dark slates of California, and some of the nuggets are beautiful. Sometimes the gold is in the form of a stalactite, which of course leads up to the well-known wire gold form.

THE LOG WASHER IN ZINC MINING

Written for Mines and Minerals, by Lucius L. Wittich

In Southern Missouri, 20 miles from West Plains, the nearest railroad point, is the Alice Mine of the Empire Zinc Co. The ore, which is zinc carbonate, or smithsonite, is shipped to the company's reduction plant at Mineral Point, Wis., where it is converted into oxide for the manufacture of paints. No other zinc producers are near the Alice Mine, which has been in almost constant operation for 12 years and has turned out as high as 58 tons of coarse and 96 tons of fine carbonates per week, 3 days of which time were devoted to conveying the ore to railroad.

To dress the Alice Mine ore, the old style Archimedean log washer, the invention of the Greek mathematician, is employed, and the log washer of today is little changed from the log washer of centuries ago. At the Alice Mine a double log washer is used, which also takes the place of jigs. Throughout the zinc and lead districts of Southern Missouri, Southeast Kansas, Northeast Oklahoma, and Northern Oklahoma, the log washer is not in use. The Alice is one of the few exceptions, and because of its remoteness from other districts it is out of the line of general travel and is seldom visited.

The hard oak log is 26 feet long and 16 inches in diameter. "Flights" of iron are attached spirally at intervals of 20 inches, from center to center, along the flat faces of the log, which is octagonal, and are so arranged that when the log revolves it has the effect of an auger. The logs are inclined at an angle of 4 degrees so that material emptied into the lower end of the trough will be carried toward the upper end. A constant stream of water empties into the trough at the upper end, washing away the fine dirt and mud, while the coarser ores are gradually worked to the upper end of the trough. Here the finer ore passes through a slat screen with ¾-inch openings while the coarser passes over. The different sizes go to different bins.

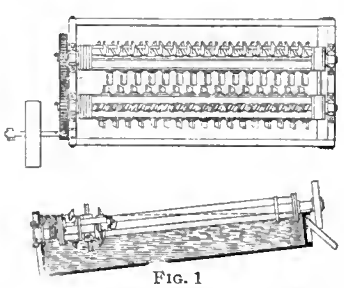

Fig. 1

Before entering the log washer the mine dirt is screened through a 5-inch bar grizzly, the coarse being culled out while all that passes through goes to the washer. The trough is built sufficiently large to permit of the easy accommodation of the logs, with the flights attached, there still being a space of 10 inches between the tips of the flights and the bottom of the trough, which, in the course of time becomes bedded with fine ore. This condition is desirable and the work of the log is more effective.

The flights are 9 inches long, 4 inches wide, and ¾-inch thick, and are attached to the log with lag screws. Fig. 1 shows how the faces of the flights are slanted to create a general forward movement of any material that is emptied into the trough.

The operations at the Alice Mine are conducted largely in open pits, although several shafts have been put down to ore, which is trammed to the odd little plant. The ore, which outcrops in places, is now being worked to a depth of 40 feet, and the

company reports 20,000 tons blocked out. It contains some iron and much flint. Of the mass hoisted for treatment, 60 per cent. is ore.

For hoisting, a 30-horsepower engine is used. For operating the washer, which revolves at the rate of 17 times per minute, there is a 10-horsepower engine stationed at a pond ¼ of a mile away; a 2-inch pump is operated by a 20-horsepower boiler. The water, after being elevated 50 feet to the mines, is used in the washer.

In the early stages of the development of the Alice Mine the ground was scooped out with scrapers, and wagons were employed to haul the dirt direct to the plant.

Laborers are hard to find, and are shiftless as a rule when found. About 12 men are employed. The cost of carting the ore to railroad is $2.75 per ton.

FAKE OIL COMPANIES

By Louis E. Aubury

Owing to the many misrepresentations and fraudulent practices resorted to by fake oil companies operating in California, resulting in continuous complaints to the State Mining Bureau, it is believed that investors at large may be benefited to an extent by the publication of a few suggestions from the Bureau, covering the initial points it is advisable to consider before delivering their money, never to return, into the hands of operators of these fake companies, where the intention is purely and simply to sell stock, and without the first idea or expectation of ever paying dividends.

The following are a few of the principal points suggested:

Has the advertising oil company under consideration a title to the alleged oil land being exploited; in what manner and for what consideration was title acquired, and is it actually within proven or unproven territory?

Many companies operating in unproven territory, advertise that they "own," or have "secured" such and such tracts of land; that they are within proven oil territory, and that the purchase was made for so much of the company's stock in addition to a cash consideration—frequently quite a large one—and added thereto is the payment of a royalty to the owner or owners when production is reached; the latter the only consideration against which the locator of the land will ever have any claim, and that a remote one.

This is of course an extreme, but not an unusual case of imposition, cited for the purpose of illustration, and with a view to opening up to prospective stockholders an avenue of thought which in turn may suggest many other material points not referred to herein.

Lands advertised in this manner are more often merely locations of government land, subject to numerous requirements of law and open to attack and litigation that may eventually render acquisition of the title from the government to the company in question an impossibility—and under any circumstances the payment of such a large and disproportionate consideration to the promoters of the company, stamps it on its face as a proposition purely for the benefit of the operators at the expense of the stockholders.

The promotion stock also is of course unloaded (since it is not intended the project shall prove a success) and the proceeds pocketed, in addition to the cash payments due on account of having discovered the land, and which are derived from the sale of the balance of the stock, which the liberal promoter in his goodness of heart also allows a grateful and eager public to acquire, with the understanding that an opportunity of a lifetime is presented and under no circumstances should be permitted to escape, even though all else is sacrificed. This, it is a matter of record, is done in only too many instances to the everlasting sorrow of the purchaser investing his or her all.

Continuing upon this subject of payment, for example, a company incorporated for $1,000,000, par value per share $1, advises in its prospectus that 500,000 shares have been "paid" for its property; which means literally that one-half of the capitalization of the company benefits only the promoters who discovered this valuable (?) tract in question—or more to the point, that the tract in question would answer their purpose. Possibly it is a location very close to the *edge of productive oil lands* acquired from the locator for a mere song, or solely upon an agreement to pay a royalty from the production derived from operating the land, there being many locators upon the edge of production, and on lands the geological formation of which precludes any possibility of striking oil in paying quantities, or at all, but who have the miners' undying faith in a bright and paying future for their claims. These claimants, usually having little or no money, are readily annexed by the fake promoter under such terms as above indicated; and operations on the land are begun and carried on upon an extensive scale, since these wily promoters in many instances extend their persuasive and convincing abilities to the supply companies, who furnish on credit all the necessary equipment and eventually seize it for failure of payment—but all that is desired has been accomplished by the fake promoter and permits him to begin immediate and elaborate operations which he advertises to the fullest extent, and more if possible; reciting in many cases just such a proposition as is outlined in the foregoing, but in perverted language so cunningly worded that the actual facts are not grasped by the uninitiated, whose attention and interest is maybe more carefully centered upon an illustration on the front page showing the oil fields and indicated in the background by an arrow, "The Lakeview Gusher," and in the foreground the company's derrick, with a note in a conspicuous place on the page something like this: "Just 9,000 feet to the northeast of our property is the great Lakeview Gusher, etc."

Since 9,000 feet is more than a mile and a half distant, it is by no means a surety that production is a possibility at the point the advertising company is operating.

A close study of the average fake prospectus will afford much food for reflection and investigation upon just such points as that above mentioned.

Are the officers of the company you have under consideration in good standing? Obtain a report on them from some commercial company.

The most extensive fake operators have followed their nefarious practice continuously for years, during which time they have repeatedly been roasted and fully exposed by the newspapers in all parts of the country. Notwithstanding this, they regularly incorporate company after company just as fast as the old ones play out, and with the same result, a certain class of the investing public never failing in its desire to contribute to the purses of these worse than highwaymen.

In addition, several other points are referred to as worthy of the most careful investigation—such as whether the company in question is overcapitalized, are commissions deducted from the sale of stock, and what are the salaries paid the officers of the company (in fake companies, of course, the promoters), all of which questions involve the scheme of such operators to make the company a paying proposition—for themselves.

It is not intended or believed that this suggestion will alarm the investing public to an unhealthy degree; nor is it intended to convey the idea that there are not any number of perfectly honest and legitimate enterprises worthy of consideration and investment, or that wildcatting in unproven territory is not the true source of the present wonderful production of oil in California, and deserves the most liberal encouragement from those who fully understand the chances they are taking and who can afford to invest in what may properly be called a gamble; but it is intended to, if possible, stimulate the stock-buying public into making a more thorough and careful investigation before placing its money in the hands of these fake operators solely upon the criminal misrepresentations contained in their exaggerated advertising literature.

CORRESPONDENCE

Haulage

Editor Mines and Minerals:

SIR:—Is it possible to have an endless-rope haulage for a distance of 1½ miles to bring coal out of a mine and pass around a curve at the foot of an incline or slope to a tipple, the length of the incline or slope to tipple top being 1,200 feet, making an angle with the horizon 35 degrees, the cars to carry from 2,000 pounds to 2,500 pounds of coal? If it is possible, what system of endless haulage would you prefer, rope on top or under cars (the cars are well topped)? What size and kind of cable would it take? What horsepower and kind of engine would you prefer?

If the above is not economically possible, what system would you prefer to hoist coal from the foot of an incline to the tipple top, 1,200 feet, making an angle of 35 degrees? Name the system of haulage you would adopt with size of cable and engine. CHESTER MOON

Alberta, Canada

THE LEYDEN, COLO., MINE FIRE

On December 14, 1910, 10 men were suffocated in lignite mines at Leyden, Colo., by a fire, the origin of which is unknown. Leyden is 14 miles west of Denver, near the foot-hills of the Rocky Mountains. The seam worked is from 8 to 12 feet in thickness and does not generate gas. The analysis of the seam, approximately 16.50 per cent. moisture, 3.25 per cent. ash, 31.25 per cent. volatile matter, 48.50 per cent. fixed carbon, and sulphur under .50 per cent., would indicate that the freshly mined coal, at least, was not inflammable. The mine was maintained in most excellent condition, but was regularly watered on Saturdays and Sundays as a matter of precaution.

The surface plant was recognized as one of the best in the state and aside from the usual head-frame and tipple, consisted of a battery of 7 boilers, hoisting engine, air compressor, electric generator with the usual machine and repair shops, all of which were destroyed by the fire, entailing a loss of between $85,000 and $100,000. The capacity of the plant was about 1,500 tons daily, and 275 men were employed.

MEXICAN TERRITORY OF QUINTANA ROO

By William W. Canada, Vera Cruz

The territory of Quintana Roo forms a part of the peninsula of Yucatan, and is to all intents and purposes "terra incognita" to both the inhabitants of Mexico and the United States. Its area approximates 25,000 square miles, between the 18th and 21st parallels of latitude. It has a coast line of about 500 miles along the eastern shore of Yucatan, and is bounded on the north by the state of Yucatan, on the east by the Caribbean Sea, on the south and southwest by British Honduras and Guatemala, and on the west by the state of Campeche. The entire coast is low and sandy, studded with reefs which extend some 500 yards from the mainland.

There are a few natural harbors on this coast where a vessel may find shelter against any winds except those from the north. The average depth of water is about 18 feet. Bahia de la Ascencion and Bahia del Espiritu Santo are the chief harbors. The Mexican Government commenced to construct an artificial harbor at Xcalak, the geographical position of which is 87° 48′ longitude and 18° 15′ 30″ north latitude. It is the only practical natural outlet for the products of the interior.

So far reefs have been blasted and an entrance has been made having an average depth of water of about 20 feet at mean low tide. The port, when completed, will cover over 100 acres. At present all construction work has ceased. There are custom houses at the two ports of entry, Bahia de la Ascencion and Payo Obispo (Puerto de Chetumal).

The territory of Quintana Roo has but one navigable river, the Rio Hondo, which empties into the Bahia de Chetumal and also forms the boundary between British Honduras and Mexico. Once across the bar at the entrance to the river, it is navigable some 80 miles from the coast; but on the bar referred to only about 6 feet of water is found. The Rio Hondo can only be entered from the Bahia de Chetumal on the Mexican side of the river, for there is an old Spanish galleon sunk in the center of its mouth, causing a silting of the British side.

The main obstacle to opening up the country is the yet incomplete subjugation of the Maya Indians, who hold the entire territory with the exception of the strip forming the coast line. Little by little, however, they are being forced farther back into the interior.

Evidence of the existence of coal, petroleum, and asphalt is not wanting, though no prospecting has yet been done with a view of developing this field. There is evidence that copper has been mined in large quantities and that it was shipped out of this country. The entire region hereabouts is cupriferous, and hence even the water is affected, for it is unfit for use and cannot even be utilized in some instances for feedwater in steam boilers.

On the shores of the Bahia de la Ascencion and at Campamento Vega piles of copper ore of a high grade are occasionally found among the wreckage, which would indicate that at some time long ago ore was shipped from here. Another strong indication of the existence of copper is proved by the Rio Azul (Blue River), an insignificant affluent of the Rio Hondo. The water is actually blue with the amount of sulphate of copper it contains. In the dry season it carries as high as 6 per cent. of copper in solution, and crystals of the sulphate are deposited on the margin of the stream. It may therefore be safely assumed that immense copper ore deposits must exist in this vicinity. Springs having their sources in the neighborhood of the Bacalar Laguna give evidence also of the presence of copper.

There are no public records to which one may refer. If they ever existed, they are now lost or destroyed, and nothing relating to former mining operations is known with any degree of certainty. In the church library at Corozal, in British Honduras, there is a small work in which two Spanish padres relate their experiences while ascending the Rio Hondo in the time of the first Spanish viceroys. Among other matters, it is mentioned by these priests that they had found in their travels a large number of copper utensils of all descriptions, which must have been turned out by the Indians of that time or before. The priests, however, did not discover the source of the copper ore.

The ancient ruins of cities throughout the present known territory are positive indications of the existence of a large and prosperous population before or since the time of the Spanish conquest, of which there are no other traces left. Izmul, one of these abandoned cities, has in its immediate vicinity the ruins of prehistoric structures, some of them of enormous size and beautifully sculptured. Judging from present indications, the ancient town must have housed at least 50,000 people. There is not even a trace to be found of a civilized being anywhere within 100 miles from there.

No doubt can exist that this region was very thickly settled at some time, that its inhabitants were highly civilized, as is proved by their architecture, and that the country must have produced something not known at the present time. The destruction and abandonment visible at every hand was doubtless due to the internecine wars among the natives themselves.

A noteworthy instance of the intelligence and civilization of the people at some time remote is clearly demonstrated by an artificial waterway constructed by them. Reference is made to what is now known as the Rio Kik. This is an artificial canal connecting the Bahia de Chetumal with the Bahia de la Ascencion, by way of the Bahia de Espiritu Santo. Unde-

niable traces of the embankments, constructed of coral rocks, and of the watch towers along its length, are plainly seen. The engineering skill, as shown in this work, was of a high order, as the construction of this canal reduced the distance between the extreme points mentioned from 300 miles on sea to 60 miles by canal, and at the same time avoided the dangers attending coastwise navigation in those days.

Present labor conditions are not favorable to the intending settler in this region. The native is not to be counted on, and all labor must be brought from other parts. Dyewood, cedar, and mahogany are gotten out by negro labor from British Honduras and Jamaica. The chicle gatherers have come from Tuxpan, state of Vera Cruz. The Maya Indian will not work. He may possibly plant a small patch of corn, and this, with his fishing, will keep him content. Should he develop a taste for meat, he finds game in the woods.

EDUCATIONAL

Various lines of research work are being carried on in the post-graduate electrical engineering course of the Massachusetts Institute of Technology. Professors Pender and Wickenden have charge of the work. Part of the research work relates to the effects of heat treatment on the magnetic qualities of silicon iron; certain transient phenomena that may occur in long electric circuits; the effect of high frequencies on the permeability of iron; the effective resistance and reactance of steel rails when conveying alternating currents; the selective action of spark-gap lightning arresters with respect to frequency; the reflection of light from walls or ceilings; the disruptive strength of rubber-insulated coatings on wires, etc. Certain of these are continuations of work started last year, and researches in each will be carried on as may be convenient and needful to get knowledge of the phenomena under investigation.

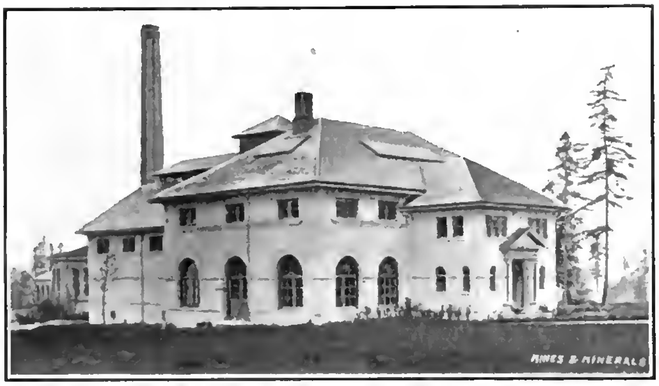

Fig. 1. Mines Building, University of Washington

The Pennsylvania State College School of Mines has a mine-rescue station whose object is to give instruction in mine-rescue apparatus and work. There is a large "smoke room" built gas-tight, in which noxious and unbreathable gases may be liberated, and in which the men may be trained in the use of the helmets in such atmospheres. In the "smoke room" there is a wooden structure representing a mine entry with an overcast, and students are trained to enter this with the helmets, and working in the noxious atmosphere, to build brick stoppings, to climb through the overcast, carrying loads, and to do other work such as would have to be done by a rescue party. On the night of the opening, the "smoke room" was filled with the fumes of burning sulphur, followed by nitrous oxide, the smoke becoming so dense that the electric lights carried by men in the room could not be seen at a distance of 6 inches. The room is provided with glass doors and windows, which permit the interior to be seen from the outside.

At the University of Washington School of Mines, Dean Milnor Roberts has started a short course in mining for practical mining men. Fig. 1 shows the Mines Building, which has been newly equipped with assay furnaces, additional balances, power-driven sampling equipment, and drafting tables. All the usual metallurgical machinery, stamps, rolls, crushers, concentrating tables, classifiers, etc., are installed, so that instruction may be given in the following subjects: The mineral industry, mining, fire assaying, metallurgy, chemistry, mineralogy, geology, mining law, and surveying. Trips to mines, mills, and smelters are also contemplated. No examinations are required for entrance to the short course, and the studies are so arranged that any person interested in mining may follow them, regardless of his previous training. There are no charges, except for books and materials actually used. A full description of the course may be obtained by applying to Dean Milnor Roberts, University of Washington, Seattle.

DIAMONDS IN GERMAN SOUTH AFRICA

Interest has been awakened during the past year by the discovery of an extensive diamondiferous region in the German colony in southwest Africa, near Luderitz Bay. The character of the newly discovered deposits is widely different from that of the peculiar "blue earth" of the great "pockets" in and near Kimberley. The diamonds of the German colony are found scattered in the coarse sand covering an extensive area, in company with agates and others of the more valued forms of quartz. For the most part they occur in the form of tolerably perfect octahedra, and are of the first quality. Their weight is, however, almost uniformly low, ranging from one-fifth to three-fourths of a carat. The average weight is about one-third of a carat.

The novel form of occurrence in these diamond fields has awakened scientific curiosity. Geologists have, in rare instances, encountered limited areas of sand containing well-formed diamonds unaccompanied by the minerals usually associated with this precious stone. But never before has the phenomenon been observed on a scale warranting industrial exploitation.

The diamonds are found in an irregular depression of a desolate region about 1 mile broad by some 30 long, stretching in an arc from Luderitz Bay to Elizabeth Bay.

As in the case of placer deposits of gold, it is evident that the diamonds are remote from their place of formation.

M. E. Frances, of Johannesburg, has carefully studied the problem, and his conclusions may be summarized as follows:

These diamonds are derived from fissures of Kimbertite, now possibly in the bed of the ocean. They are not wind transported, save as they are blown with other small pebbles a few yards from one place to another. At the time when the land was under water these diamonds lay in fissures in the bed of the ocean. The land slowly rose, and for a long geological period, and a comparatively recent one, the long depression was a shallow arm of the sea. From the south, where now is Elizabeth Bay, swept a strong current to the northern outlet, and in the shallow water the action of this current and of the waves deposited the diamonds in the sands. The lands then rose above the surface. The high winds have since blown the finer particles away, and the present gravel deposits where the diamonds are found represent the concentrated result.—*United States Consular Report.*

According to statistics compiled by the United States Bureau of Manufacturers, the consumption of coal in the United States is more than twice as great as that in any other country, and nearly equals the combined consumption of the United Kingdom, Germany, France, and Belgium, and is actually greater per capita than in the United Kingdom.

THE SIPHON IN MINING

Written for Mines and Minerals, by J. T. Beard

Its Use, Adaptation, and Limitations in Practice. Method of Calculating Dimensions

Among the common appliances used in mining, probably none possess a greater interest, considered from the standpoint of economy, than the ordinary siphon. Also, it would appear to be equally true that notwithstanding its simplicity and common use, few of these appliances are as little understood in respect to the theory of their action as the siphon. The writer's attention has been called to this lack of understanding recently by replies of correspondents to a question asking what would be the discharge of water through a 4-inch siphon pipe, rising a vertical height of 17 feet in a distance of 800 feet, and then falling 75 feet vertically, in the remaining 300 feet, the entire pipe line having a length of 1,100 feet, and the difference of elevation between the intake and the discharge ends of the pipe being 75 − 17 = 58 feet. The replies given to this question found, by the use of Eytelwein's formula for the flow of water in pipes, that this siphon would discharge 259+ gallons per minute; and, by the use of Hawksley's formula, 179+ gallons per minute. Here is a wide difference of 80 gallons each minute, and it is not surprising to find on investigation that neither of these answers are even approximately correct. It is never safe to consider the siphon in the same manner as a pipe line in which the flow is caused by gravity. Attention has been called to this on former occasions.

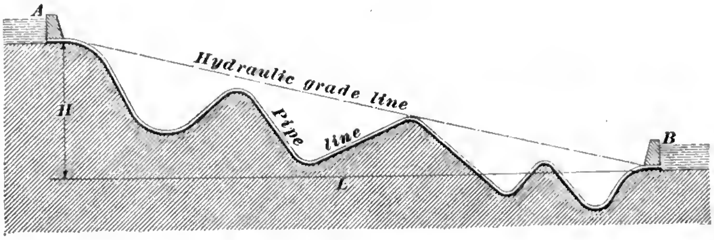

FIG. 1

To properly understand the action of the siphon it must be remembered that it consists of two legs or branches in each of which the flow of water is induced by different means. The two branches, though connected and forming one continuous line of pipe, act, for the most part, independently of each other. In the upper or suction leg of a siphon the water flows from the upper basin to the crown, or summmit, which is the highest point in the pipe line. This flow is not due to gravity, as the water rises instead of falls. It is caused by the atmospheric pressure acting on the surface of the water in the basin, less the gravity head or rise in the pipe. The action here is the same as in the suction pipe of a pump. The water will not rise to a greater height than what the atmospheric pressure will support, which at sea level, under normal conditions, is about 34 feet, and then allowance must be made for the necessary friction and velocity heads required to produce the flow. In the discharge leg of the siphon, on the other hand, the water flows by gravity. Here the head producing the flow is the gravity head or fall in the pipe from the crown to the surface of the water in the lower basin, or the point of discharge, less the atmospheric head, which now acts to oppose the flow. As before, allowance must be made here also for the necessary friction and velocity heads.

The usual method in dealing with siphons is to consider the siphon acting as a whole. In this case the atmospheric pressure at the intake balances the same at the discharge end of the siphon, while the head producing the flow (effective head) is the difference between the discharge and the suction heads, or the vertical fall and rise of the pipe. The friction head is calculated for the entire length of the siphon, and the velocity head is constant for a uniform diameter throughout the pipe. It will be seen shortly that this method of procedure is correct only under certain favorable conditions. The method does not show when the siphon will fail to work, or run perhaps for a short time and then go dry, nor does it in any way suggest the reason for such failure to operate.

The old Bernouilli theory or principle, which applies to the flow of fluids, makes the head (H) producing the flow equal to the sum of the gravity, friction, and velocity heads, as expressed by the formula

$$H = h_g + h_f + h_v \qquad (1)$$

The gravity head (h_g) is the total net vertical rise or fall in the pipe considered. It may be either positive (rise) or negative (fall). In the former case it acts to balance an equal portion of the original head (H) producing the flow (often called the pressure head), the difference between the pressure head and the gravity head being then the effective head. This condition is expressed by the formula

$$H - h_g = h_f + h_v \qquad (2)$$

When the pipe line considered has a net fall, the gravity head (h_g) in formula 1 is negative and acts to assist the pressure head to produce the flow. In this case, the effective head is equal to the sum of the two heads, as expressed by the formula

$$H + h_g = h_f + h_v \qquad (3)$$

It will be readily seen that formula 2 applies to the suction leg, and formula 3 to the discharge leg of the siphon.

Before going further it will be well to write the formulas for calculating the friction and the velocity heads in terms of the flow of the water in the pipe. The friction head is a measure of the pipe resistance, and depends upon the condition of the pipe, its length and diameter, and the quantity of the flow, as given by the formula

$$h_f = \frac{f\,l\,G^2}{8\,d^5} \qquad (4)$$

in which

h_f = friction head (ft.);
f = coefficient of friction;
l = length of pipe line (ft.);
d = diameter of pipe (in.);
G = quantity of flow (gal. per min.).

In mining practice, the pipes become corroded by the action of the mine water, and for this reason it is not generally safe to assume a less value for the coefficient of friction than $f = .01$, which is a fair average value.

The velocity head is found by transposing the well-known formula for velocity due to a given head, $v^2 = 2\,g\,h$, and substituting equivalent values for v in terms of the flow G and the diameter of pipe d; thus:

$$h_v = \frac{v^2}{2\,g} = \frac{1}{64.32}\left(\frac{231\,G}{60 \times .7854\,d^2 \times 12}\right)^2 = .0026\,\frac{G^2}{d^4} \qquad (5)$$

Now, substituting for h_f and h_v in formula 2 their respective values taken from formulas 4 and 5

$$H - h_g = \frac{f\,l\,G^2}{8\,d^5} + .0026\,\frac{G^2}{d^4}$$

or

$$H - h_g = \frac{G^2}{d^4}\left(\frac{f\,l}{8\,d} + .0026\right)$$

and

$$G = d^2\sqrt{\frac{H - h_g}{\frac{f\,l}{8\,d} + .0026}} \qquad (6)$$

Formula 6 gives the flow (G) in gallons per minute, in any pipe having a length l, in feet, and a diameter d, in inches, when the effective head ($H - h_g$), in feet, is known.

In siphon work this formula should be applied to the suction leg first, to ascertain what quantity of water the atmospheric pressure will cause to flow from the upper or supply basin up the pipe to the crown, from whence it will gravitate naturally to the lower basin. The flow of water in the siphon is limited to the flow in the suction leg induced by the pressure of the atmosphere, since the discharge can never exceed the

intake. The discharge, however, may reduce the flow in the siphon below what the atmospheric pressure could supply. This analysis of the proposition it will be granted is correct when it is remembered that in a perfect siphon there exists a more or less perfect vacuum at the crown, or the space here is filled with water, depending on conditions now to be explained.

Considered as a whole, the siphon is a pipe of various length bent upward at some point so as to present in profile one ascending and one descending portion or leg. The point of bend is

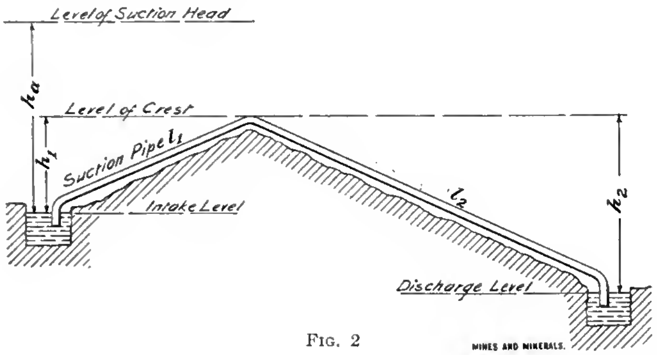

FIG. 2

called the crown or summit of the siphon. The two legs may have any lengths and inclinations, provided only that the mouth of the ascending portion or suction leg is at a sufficient elevation above the mouth of the descending portion or discharge leg to cause the water to flow through the pipe from the upper or supply basin to the lower or discharge basin. The difference between the elevations of the surface of the water in these two basins is called the effective head of the siphon. The intake end of the siphon or mouth of the suction pipe must be sufficiently submerged beneath the surface of the supply basin to prevent the entrance of air into the pipe with the water. Preferably, the discharge end of the siphon should likewise be submerged in the water of the lower basin, but this is not always necessary for the successful operation of the device.

In order that a siphon may work, the following requirements must be fulfiled: (1) The suction head (h_1, Fig. 2), which is the gravity head or vertical rise of the suction pipe, must be less than the atmospheric head (h_a), and the difference between them ($h_a - h_1$) must be sufficient to provide for the required friction head (h_f) and velocity head (h_v) in the suction pipe or leg, as expressed by the formula

$$h_a - h_1 = \frac{G^2}{d_1^4}\left(\frac{f\,l_1}{8\,d_1} + .0026\right) \qquad (7)$$

Formula 7 shows that the required effective head for any flow G is determined by the diameter and length of the pipe, and the flow will cease ($G=0$) when $h_1 = h_a$. Also, it is possible to increase the flow for any given effective head by increasing the diameter or decreasing the length of the pipe. (2) The flow of water in the suction leg of the siphon induced by the pressure of the atmosphere must at least be equal to the flow in the discharge leg induced by gravity. If this requirement is not fulfilled the siphon will have a tendency to empty itself, and will continue in operation but a limited time when it will run dry, unless the discharge is controlled by a cock, reducing nozzle, or other device. Equating the two expressions for the natural flow in the two legs of the siphon by means of formula 6, gives

$$d_1^2\sqrt{\frac{h_a-h_1}{\frac{f\,l_1}{8\,d_1}+.0026}} = d_2^2\sqrt{\frac{h_2-h_a}{\frac{f\,l_2}{8\,d_2}+.0026}}$$

Which, after simplifying, may be written:

$$\left(\frac{d_1}{d_2}\right)^5 \frac{h_a-h_1}{h_2-h_a} = \frac{f\,l_1+.0208\,d_1}{f\,l_2+.0208\,d_2} \qquad (8)$$

Any siphon in which the valuation of the first member of formula 8 is not equal to or greater than that of the second member of this formula, will tend to empty itself, and will run dry after a limited period of time.

To show the application of formula 8 and to verify the statements made at the beginning of this article in criticism of the answers given to a certain siphon question, let us investigate the same question, which was as follows:

Question.—What would be the quantity and velocity of water flowing in a 4-inch siphon line of the following dimensions: Distance to crest, 800 feet; from crest to discharge, 300 feet; difference of elevation from bottom of sump to top of crest, 17 feet; and from top of crest to discharge, 75 feet?

According to the data given, the suction head of this siphon is, as shown in Fig. 3, $h_1 = 17$ feet, and the length of the suction pipe $l_1 = 800$ feet; the discharge head is $h_2 = 75$ feet, and the length of the discharge pipe only $l_2 = 300$ feet. The diameter of the pipe is uniform, 4 inches throughout the entire length of siphon. Assuming the siphon is located at sea level, and the atmospheric head expressed as water column is $h_a = 34$ feet, and using a coefficient of friction $f = .01$, and substituting these values in formula 8, we have, since the diameter ratio $\left(\frac{d_1}{d_2}\right)$ is 1, in this case,

$$\frac{34-17}{75-34}\left\{\begin{array}{c}\text{equal to}\\ \text{or greater than}\end{array}\right\}\frac{.01\ (800)+.0208\times4}{.01\ (300)+.0208\times4}$$

or

$$\frac{17}{41}\left\{\begin{array}{c}\text{equal to}\\ \text{or greater than}\end{array}\right\}\frac{8.0832}{3.0832}$$

but

$$.4 \text{ is less than } 2.6$$

Since the valuation of the first member of formula 8 is shown in this case to be less than that of the second member, the siphon will speedily empty itself if started full.

We can investigate this case in another way that may appeal more strongly to the practical man. For example, apply formula 6, first to the conditions that exist in the suction pipe to ascertain what quantity of water the atmospheric pressure (sea level) will deliver at the crest of the siphon; and second, by means of the same formula, with the change of the effective head only, so as to represent the conditions in the discharge pipe, find the quantity of water that would gravitate through this pipe from the crest of the lower basin; thus,

$$\text{Suction flow } G = 4^2\sqrt{\frac{34-17}{\frac{.01(800)}{8\times4}+.0026}} = 16\sqrt{\frac{17}{.2526}}$$

$$= 131.2 \text{ gal. per min.}$$

$$\text{Discharge (full pipe) } G = 4^2\sqrt{\frac{75-34}{\frac{.01(300)}{8\times4}+.0026}} = 16\sqrt{\frac{41}{.09635}}$$

$$= 329.6 \text{ gal. per min.}$$

This shows clearly that the water will flow from the crest to the lower basin under the influence of gravity very much faster than the atmospheric pressure can force water up this long suction pipe.

One step further will be of interest, in the practical operation of siphons, and that is to determine what size of pipe

FIG. 3

(diameter) could be used for the discharge pipe, in the case just cited, in order that the pipe would continue to run full. Formula 8 may be written

$$d_2 = d_1\sqrt[5]{\frac{h_a-h_1}{h_2-h_a}\left(\frac{f\,l_2+.0208\,d_2}{f\,l_1+.0208\,d_1}\right)} \qquad (9)$$

The value of d_2 in this formula can only be found by trial. Taking $d_1 = 4$ and substituting the other values given previously it is found by trial, $d_2 = 2.76$; or a $2\frac{3}{4}$-inch discharge pipe

could have been used, in this case, with good results. The quantity of water the siphon would discharge in that case would be the same as found above for the suction flow; namely, 131+ gallons per minute. This flow may be calculated for the entire siphon when the diameter is not uniform by the formula

$$G=\sqrt{\frac{h_2-h_1}{\frac{f}{8}\left(\frac{l_1}{d_1^5}+\frac{l_2}{d_2^5}\right)+.0026\left(\frac{1}{d_1^4}+\frac{1}{d_2^4}\right)}} \qquad (10)$$

Thus, substituting the given values

$$G=\sqrt{\frac{75-17}{\frac{.01}{8}\left(\frac{800}{4^5}+\frac{300}{2.76^5}\right)+.0026\left(\frac{1}{4^4}+\frac{1}{2.76^4}\right)}}=131+ \text{ gal. per min.}$$

The same formula may be extended indefinitely, and be applied to any pipe line, not a siphon, where the diameter of the pipe is different for different sections of the pipe line, regardless of the number of such sections. The practical application of such formula is found in determining the flow in a pipe line that crosses several valleys and hills, as shown in Fig. 1, where the diameter of the pipe in each section is proportioned to the fifth root of the ratio of the length of pipe in that section to the head for the same section.

MINING IN SPAIN

By Consul Robert Frazer, Jr., Valencia

Spanish mining industries are passing through a severe crisis. Partial strikes for shorter hours in principal mining centers have culminated in a struggle between capital and labor in the iron-mining district of the Basque Provinces, in which both sides have declined arbitration and direct government intervention, rejecting every proposition to compromise.

In view of the strained situation created affecting one of the chief sources of Spain's natural wealth, the government, aided by the Institute of Social Reforms, whose mission is to solve labor and social problems, is preparing legislation dealing with the question of mining labor in its economic and social aspects. The following official statistics of daily wages and hours of labor in the principal mining regions of the peninsula are illustrative of the conditions obtaining in the country:

District	Mine	Hours of Labor	Under-ground Wage	Outside Wage
Albacete	Sulphur	10	$.73	$.55
Cartagena	Lead	8	.55	.37
Murcia	Lead	12	.54	.36
Teruel	Iron ore	10	.58	.58
Ciudad Real	Lead	8	.68	.36
Jaen	Lead	8	.90	.45
Cordova	Lead and coal	8	.65	.42
Seville	Lead and coal	10	.63	.36
Asturias	Coal	8	.81	.32
Leon	Coal	10	.81	.45
Palencia	Coal	7	.83	.42
Santander	Iron ore	10	.59	.45
Basque Provinces	Iron ore	*	.58	.42

* Eleven hours, summer; nine hours, winter; and ten hours in intermediate seasons.

The first four mines are in the region of Valencia. The last named have produced in the 32 years they have been operated by modern methods and machinery, 150,000,000 tons of iron ore, valued at about $246,000,000, of which about 140,000,000 tons went to Great Britain. The reserve yet to be mined in remunerative conditions is estimated at 61,000,000 tons.

The position of mine owners in the present dispute is that, in the actual precarious situation of Spanish mining industries in their relation to foreign competition in the world's markets, no concession whatever is possible in the reduction of hours of work or increase of wages, while miners hold that the hours of labor in the north of Spain, the low wages and increased cost of food, clothing, house rent, and other elements of living, place them at a disadvantage in comparison with the miners of nearly every other European country.

The difference between the wages of miners and those who handle ore on the surface is very marked, except in the iron mines of Tetuel (Ojos Negros), where little underground mining has been necessary, as ore is dug mostly from the surface.

Finally, the difference in hours of labor and wages in various mining sections of the country does not argue a difference in the supply of labor available, but is due to the kind of ore operated, and the depth, humidity, ventilation, and general sanitary conditions under which the miner works.

HEAT OF COMBUSTION OF EXPLOSIVES*

In order to obtain the true explosion temperature and heat of combustion, it is necessary to know the composition of the explosion gases at the moment of completion of the explosion in the closed vessel. This differs considerably from that found on analysis, on account of the reactions taking place during the cooling. If $A=CO_2$, $B=$the hydrogen, $C=$the CO plus three times the methane, $D=$the water less the methane, all expressed from the analysis as gram molecules per gram of explosive fired, then

$$\frac{(C+x)(D+x)}{(A-x)(B-x)}=K$$

For temperatures about 2,000°, $K=6.6$ (Langen), or 5.5 (Mallard and Le Chatelier). The composition of the gases before cooling is thus obtained by deducting x from the gram molecules of CO_2 and H_2, determined analytically, per gram of explosive, and the addition of x to those of CO and H_2.

The true heat of combustion is calculated from that determined experimentally by deducting 50,600 calories for each gram molecule of methane found, and 10,000 (Ostwald) or 10,100 (Berthelot) calories for each gram molecule of CO_2 formed during cooling.

In order to obtain more accurate results, gravimetric methods are substituted for the usual gas analysis by absorption and measurement of volume. The sample is placed in the bomb usually 1 to 1.5 grams of dry powder in a bomb 10.1 cubic centimeters content, or 10 grams of other explosive in a bomb of 750 cubic centimeters. After sweeping out free air with dry CO_2 and closing the valves, the charge is fired, the bomb allowed to cool, and the gases—consisting of H_2O, CO_2, CO, CH_4, H_2 and N_2—passed slowly through a weighed $CaCl_2$ tube and potash bulbs. The mixture of CO, CH_4, H_2, and N_2 is then led over hot copper oxide in a hard glass tube 25 to 50 centimeters long, connected to a $CaCl_2$ tube and potash bulbs. The CH_4 and (by difference) the CO are determined in a fresh analysis by leading the gases issuing from the first potash bulbs into an absorption apparatus containing cuprous chloride solution, which is renewed several times during an analysis from a vessel at a higher level, through towers containing dilute sulphuric acid (to absorb ammonia), concentrated sulphuric acid (to keep back moisture), and thence to the combustion tube. The CO_2, weighed in the second potash bulbs, will now be due to the CH_4 alone. If the two firings are carried out under exactly similar conditions, the results of the two analyses will be directly comparable. The gases are finally swept out of the bombs, $CaCl_2$ tube, and potash bulbs by a stream of dry CO_2 free air, which, to avoid oxidation of the CO absorbed in the cuprous chloride, has been passed through alkaline pyrogallol, and the rubber connection leading to the cuprous chloride apparatus closed with a pinch cock. By raising the level of the cuprous chloride solution the gases are driven over into the sulphuric acid towers, and thence, with a stream of dry CO_2 free air, into the combustion tube and bulbs. By means of a pump with a drying tube interposed, the $CaCl_2$ tube and bomb, which is warmed to 50° C., are evacuated, and the water remaining in the bomb thus transferred. The nitrogen is determined as described in the preceding abstract.

*O. Poppenberg and E. Stephan (Zeit. f. d. ges. Schiess-und Sprengstoffwesen, 1909, 4,281 and 305). The Analyst, November, 1909, pages 497-498 (E. H. C.).

TESTS FOR COPPER MINERALS

Written for Mines and Minerals, by Evans W. Buskett

Early Discoveries of Copper in America. Properties of Copper and Description of Its Ores

Copper was used by prehistoric man for tools, weapons, ornaments, and domestic utensils. The use of copper and bronze was a step toward civilization, and great progress was made in working these metals. The ancients probably made their bronzes by melting copper and zinc ores with carbon, the product being a crude mixture of the two metals, with copper predominating. The Romans obtained their supply of copper from Cyprus, in the Mediterranean Sea.

Probably the first mention of copper in the United States was by Verrazano, who reported that he saw beads of copper in the ears of Indians along the New England coast. The Indians along the St. Lawrence River told Jaques Cartier that the copper they had came from the Northwest. Champlain, in 1632, mentioned finding copper on an island in a lake northwest of Lake Huron. Alexander Henry visited the Ontonagon River in 1765 and again in 1771, and with him went men who mined copper along the banks of the river. In 1832, Schoolcraft visited the Ontonagon River and found copper, thus confirming the reports of Henry and his men.

Copper was mined in colonial times in Connecticut, New Jersey, Pennsylvania, and Maryland. The Schuyler Mine, at Arlington, N. J., was the first producer in the United States, but copper mining was not firmly established until the discovery of the native copper deposits of Keweenaw Point, Mich. This was followed by the discovery of the Cliff mines in the Lake Superior district, from which shipments were made in 1846. The Calumet was discovered in 1864, and consolidated with the Hecla in 1866.

The Anaconda Mine, at Butte, Mont., was opened in 1880, and large bodies of sulphide ores were discovered carrying as high as 50 per cent. copper. This find resulted in the rapid development of the district, which soon took the first place in the copper production of the United States.

Copper is red in color by reflected light, but in thin sheets transmits a greenish-blue color. The metal in the volatilized state shows these same greenish-blue tints. Copper is excelled in malleability by gold and silver, but is not as ductile as it is malleable. In tenacity it ranks next to iron, its tensile strength often being as high as 60,000 pounds per square inch. It conducts heat better than any metal except gold, and is next to silver in its electrical conductivity. Copper does not oxidize in dry air, but in moist air becomes coated with a film of oxides which protects the metal from further oxidation; moist air containing carbon dioxide forms a green coating of verdigris, which is a copper carbonate.

Copper alloys with gold, silver, lead, and zinc in various proportions. Bronze is an alloy of copper and tin, or aluminum and copper. Brass is copper and zinc, but sometimes contains lead. German silver is composed of copper, nickel, and zinc. The silver coins of the United States contain 10 per cent. copper, and 90 per cent. silver, the copper making the coin harder.

The specific gravity of copper varies according to its physical treatment. The specific gravity of electrolytic copper is 8.914; melted, 8.921; rolled and hammered copper, 8.952 to 8.958 (Marchand & Scheerer). The hardest of copper varies from 2.5 to 3.

Copper melts at 1,080.5° C. It is only slightly volatile. Its linear expansion is .0017; its specific heat is .094.

The valence of copper is one and three, the metal forming two series of salts, cupric and cuprous. Its atomic weight is 63.6; atomic volume, 72. Cuprous oxide, Cu_2O, occurs native, but may be prepared by igniting cupric oxide with metallic copper. Cupric oxide also occurs in nature in the mineral tenorite, but may be prepared by igniting cupric nitrate, sulphate, or carbonate, in air.

Copper dissolves readily in nitric acid, and is soluble in concentrated sulphuric acid. A saturated solution of hydrochloric acid will dissolve copper forming copper chloride.

Fixed alkalies added to solutions of cupric salts precipitate cupric hydroxides, which are soluble in ammonia and give a deep blue solution. Ammonia first precipitates pale blue basic salts, then deep blue hydroxide, which dissolves in an excess of the precipitant. Potassium cyanide precipitates a yellowish-green cupric cyanide which dissolves in excess of cyanide, forming a double cyanide of copper and potassium.

Hydrogen sulphide precipitates from solutions of cupric salts a black sulphide CuS, soluble in nitric acid, difficultly soluble in hydrochloric acid; insoluble in hot dilute sulphuric acid; insoluble in fixed alkalies; and but slightly soluble in ammonium sulphide. The copper sulphide is soluble in potassium cyanide, and by this means may be separated from cadmium.

Copper is easily precipitated from solutions of both cupric and cuprous salts by the following metals: Zinc, cadmium, tin, aluminum, lead, iron, cobalt, nickel, bismuth, and magnesium.

Copper occurs in many countries, but only in a few where the deposits are concentrated sufficiently to be worked at a profit.

The principal copper ores are the native copper deposits, copper sulphides, and carbonates.

The sulphides are:

Bornite: Luster, metallic. Color, copper red to brown. Tarnishes on exposure to the air. Streak, grayish black. Brittle. Composition $FeCu_3S_3$; copper, 55.58 per cent.; iron, 16.36 per cent.; sulphur, 28.06 per cent.

Chalcocite: Copper glance. Luster, metallic. Color, blackish lead gray. Streak, lead gray. Hardness, 2.5–3.0. Specific gravity, 5.5–5.8. Composition Cu_2S; copper, 79.8 per cent.; sulphur, 20.2 per cent.

Chalcopyrite: Luster, metallic. Color, brass yellow. Streak, greenish black. Hardness, 3.5–4.0. Specific gravity, 4.1–4.3. Composition $CuFeS_2$; copper, 34.6 per cent.; iron, 30.5 per cent.; sulphur, 34.9 per cent.

The oxides are:

Cuprite: Luster, metallic. Color, red. Streak, red, shining. Brittle. Hardness, 3.5–4.0. Specific gravity, 5.85–6.15. Composition Cu_2O; copper, 88.8 per cent.; oxygen, 11.2 per cent.

Tenorite: Luster, metallic. Color, iron gray. Hardness, 3.0. Specific gravity, 6.25. Composition CuO; copper, 79.85 per cent.; oxygen, 20.15 per cent.

The carbonates are:

Malachite: Luster, vitreous. Color, green. Streak, green. Hardness, 3.5–4.0. Specific gravity, 3.7–4.01. Composition $Cu_2Co_4 + H_2O$; copper oxide, 71.7 per cent.; carbon dioxide, 19.9 per cent.; water, 8.2 per cent.

Azurite: Luster, vitreous. Color, blue. Streak, blue. Brittle. Hardness, 3.5–4.25. Specific gravity, 3.5–3.831. Composition $Cu_3C_2O_7 + H_2O$; copper oxides, 69.2 per cent.; carbon dioxide, 25.6 per cent.; water, 5.2 per cent.

Detection:

Copper may be detected by fusing the finely powdered ore on charcoal. A metallic button is obtained having malleability and red color. It may also be detected by dissolving the ore in nitric acid and adding ammonia in excess. A blue color indicates copper. If there is much iron present the blue coloration will not at first show unless the solution is filtered.

Qualitative determination:

Copper is precipitated in Group III with mercury, lead, bismuth, and cadmium. To make the separation, dissolve the ore in nitric acid and evaporate to dryness. Take up the water and a little nitric acid and filter. Add hydrochloric acid which will precipitate the first group (lead, silver, and mercury). Filter. Warm the filtrate and pass hydrogen sulphide through

the solution, which will precipitate the members of Groups II and III. Wash the precipitate and transfer it to a beaker containing yellow ammonium sulphide and heat without boiling for 10 minutes. Filter and wash with ammonium sulphide water. The residue on the filter will contain the members of Group III. Place the precipitate in a beaker and dissolve in strong nitric acid. Heat to boiling and filter. The filtrate may contain lead, besides copper, bismuth, and cadmium. Add sulphuric acid, filter, and wash. To the filtrate add ammonia and filter. If the filtrate is blue, copper is present. It may be separated from cadmium by adding to the solution acetic acid, hydrogen sulphide, and then a solution of potassium cyanide. The cadmium will come down as a yellow precipitate which may be separated from the solution containing the copper by filtration. To recover the copper, add hydrochloric acid to the filtrate, when the copper will be precipitated as sulphide free from impurities. This precipitate may be dried, mixed with soda, and fused on charcoal to a metallic copper button.

Quantitative estimation:

The fire assay is not used to any appreciable extent for copper. The method of estimating copper by titrating an ammoniacal solution of the metal with potassium cyanide is probably the simplest, and when properly conducted, is nearly accurate.

The standard solution of potassium cyanide is made by dissolving 60 grams of the salt in 1 liter of water. One cubic centimeter of this solution should correspond to 1 per cent. of copper, but as it changes with age it should be standardized at least once a week. To standardize, weigh out .2 gram of chemically pure copper foil. Place in a beaker and add 5 cubic centimeters of strong nitric acid, and boil until the fumes are expelled. Dilute to 200 cubic centimeters and add 10 cubic centimeters of strong ammonia and titrate until the blue color of the solution disappears. The weight of the copper taken divided by the number of cubic centimeters of solution taken will give the amount of metal which 1 cubic centimeter of the solution will precipitate.

To assay a copper ore, weigh 1 gram of the ore into a beaker or casserole and dissolve in nitric acid. Evaporate to dryness and take up with a little nitric acid and water, and add sulphuric acid. Evaporate to white fumes, cool, and add water. Boil, add about 50 cubic centimeters of cold water and filter into a beaker. Add aluminum foil and boil for about 5 minutes. Remove the aluminum foil, washing it free from particles of copper, stir the solution with a glass rod, giving it a rapid circular motion. Remove the rod and the copper will settle in the center of the beaker. Pour off the solution, fill the beaker with water, and repeat the stirring and decantation several times in order to get rid of all the acid. Add 5 cubic centimeters of strong nitric acid and boil until the brown fumes are driven off. Dilute to 200 cubic centimeters, add 10 cubic centimeters of strong ammonia and titrate until the blue color disappears. If silver is present the solution should be diluted to 100 cubic centimeters and a few drops of hydrochloric acid added and then filtered. Then dilute to 200 cubic centimeters and add 10 cubic centimeters of strong ammonia and titrate. One per cent. of silver, 292 ounces per ton, will increase the assay .29 per cent.

Metallurgy.—The metallurgy of copper has undergone many changes during the past 15 years. The trend of the development has been toward a simplification of the processes used until now, instead of having a dozen or more processes, with a multiplicity of by-products, the metal is won from the ore by three or four comparatively simple processes. Copper may be reduced from its ores to a metallic form containing 98 per cent. metal in three operations; viz., roasting the sulphide ore to drive off the sulphur, smelting the roasted ores in the blast furnace to form a high-grade matte, and bessemerizing the matte, which operation drives off the remaining sulphur and slags the iron of the matte, leaving the copper with only about 2 per cent. impurities. This metal is then refined by electrolysis, which deposits the copper almost chemically pure.

ZINC ORE NOTES

A steam shovel working on the Kansas City Southern Railway 4 miles southeast of Joplin, struck lead ore. The employes commenced to gather the ore and collect it in heaps alongside the track. According to reports one man had a pile of 800 pounds, which should bring him something like $18 from the lead buyer. The land has been sold for $5,000 to mine operators.

The Missouri Lead and Zinc Co., once the leading zinc producer in the Joplin district, is now abandoned, and the shafts are being filled. There were scores of grass-root bonanzas on the so-called "Bankers Land," which extended down 100 feet and more. A custom mill was operated and small lease holders availed themselves of this to clean their ore. Hand-jig outfits were in operation, but a certain proportion of the dirt required milling. After the surface had been worked and reworked and the development extended to deeper levels, the operators were troubled with acid water that corroded their pumps to such an extent that work was abandoned.

The one-time bonanza Alpha Mine, at Spring City, Mo., is producing 10-per-cent. zinc ore after being reopened by Adam Scott. For some time the mill has been working on tailing which became so lean that Mr. Scott determined to abandon that class of work for ore. Two shafts are available from which to get ore to the mill.

Among the mines resuming operation after a long period of idleness is the Symmes, west of Joplin, where a short time ago a large pile of ore was held for higher prices, and which was finally sold at from $44.50 to $45. The ore had accumulated from a long period of active work during the time of low prices. As the price of ore has advanced above $45, the company is again preparing to actively develop its large holdings in that part of the district.

The tailing piles of the old B. & H., A. & R., and the Omega mines on the Granby Mining and Smelting Co.'s land, at Chitwood, are to be reworked by Clarke Marshall, who is an extensive operator on the Granby property. Mills are now in operation at the three mines mentioned, but Mr. Marshall intends to handle the tailings from former operations first, as these promise to be richer. Mr. Marshall has also taken a lease on nine lots of the Granby Mining and Smelting Co.'s land at the head of Poor Man's Gulch, north of Chitwood, and has started a shaft on a drill hole which showed ore from 80 to 130 feet.

The Amalgamated Mining Co., operating in the Granby land at Smelter Hill, is hoisting from two shafts to supply its 300-ton mill, and from one shaft for the old Blackberry mill.

The Church Mining Co., operating in the north part of the Miami, Okla., camp, expects a heavy flow of water. Until the ore is struck the water will be light. The shaft was sunk in a soapstone bar and the ore will not be encountered until the 250-foot level is reached. This is the deepest development in the Miami camp.

The Miami Amalgamated Mining Co., operating on the Sullivan tract of the Miami Royalty Co.'s lease in the Miami, Okla., camp, is producing ore after a shut-down of several weeks due to heavy water which flooded the workings.

Zinc mining in Mexico, which in many camps is crippled, and in some districts suspended, by the prohibitive rate of impost upon shipments to United States smelters, appears recently to be taking on new life and borrowing hope from two sources, the likelihood of the erection of zinc smelters in the republic and the popular belief that there will be amendments to the tariff levied upon imports by the United States.

The Webb City, Mo., Lead Smelting Co. has erected a smelter at a cost of over $60,000 which, with the necessary buildings, covers an area of 10 acres, and the company anticipates having at least 75 men on the pay roll by February 1, 1911.

The Philadelphia Co., near Yellville, Ark., drove a tunnel 100 feet into the mountain several feet above the bottom of the

ore. This ore is being stoped and stacked for the mill, which was expected to be in readiness for work by January 1, 1911.

Pearl Brothers are constructing a 100-ton mill on the Granby Mining and Smelting Co.'s land on the east side of Lone Elm Road, Joplin. They have a lease on the tailing piles on 346 acres which it is expected will keep them operating several years.

Dirt containing less than 4-per-cent. ore is being taken from the Granby Mining and Smelting Co.'s mine on its own land in the Chitwood camp. The company had been led to believe that the dirt might prove richer than this, and it is with the hope of finding better stuff that drifts are being driven. Unless the ore body becomes more promising it is doubtful whether the Granby company will undertake to operate a mill on this property, as had been originally planned. The shaft is now down 170 feet, and two drifts have been started. One is now about 50 feet long running due north from the shaft and the other is of the same length, running due south from the shaft. A good big ore face is being worked and the quality of the zinc blende is said to be excellent. However, as other companies on the Granby land are working in much richer dirt it is possible the Granby company may undertake to open a better proposition before trying to produce concentrates.

THE LARGEST ORE CRUSHER

Written for Mines and Minerals

When in 1890 the gyratory or Gates rock crusher was making its bow to the public, one on the Erie Railroad near Southfields, N. Y., was considered a wonder, because it crushed granite-gneiss to railroad ballast at the rate of 150 tons per day. In 1900 the gyratory crusher was being adopted a little more generally both in the East and in the West. However, the Blake ore crusher was considered to be better adapted to ore crushing, although its capacity was much less. It is difficult to eradicate this impression from the minds of some conservative metal miners, although it is evident that where a rock is at all brittle the gyratory crusher is as suitable as the jaw crusher for this class of work.

In 1910, when the American Institute of Mining Engineers visited the Ancon quarry on the Panama Canal, they saw a No. 12 gyratory crusher which was crushing stone for concrete work at the rate of 400 tons an hour, and this was considered nothing extraordinary. In fact, gyratory crushers have come to be looked upon as machines whose capacity is only regulated by the demand of the purchaser, and the limit of their practicable size has not been determined.

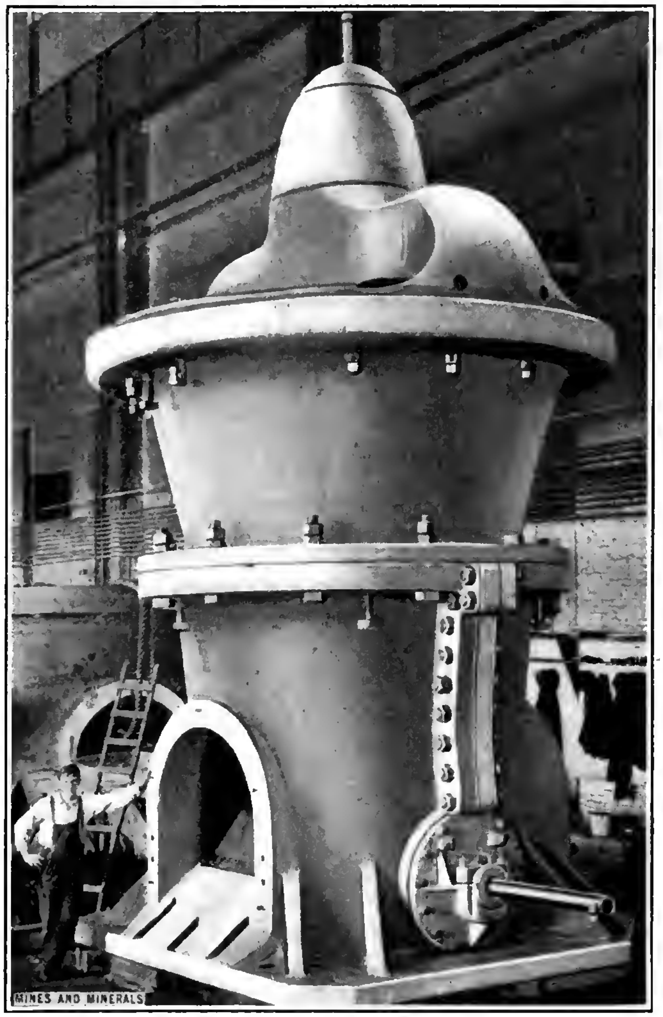

Fig. 1. Gyratory Crusher for Iron Ore

In 1901 the Biwabik Iron Mining Co., working on the Mesabi Range, Minn., installed the No. 21 gyratory crusher shown in Fig. 1. This machine was the largest and most powerful that had ever been built up to that time, and naturally attracted considerable attention. Although it has been in practically continuous service, the developments of the company have increased to such proportions that a new crusher, again larger than ever before constructed, was ordered. The new one that is shown partly loaded on cars in Fig. 2, when erected, stands 28 feet high, weighs 250 tons, and has two openings 4 feet by 9 feet capable of receiving 10-ton pieces of ore. These the crusher reduces to the desired size without exhibiting undue excitement over the strenuous work. The capacity of this huge affair is 40 broad-gauge cars of crushed ore each hour, or practically 800 tons per hour.

The Biwabik iron mines are worked in open-cut benches and after the ore is broken from the bench it rolls down to the steam shovel which loads it into cars. In order to break the ore from the benches it is blasted, and as a result falls in all sizes. Some of the pieces are so large they cannot be handled or used in the iron furnace, so that it is necessary to break them to suitable sizes. It is for this purpose that the crusher is to be used, and although it is to work on iron ore, the ore is hard and could not be broken as economically by any other means.

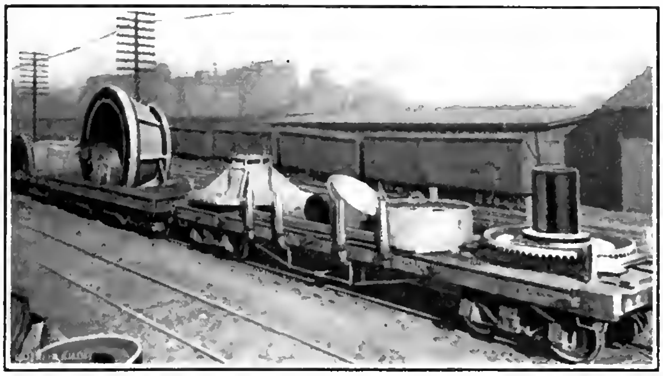

Fig. 2. Crusher Loaded on Cars

According to a commercial letter from Mr. C. H. Sherrill, United States Minister at Buenos Aires, about one-fifth of the world's wolfram is mined in Argentina. Wolfram, or wolframite, is a tungstate of iron and manganese. It is the ore from which the metal tungsten is usually obtained. One mining company, the Hansa Sociedad de Minas, produces six-sevenths of the entire Argentine output. It mines 60 to 100 tons of ore a month, ranging from 65 to 75 per cent. pure wolfram. The price of wolfram is about $1 a kilo (2.2 pounds) of pure metal. The amount of metal in a ton is estimated by the government chemical assayer in Hamburg, Germany, where the ore is sent.

THE CLANCY CYANIDE PROCESS*

The Clancy process is particularly concerned with the treatment of refractory gold and silver-bearing minerals. In this paper Mr. Clancy recounts his experience and his deductions while making his experiments leading up to the final stage employed in his process. From a chemical and metallurgical point the paper *in toto* is so valuable that it would be well for those interested in the theory of the cyanide process to send for it, as only the practical work can be given here on account of the length of the paper.

Chemistry of the Process. Action of the Solutions—Method of Operation and Costs

When a solution of calcium cyanamide is mixed with a solution of alkaline ferrocyanide and allowed to stand a few hours, it becomes an active solvent for gold, and when applied to the treatment of ores amenable to cyanide solutions, gives equivalent results, even in very dilute solutions. The process, Mr. Clancy says "can be used on cyanide tailing that contains a large proportion of Prussian blue $KFe(CN)_6$, which, when treated with alkali becomes potassium ferrocyanide $K_4Fe(CN)_6+3H_2O$ and potassium ferricyanide, $K_3Fe(CN)_6$ or soluble prussiates."

This furnishes an inexpensive method of treating material containing gold or silver, that could not be treated economically by straight cyaniding. For example, subject one part of the gold-bearing material for 8 hours or more to two parts of solution made as follows: Water, 2,000 pounds; calcium cyanamide, 1 pound; alkaline ferrocyanide, 1 pound; lime, 1 pound. When the material is tailing from a former cyanide process and contains Prussian blue, etc., one part of tailing used with two to three parts of the following solution will furnish results equivalent to straight cyaniding: Water, 2,000 pounds; cyanamide, 1 pound; lime, from 1 to 5 pounds, depending on the acidity of the tailing. If the mixtures of the gold-bearing material and solution are subjected to electrolysis the solution of the gold is rapid.

Calcium cyanamide mixed with alkaline sulphocyanide, electrolyzed, immediately becomes cyanide and dissolves gold rapidly.

To show the action of another amide compound, for example—guanidine carbonate $C_3H_{12}N_6O_3$ mixed with potassium cyanate, in conjunction with electrolysis of the solution, dissolves gold leaf in less than 10 minutes.

In the midst of this work on cyanogen-bearing materials I made a solution of calcium cyanamide, adding a solution of iodine to see if this combination would dissolve tellurium, and was rewarded by finding it to be an excellent solvent. I next tried gold leaf on the same combination and had the satisfaction of seeing the gold go into solution in a short time—a scum of calcium carbonate forms on the surface preventing of more rapid dissolution. From this I deduced that the addition of iodine formed cyanamidogen iodide. I am unable to find any reference to this compound in chemical literature, and take the liberty of calling it by the above name, and further presume the formula to be CN_2I_2. I next applied cyanogen iodide ICN, in a solution of calcium cyanamide to telluride of gold, which at once dissolved, showing that the reaction was probably due to cyanamidogen iodide and I again presume the reaction to be in accordance with the formula

$$2ICN+CaCN_2=Ca(CN)+I_2CN_2$$

I will now describe the general method of using the Clancy process on the working scale. The ore is crushed by stamps, rolls, ball mills, or any other efficient grinding mills. The degree of fineness necessary for the process being about 100 mesh, it is probably most economical to use tube mills. The ore is crushed in cyanide solution containing calcium cyanamide, sulphocyanide, and the halogen salts; it is, therefore, under the influence of straight cyanide treatment practically after leaving the rock breakers until it reaches the agitation tank. In the agitation tank it meets with electrolysis, which acts upon the cyanide containing the additional chemicals in solution, as already described. Calcium cyanamide of commerce comes as a black powder and is from 58 to 65 per cent. soluble in water. It is necessary, therefore, to dissolve the cyanamide in a separate tank and filter from its insoluble residue. A small air agitating tank is admirably suited for this purpose, and at the same time will act as a cyanamide storage tank. The cyanamide solution may be made as saturated as desired and the calculated quantity drawn off when required, and added to the cyanogen-bearing solution. The treatment solution is made up to 2,000 pounds of water containing 1 pound of cyanide, 2 pounds of alkaline sulphocyanide, 2 pounds of calcium cyanamide, and $\frac{1}{2}$ pound alkaline iodine. If using after the rock breakers, say, for example, crushing rolls, the product leaving the rolls about 12 mesh is fed into the tube mill and converted into a pulp, by feeding the mill with the treatment solution and ore in the proportion of one part of ore to one part of solution. The discharged pulp after separation of the oversize is transferred to the agitation tank to undergo electrical treatment. If it is thought necessary to remove the sulphides before, after, or during the treatment, the following method presents an ideal scheme. When solution containing finely divided ore in suspension is contained in the well-known cone-shaped tank and agitated in the proportion of two of solution to one of ore, or in the proportion of three of solution to one of ore—if the agitation is stopped for a few minutes, the finely divided sulphide particles settle to the bottom of the cone, and by simply opening the discharge valve at the cone apex, the sulphide may be completely drawn off together with a small proportion of the non-sulphide pulp. This sulphide product may be run over blankets or similar contrivances and the finely divided concentrate collected, the excess of pulp solution being returned to the agitation tank for treatment. Here is a means to eliminate the use of concentrating tables and obtain a product of very high value in a very small bulk. Again, the pulp being in a very finely divided state the pyrite or sulphide portion is not accompanied with quartz or gangue—therefore, a clean high-grade concentrate—a result not capable of accomplishment by the use of concentrating tables, without the employment of a large quantity of solution with its attendant expenses.

The pulp now in the agitating tank carries the correct alkalinity, this being previously established in the tube mill by adding lime so as to contain from $\frac{1}{10}$ to $\frac{2}{10}$ of a pound "protective" alkalinity per ton of solution.

The conductivity of the pulp is adjusted by adding common salt until the required voltage is obtained, 20 pounds of salt per ton of solution, as already stated, will invariably decrease the resistance of the pulp so that the voltmeter will register from 5 to 6 volts. In the majority of cases a current of about 50 amperes per ton of ore is adequate. It will be easily seen from this that the cost for electrical energy is not prohibitive. With iron oxide electrodes it is possible to obtain a current density considerably over 50 amperes per square foot of anode surface, so that one electrode 3 feet in length by 3 inches in diameter will be sufficient for the treatment of from 3 to 4 tons of ore; in other words, approximately 30 of these iron oxide electrodes would be required for the treatment of 100 tons of ore per day. If the treatment tank is constructed of iron it may be used as the cathode. This arrangement would of course decrease considerably the cost of installation. The electric generator is the chief item of cost, a low-voltage generator, say a 10-volt machine capable of giving the necessary amperage, can be obtained at any of the electrical warehouses. The process may be applied to any existing fine-grinding plant provided with agitating tanks; all that is necessary is simply to introduce the electrodes into the circulating ore pulp containing the necessary chemicals and switch on the current. It is essential in every

*Abstract from a paper read by John C. Clancy before the American Electro-Chemical Society in New York City, entitled "The Clancy Electro-Chemical Cyanide Process."

case to maintain the protective alkalinity at about $\frac{1}{10}$ of a pound alkali per ton of solution so as to allow of the formation of cyanogen iodide and cyanamidogen iodide. About 8 hours treatment under electrolysis usually is sufficient to obtain the necessary extraction.

After treatment with the current, the pulp solution is brought up to about 1 pound per ton of protective alkalinity by adding caustic soda, and the cyanide contents regenerated up to about $\frac{5}{10}$ to $\frac{6}{10}$ of a pound cyanide per ton of solution. The regeneration of the cyanide is then accomplished by giving the pulp about 2 hours more current. It will be understood that the reason for adding the extra alkali is that cyanide regeneration cannot take place in the presence of a halogen compound unless the solution containing sulphocyanides and cyanamide is made alkaline.

It will be seen that the value of the process depends upon the recovery of the halogen compound. While in the examples a proportion of two parts of solution to one part of ore was used, a proportion of three parts of solution to one part of ore may be used with advantage, that is to say, by using three parts of solution to one part ore, a much smaller amount of alkaline haloid may be used per ton of solution; thus giving the same ratio of haloid salt per ton of ore as in the two of solution to one of ore pulp, and consequently a less proportion of soluble haloid to be displaced by the water wash in the final slime cake.

In this incomplete description of the process the use of chemicals and current have been described, but no mention of costs has been referred to. I will, therefore, take the following to represent the typical working solution: 2,000 pounds of water containing 1 pound of cyanide, 2 pounds of sulphocyanide, 2 pounds of calcium cyanamide, and $\frac{1}{4}$ pound alkaline iodide. This appears a formidable mixture when looked at cursorily, but on analysis it does not work out beyond the limits of economic treatment. For example:

	Cents
1 pound of cyanide	18
2 pounds of cyanamide	6
2 pounds of alkaline sulphocyanide	12
$\frac{1}{4}$ pound of alkaline iodide	35
Total	71

This does not represent the total cost of 1 ton of solution, for, notwithstanding the effect of electrolysis, practically all the haloid salts previously added, together with the sulphocyanide will be found unimpaired at the end of the operation, the cyanide and cyanamide alone suffering decomposition. It is clear, therefore, that no matter what the proportion of solution to ore, only the consumption of cyanide and cyanamide per ton of ore is to be taken into account. The amount of cyanide consumption on the ore in presence of cyanamide works out at about 1 pound of cyanide per ton of ore treated. This cyanide is regenerated at the expense of 3 cents for cyanamide and at the very outside 3 cents for current (figuring current at 1 cent per kilowatt hour), making a total cost of 6 cents per ton of ore.

Added to the above cost is the cost of the electrical energy necessary for the electrolysis of the ore pulp. The cost of electrical energy for this purpose works out at about 10 cents per ton of ore treated, this added to the cost for cyanogen-bearing material and regeneration would make a total of 16 cents per ton of ore. These figures would represent the total cost provided that all the solutions were recovered without mechanical loss. From this it is evident that the recovery of the solutions for reuse is a matter of vital importance to this process. The mechanical recovery of the solutions is, therefore, entirely dependent upon the efficiency of the filter employed.

This filter process is too well known to describe minutely, suffice it to say that when the cake has been washed with barren solutions, the soluble salts in the solution saturating the cake at this juncture, may be completely water washed by giving it the requisite amount of water for displacement. The necessary amount of water for displacement is readily observed by the diminution of the water level in the wash tank, further, this can be adjusted to a nicety at the will of the operator. In a properly constructed filter the loss of solution under proper manipulation should not exceed 10 per cent. of the total solution.

It should be understood that the above figures are based on the treatment of refractory ores and that they would in all probability be much reduced when dealing with non-refractory ores.

NORTHWESTERN ORES

By August Wolf

Veteran prospectors predict that an important miners' rush will follow the passage of a bill at this session of Congress, opening to entry the mineral lands of the Spokane Indian reservation. United States Senator Wesley L. Jones, of Washington, who introduced the bill, advises that its adoption seems assured. More than 25 syndicates have been formed in Spokane in anticipation of the passage of the bill, and as soon as it becomes a law several hundred prospectors will be rushed into the district to stake claims. Large deposits of silver, copper, and tungsten have been traced across the boundaries of the reserve, part of which was opened to homesteaders last spring, and at one time development work was under way on 70 claims, when the prospectors were ejected by agents in the employ of the United States Government. Senator Jones' bill provided that "from and after the passage of this act any lands of the Spokane Indian reservation, classified and reserved as timber lands under any act of Congress heretofore passed, shall be opened to exploration, location, occupation, and purchase under the mining laws of the United States." L. K. Armstrong, secretary of the Western Conservation Association, who interested Senator Jones in the new measure, declares that the timber and mineral provisions were purposely left out of the original act opening the reservation, adding that, while the responsibility has not been fixed, he believes it was brought about by some one friendly to the Indian Bureau.

Sixty-five per cent. interest in the Standard Mine, a silver-lead property in the Dominion of Canada, has been acquired by Patrick Clark, of Spokane, on the basis of $2,500,000 cash. The property, located near Silverton, B. C., was originally bonded for $30,000 and financed for a half interest in the mine. Thus one man became a millionaire without the investment of a penny. The bonanza ore shoot was encountered about 6 months ago. The No. 5 tunnel level, in which the development of the ore body is in progress, is about 400 feet from the surface, and has been driven 175 feet on the ore shoot. When first found the ore shoot was 12 feet thick, where cross-cut; at the present face, it is 40 feet wide with only one wall in sight. From this ore body 36 samples averaged 38 per cent. lead and 51 ounces of silver to the ton. The cleanest of the ore taken out while this level was being driven was sent to the smelter at Trail, B. C., and averaged $62 a ton net.

The Bunker Hill & Sullivan Mine at Wardner, Idaho, ranks fourth among the dividend-paying gold, silver, and lead mines of America for the first 11 months of 1910, according to government statistics. The 60 largest dividend-paying mines in the United States for the current year disbursed a total of $17,783,631. The four largest profit-sharing mines are given as the Goldfield Consolidated, $7,118,196; Tonopah, $1,500,000; Homestake, $981,000; and the Bunker Hill, $925,350. According to Stanley A. Eaton, manager of the Bunker Hill & Sullivan mines, much of the lead now being produced in the United States is mined at a very small profit, and this is especially true at the mines in Missouri. It is out of question for American lead mines to compete with those of Spain, a country which produces a tonnage equal to that of the United States and consumes hardly any lead because of the poverty of the people. Competition with Canadian mines is not to be feared, as con-

ditions under which they are operated are similar to our own, and there might be no objection to reciprocity with Canada in lead and lead products. But for the uncertainty of the tariff, the lead market would be in a much stronger position than that which obtains for copper, chiefly because no great lead producers have been developed in the United States in years, while enormous deposits of copper ore, the product of which can be profitably marketed in New York as low as 8 cents a pound, have been opened recently. At the Bunker Hill the old mill is running at its proper capacity, which is about 800 tons a day, instead of overcrowding it as sometimes in the past. The first unit of the new mill is in operation and is treating 550 tons a day. The second unit is entirely enclosed and ready for the installation of machinery. It will be put into operation early in the spring, when the present production of 40,000 tons a month will be increased to 55,000 tons or more. An electric hoist is to be installed in the Kellogg tunnel, the present lowest working being 600 feet below that level. The plant will be of a type similar to that installed by the Hecla company at Burke, which has proved satisfactory.

JOPLIN ZINC AND LEAD PRODUCTION

Written for Mines and Minerals, by L. L. Wittich

The total valuation of zinc and lead ores shipped from the Missouri-Kansas-Oklahoma district in 1910 was $14,225,015, compared to $14,615,048 in 1909, $11,069,969 in 1908, and $15,419,727 in 1907, the record year of the history of the district.

The zinc ore production, including both blende and calamine, was 296,670 tons, compared to 301,206 tons in 1909, 259,598 tons in 1908, and 286,587 tons in 1907.

The lead ore production was 44,415 tons, compared to 44,186 tons in 1909, 39,119 tons in 1908, and 42,034 tons in 1907.

The accompanying table shows shipments, with their values, of zinc and lead ores from the various cities, towns, and camps of the Missouri-Kansas-Oklahoma district for the year 1910:

JOPLIN ZINC AND LEAD PRODUCTION, 1910

Camps	Blende		Calamine		Lead		Totals Values
	Pounds	Value	Pounds	Value	Pounds	Value	
Webb City–Carterville, Mo.	215,713,555	$ 4,515,466			47,716,005	$1,258,799	$ 5,824,265
Joplin, Mo.	98,758,190	2,075,844	3,573,690	$ 42,744	14,426,465	379,608	2,498,196
Duenweg, Mo.	37,999,160	780,960	6,413,180	85,543	5,761,160	149,293	1,015,796
Galena, Kans.	38,589,230	801,557	287,220	3,364	4,136,710	108,729	913,650
Alba–Neck City, Mo.	37,168,990	805,190	87,040	1,076	403,150	10,439	618,705
Miami, Okla.	20,311,390	332,250			6,775,025	176,489	508,739
Granby, Mo.	10,692,790	194,424	19,217,190	250,474	826,000	19,739	464,637
Oronogo, Mo.	16,828,545	347,059			2,576,050	70,828	417,887
Spring City, Mo.	4,900,480	99,436	8,375,000	106,068	3,818,980	98,617	304,121
Badger, Kans.	12,982,930	273,589			925,630	25,673	299,362

Peoria, Okla.			111,320	1,228			1,228
Springfield, Mo.	10,510	210					210
Totals	545,129,025	$11,303,264	48,211,340	$616,319	88,831,050	$2,335,432	$14,255,015
Average values per ton, 1910		$41.47		$25.56		$52.56	
Average values per ton, 1909		$42.29		$24.38		$54.81	

Fluorspar, as mined near Jamestown, Colo., contains 70 to 85 per cent. calcium fluoride. Veins less than 1 foot thick can hardly be worked profitably. Few veins exceed 6 feet in thickness. The principal handicap to the industry is the absence of railways. Wagon hauls of 13 miles are not uncommon.

PROSPECTING ADVICE

Mr. Stanley A. Eaton, manager of the Bunker Hill and Sullivan Mine, recently said that if he were to go prospecting he would devote his attention to the older camps, adding that the operator who rushes into a new district takes double chances, while in approved districts he has to take chances only on the property. Continuing, he said:

"What has made me a convert to this idea is the way the old mining districts of the United States are coming to the front with new discoveries of the first magnitude. Recall what has been done of late years in Nevada, the oldest mining state in the Union, which was almost abandoned for a generation. During the last year Leadville has surprised the world once more with ore discoveries of almost equal importance to anything in its wonderful history. This time large bodies of zinc ore have been found and are being worked.

"Coming nearer home, we find that the old camp of Butte, is opening up great and rich ore bodies in many unexpected places, while such districts as the Republic camp in Washington and Sheep Creek and Slocan, in British Columbia, are proving that the neglect they experienced at the hands of mining men the last decade was due to lack of knowledge and appreciation of their mineral resources.

"The Wardner district, though the oldest of the Coeur d'Alenes, seems to be holding out better than any other part of that field. The Wardner Hill has produced to date more than $80,000,000 that can be accounted for, and probably a good deal more than that, because many of the records of the early days, which were poorly kept at best, have been lost.

"Such mines as the Tyler, Stemwinder, and Sierra Nevada were big producers in their day, but that is about all known about them now.

"The Bunker Hill & Sullivan Mine alone is known to have produced $60,000,000, and in view of the fact that the older records are missing, it may have produced considerably more than that amount.

"The early ideas regarding ore occurrences in the Wardner camp have had to be revised as the result of the last 2 years' developments. The statement made some time ago by Robert N. Bell, former state mining inspector of Idaho, regarding the Frances property, was just about right. In that case deep development proved a great ore shoot where, according to the old ideas, it could not possibly occur. There are also other instances."

LEADVILLE, COLO., ZINC DEPOSITS

*Written for Mines and Minerals, by Howard E. Burton**

Recent Discoveries of Zinc Carbonate That Had Been Passed by When the Mines Were First Worked

Zinc carbonate was unknown in the Leadville district of Colorado until a few months ago. Zinc sulphide has been shipped from Leadville in large quantities for many years, but zinc in its oxidized forms was not thought of until recently.

Calamine was first found in the Monarch district, above Salida, in the Madonna Mine, which is still shipping this kind of ore.

It was next heard from two years ago in the Horseshoe district on the divide between Lake and Park counties. James B. McDonald, who was working the Hilltop and Last Chance mines under lease, when examining some old stopes and drifts, noticed a brown, heavy material that aroused his interest. He took liberal samples, not knowing what it was, and after having it assayed found it contained 50 per cent. zinc. Shipments were at once made to the different smelters, and the returns held up to the assays. The properties are still shipping this class of ore.

The next discovery was made in Leadville, in the famous Robert E. Lee Mine, on Fryer Hill, by W. E. Jones, a leaser. He opened a large body of carbonate of zinc, but the material was very low grade and valueless. That was a little over a year ago. This class of ore did not appeal to the miners of the district, consequently no attempt was made to discover it. The general opinion held was that the zinc had leached out of the original ore bodies and been precipitated below only in the form of sulphide, and it was thought no carbonate of zinc worth mining would be found in the district. Very few men in Leadville mines were familiar with carbonate of zinc ore, and as a result it was not recognized even when seen.

The next property to open up zinc carbonate was the May Queen in Leadville. The writer became identified with Messrs. H. K. White and Alfred Thielen in a lease on the Hayden shaft of the May Queen. This was the property first to find and ship high-grade calamine, and shipments have been continuous since its discovery. The shipments attracted little attention at first, but soon the possibilities of finding zinc in the other old mines of the camp became apparent.

S. D. Nicholson, manager of the Western Mining Co., which has always been a heavy shipper of zinc sulphides, started an investigation of the old workings of the Maid of Erin, Henriette, Waterloo, Adams, Wolftone, Mahala, Big Chief, and other mines, and large bodies of smithsonite were found in all of them, with an average value of 37½ per cent. One drift in the Maid of Erin alone was driven through this class of ore for over 750 feet. Following the discovery in the large producers of the camp the miners got busy, with the result that calamine has now been found from Fryer Hill south to Weston Pass. The ore is found from the parting quartzite to the gray porphyry, and also below the parting quartzite wherever the formation is oxidized.

Mr. E. W. Keith, of the Empire Zinc Co., who has examined the principal zinc deposits of this country and Mexico, says that the Leadville deposits are the largest he has ever seen.

Prof. S. F. Emmons, chief of the United States Geological Survey, 1880, writing to the editor of the Leadville *Herald-Democrat*, says: "It is in the normal order of development of a mining district that when exploitation has gone so deep that increasing expenses and decreasing yield have reduced the margin of profit, exploitation turns again to upper levels in search of ore that may not have paid to work when first opened, but which under present changed conditions may be profitably extracted. At the time of my first study of the Leadville district in 1880, I was much puzzled to know what had become of the zinc, since by analogy with similar deposits in the Ten Mile district, I reasoned that the original sulphides of Leadville must have contained much zinc as well as lead. I only succeeded in finding a few needle-like crystals in limestone joints that resembled gypsum, but proved on chemical examination to be 'silicate of zinc.' I assumed then that owing to the inferior solubility of the zinc sulphate, the oxidation products of that metal had been carried much further than those of lead before being transformed into the now stable carbonate and had possibly been entirely removed in the run off. Blow's observation that on Iron Hill secondary zinc blende had accumulated in the upper part of the sulphate zone seemed to account for some of the missing zinc, and from the accounts published by you it is evident that much of it has accumulated as calamine in the zone of change from sulphide to oxide. Though I have particularly desired to study the zinc of Leadville I have never been able to, because in 1880 mine workings had not reached it and when I next visited the district, 1890, they had gone beyond it and, owing to the soft nature of the ground in that zone, the drifts leading to it were for the most part caved and inaccessible.

"It certainly seems rather strange that those in charge of mines, when the zinc was exploited, did not notice such bodies of calamine as you describe, but it must be borne in mind that calamine is generally a white-brown, earthy looking material which would not attract attention unless especially sought for, and that it was pay ore rather than material of only mineralogical interest that they were seeking, and at that time zinciferous ores were a particularly undesirable product."

The original ore bodies of Leadville were undoubtedly sulphides. These bodies became oxidized through the action of percolating waters. The zinc was taken into solution in the form of sulphate. This solution was carried down until it came to the impervious quartzite formation and was precipitated as the insoluble carbonate by the limestone formation. In other words it is a replacement of the limestone by the zinc. The same process can be seen in operation on a small scale today in the old workings of some of the mines. Where a drift has cut a body of sulphide ore the water percolating through the zinc takes it in solution as sulphate. This solution when it drops into the drift evaporates and leaves big stalactites of zinc sulphate. If this solution had gone a little further and remained in the limestone it would have been precipitated as insoluble zinc carbonate.

There are several reasons why the mine manager did not discover calamine years ago. When the large bodies of this material were opened he was not looking for zinc in any form, as what had been found had so penalized the lead and iron with which it was associated that these large bodies could not be shipped at a profit. The miner was hunting for other ore bodies and when the carbonate of zinc was encountered he took it for "waste" and allowed it to remain standing. When the time came so that zinc could be mined at a profit he was hunting for zinc sulphides which everybody recognized. Calamine has been recognized now, new mines have been discovered within old ones and the discovery has again brought to the front the town of many surprises and again astonished the world by the immensity of the ore bodies of carbonate of zinc now in sight.

At present the only grade of this ore being shipped is what is known as high-grade material, that will run 30 to 40 per cent. In opening the ore bodies of this grade, mountains of low-grade matter that carries 15 per cent. or more have been encountered, and when a process has been discovered for treating this low-grade material at a profit, Leadville will be in a position to supply the world for years to come. The School of Mines at Golden, has taken up this problem in the new experimental ore-testing plant, and it will probably be solved by the use of fire concentration or some chemical process, and not by mechanical separation, because the smallest particle of ore that one can take is still a mixture of zinc, iron, etc. People in Leadville are very much interested in this problem and any one that can solve it will find a rich field to operate here.

* Assayer and chemist, Leadville, Colo.

DEL CARMEN ZINC MINE

Written for Mines and Minerals

The Del Carmen Mining Co., at Boquillas, Coahuila, Mex., uses three different systems of surface haulage in moving its ore to the Southern Pacific Railroad station, at Marathon, Tex.

A Transportation System Composed of Mules and Wagons, An Aerial Tramway, and Traction Engines

The company owns a large zinc deposit which is high grade, but about 100 miles from the nearest railroad station. Between the mine and the shipping point the country varies in topography; stretches being rough and precipitous, others arid, while the Rio Grande has to be crossed.

As no gold or silver exists in the ore, the cost of shipment by the system shown in Fig. 1 was too expensive, and after deliberation it was decided to divide the transportation into three stages.

Fig. 1. Burros Packing Water

The first stage of 5 miles commences at the mine and ends at the storage bins of an aerial tramway. The ore is hauled in wagons drawn by mules over a fairly good road.

The second division of the transportation system is an aerial tramway 6 miles long. It begins at a point in Mexico 2¼ miles from the International boundary line, crosses the Rio Grande, and extends 3¾ miles in Texas. Owing to the tramway being an international means of transportation, it is necessary for the Del Carmen Mining Co. to establish ports of entry and custom houses at the loading terminal in Mexico and discharge terminal in Texas, as there is a duty on zinc ore. The ore is weighed by Mexican customs officials at the loading station, shown in Fig. 2, and is then dumped into storage bins. In the discharge terminal, shown in Fig. 3, which is also the United States customs house, the inspectors weigh the ore in the tramway buckets by means of a tramway dial scale. This is a clock dial on which are marked the graduations in pounds from zero up to whatever weight may be required for the load. By means of a pointer the weight of each bucket as it passes over the scale is indicated on the dial. By setting the pointer to the left of zero to take care of the weight of the bucket the pointer will indicate the exact net weight of ore in each bucket. There is a short section of the terminal rail connected with the fulcrums of the scale, and when a bucket passes over this section the weight is indicated by a series of levers on the dial. The weight is not automatically recorded; the man in charge of the terminal records the weight as it is indicated on the dial. Surrounding the discharge terminal is a wire fence with a gate to establish a boundary and safeguard the custom house officials in their duties.

The wire-rope or aerial tramways being independent of differences in elevation can be made to carry material either up or down hill, across deep valleys or wide streams, and deliver it at destinations inaccessible to other transportation systems. Aerial tramways are constructed in favorable situations to be worked as gravity planes; in other situations where the topography varies they are designed to work partly by gravity and partly by power; and in flat countries power is required to move the loads over the system. The Del Carmen Co.'s tramway requires power to assist gravity in moving the loaded buckets, and this is obtained from a 45-horsepower gas engine.

In many instances where water is scarce and fuel for boilers is expensive suction gas producers are installed to supply gas engines with gas. Charcoal for the gas producer at the Del Carmen loading terminal is burned in pits situated near the plant, any available wood being used for the purpose.

The tramway was constructed by A. Leschen & Sons Rope Co., of St. Louis, Mo., who also kindly permit the use of the illustrations for this article. It consists of two track ropes and two traction ropes, supported on towers spaced at distances to conform to the contour of the ground. The track rope for the loaded buckets is 1-inch diameter crucible steel, flattened-strand rope, well adapted to this purpose owing to its strength and to the ease with which the carriage wheels run over it without excessive wear. Empty buckets do not require the same strength of rope as the loaded buckets, owing to the decrease in tension stress produced by the load, therefore, the

Fig. 2. Bucket Leaving Mexican Loading Station

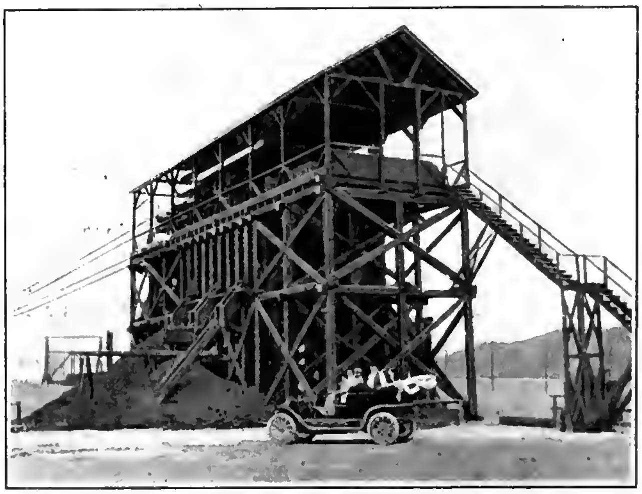

Fig. 3. Discharge at American Terminal

return rope on this system is ¾-inch diameter. Movable or grip ropes are the well-known ⅝-inch in diameter flexible Hercules hoisting rope, having six strands with each strand made of 19 wires.

In Fig. 2 a loaded bucket is shown at the commencement of its 6-mile journey.

When a wire rope is suspended between towers of an aerial tramway it will sag from its own weight and form a catenary

Fig. 4. Loaded Bucket Passing Over Tower Saddle

curve. At the center of the span there will be a horizontal distance where there is tension due to the weight of the rope on each side of the center. If the cable is loaded, the tension will be increased by the tension due to the load and the deflection it sets up. The tension at the point of greatest deflection where the track ropes become horizontal equals the load between the points at which a horizontal line from the top of the lower tower intersects the cable, multiplied by the distance between these points of intersection, divided by eight times the deflection below this line. The tension at either tower equals the square root of the sum of the squares of the horizontal tension so obtained and of the load between the tower and the point of greatest deflection. When the towers are on the same level this becomes:

$$\text{Tension of span} = \frac{\text{total load} \times \text{span}}{\text{deflection of cable} \times 8}$$

$$\text{Tension at towers} = \sqrt{(\text{tension at center})^2 + \left(\frac{\text{total load}}{2}\right)^2}$$

$$\text{Length catenary span} = \frac{\text{span} + (\text{deflection of cable})^2 \times 8}{\text{span} \times 3}$$

To obtain the total deflection, that of the rope alone must be added to that of the load alone. When towers are at different elevations the formula becomes complicated and lengthy, for which reason a graphical method is adopted which gives results of sufficient accuracy for the requirements.*

Long wire-rope tramways are divided into divisions in order to relieve tension on the track ropes and to compensate for variations in length due to stretching or temperature changes. For this purpose an anchor station is arranged at one end of a division where the track ropes are securely fastened in the ground; and at the other end a tension station is arranged where the ends of the track ropes have weighted boxes attached to them. Each track rope of the Del Carmen tramroad is divided into five sections with a tension station at one end, while the other end is fastened at an anchor station. Wire ropes may be obtained in any length within reasonable limits; for instance, it is possible to produce a ⅞-inch cable as long as 2,000 feet, but owing to the difficulties in transporting such heavy ropes it is customary to use shorter lengths and join them with suitable couplings.

The details of tower construction are shown in Fig. 4. The upper crosspiece has a grooved iron saddle at each end, in which the track ropes rest, and which are of such diameter that the carriages have no trouble in passing over them. The next lower crosspiece has a sheave wheel at each end, in the grooves of which the traction ropes run. This arrangement supports the ropes, takes up tension, thus relieving the track ropes, and further allows the traction rope to travel without excessive friction. In the figure a loaded bucket is shown passing over a tower saddle, with the clip on the bucket arms passing over the traction rope pulley. Universal clips on the bucket arms furnish positive grips on the traction rope, obviating all danger of the buckets becoming detached and running away on an incline.

Tower spacing, as has been stated, depends on the contour of the ground, and while horizontal tension is the same on each tower, yet the vertical tension will be more at the higher of two towers placed at different elevations. The vertical components of the catenary curve tend to promote stability by pressing down on the towers while the horizontal components tend to overturn them. The longest span on this tramway is 1,500 feet; the next longest is the span over the Rio Grande, which is 1,300 feet. Just beyond the first tower shown on the Mexican side of the river in Fig. 5, there is a tension station fitted with a water tank. At this station cylindrical tanks holding 40 gallons of water each, suspended from carriages the same as the ore buckets, are filled. The country through which the tramway extends is an arid desert, and as water is needed at both terminals, 15 water carriers pass over the line from a point near the Rio Grande, where there is a pump station erected for the purpose of filling the water tank.

Fig. 5. Cable Across the Rio Grande

When a water carrier reaches the water station an attendant switches the carriage from the track rope where it can be filled without interfering with the working of the tramway. All water carriers are supplied with friction grips, and can be attached and detached between buckets readily.

On the Del Carmen tramway, 90 steel buckets having a capacity of 600 pounds each, travel at a speed of 300 feet per

*See Mines and Minerals, Vol. 24, p. 423.

minute, thus requiring 3.5 hours to make a round trip. About 25 buckets are loaded and discharged every hour, and if necessary, their number may be increased. The buckets are automatically loaded without stopping for the purpose, by means of the hopper loader shown in Fig. 6. The operator standing on the platform to the rear of the loader fills it from the ore bin. When the bucket approaches, the loader commences to move, and while both are traveling together side by side at the same speed, the ore slides from the loader to the bucket. The loader travels on a four-wheeled carriage, and after discharging its load into the bucket returns by gravity to the ore bin for another load. There is a buffer composed of an air cylinder with a piston which checks the speed of the loader on its return. At the discharge end of the tramway the bucket carriages run from the loaded track rope on to a rail with about a 10-foot curve, then on this curved rail to the empty track rope. As the bucket goes on the rail it is weighed by the dial scale mentioned, the latches are unhooked automatically, and because the bail is attached to trunnions below the center of gravity the bucket turns upside down and discharges its contents into a bin. All this is done automatically while the traction rope continues to move the bucket around the curve toward the return-rope track, where the bucket is automatically righted and latched ready for its load when it reaches the distant loading terminal. The entire system is connected by telephones, and is almost automatic throughout. The third and final transportation stage is from the Texas terminal of the aerial tramway to Marathon station of the Southern Pacific Railway, 90 miles distant. This is accomplished by means of traction engines which haul ore-loaded wagons over the desert roads.

The diversified haulage systems used in connection with the Del Carmen Mine show conclusively that no one system of haulage will meet all requirements; further that it may require the adoption of several systems before the ore reaches its destination. The writer is indebted to A. Leschen & Sons Co. for the data from which this article is prepared.

BROKEN HILL, N. S. W., MINERALS

Written for Mines and Minerals

Mr. Aldridge, of Broken Hill, New South Wales, had an opportunity to collect from the Broken Hill mines, silver, lead, copper, and zinc mineral specimens, which are marvels of beauty. A large part of this collection is now at the Sydney

Fig. 7. Traction Engine Hauling Ore in Wagons

University, at least it was intended to send it there. The Aldridge collection of minerals is a unique collection of specimens obtained during the palmy days of Broken Hill.

The history of mining at Broken Hill forms one of the most remarkable and sensational chapters in the story of economic progress Discovered quite accidentally, the huge barren outcrop along the summit of the ridge was opened up by a small syndicate of proprietors, and, after some vicissitudes, the little party of poor men found themselves almost fabulously wealthy. Few mines have ever yielded such an output of precious metal, and certainly none has ever surpassed Broken Hill in the scientific interest of the problems in ore deposition which it presents.

Without going into technical details, it may be stated that

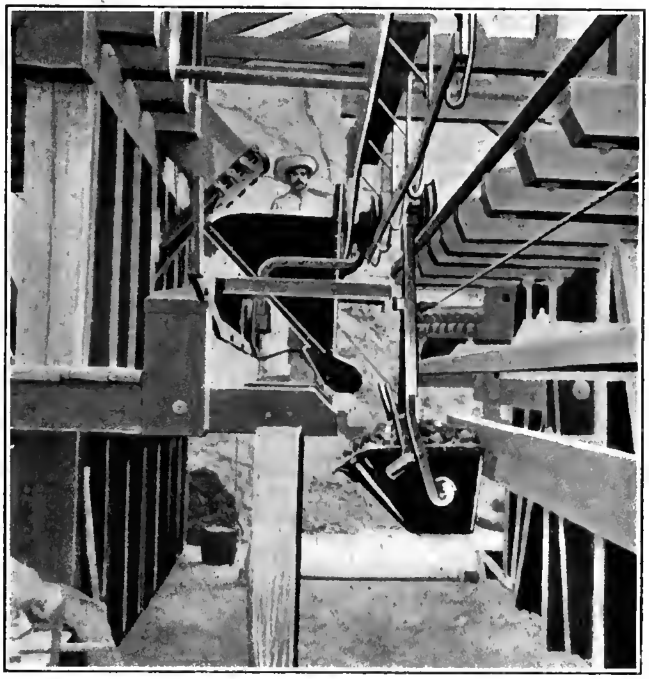

Fig. 6. Loading Bucket While in Motion

the ore below water level consists of an intimate mixture of galena (sulphide of lead), blende (sulphite of zinc), rhodonite (silicate of manganese), and garnet (a complicated silicate).

The galena and blende both carry relatively large percentages of silver. The minerals mentioned by no means exhaust the list of those found in the sulphide zone, though they bulk most prominently there. On this complex mixture the even more complex processes of Nature's chemistry have been at work for untold ages. Solutions ascending, solutions descending, have mingled, acted, and reacted until certain parts of the lode have been converted into an enchanted palace of wonders. Rare elements like bromine and iodine, tungsten, and molybdenum, present in unprecedented proportions, have combined into unique mineral species. Some types have never been met with elsewhere in the world, as, for instance, raspite (a tungstate of lead), marshite (an iodide of copper). Others, while known previously, were regarded as scientific curiosities, but at Broken Hill they were found in masses of almost unlimited extent. It was due to this fact that in the early days the silver output of the mine was phenomenal. Embolite (a chloride and bromide of silver) became a commercial ore of that metal.

Marvelous as is the variety of the minerals, even more wonderful is the beauty of the forms in which they occur. In the "oxidized zone" above the water level, the chemistry of Nature excavated cavities, large and small, and lined them with brilliant crystals of varied shapes and colors. So wonderful and unique are the forms presented by native silver and copper, cerussite (carbonate of lead), smithsonite (carbonate of zinc), azurite (carbonate of copper), embolite, and a host of others that specimens have been eagerly sought by collectors, and hold places of honor in museums the world over.

On account of the intrinsic value of the minerals, the companies operating the mines at length found it imperative to issue very stringent commands to prevent specimens leaving

the mines. Thousands of pounds worth of crystallized minerals were sent to the smelters, and it became increasingly difficult to obtain specimens. At the present time all the mines have worked out their oxidized zones, and, excepting a little patch left here and there, no more crystals are obtainable.

LAKE SUPERIOR IRON ORES

Hoisting has been suspended at the Cleveland-Cliffs Iron Co.'s Maas Mine at Neguanee, Marquette Range, because the upper portion of the shaft is being given a thick lining of concrete. It will take at least 6 months to finish the work.

The Lake Superior Iron and Chemical Co., which has absorbed a number of plants, is reputed to be controlled by Standard Oil capital. In its attempt to dominate the charcoal-iron industry of the West, it has for one competitor the Cleveland-Cliffs Co. This latter concern's Pioneer furnace at Marquette, Mich., is the largest charcoal-iron furnace in the world, and, in addition, it owns the Carp furnace at Marquette, and the Kipling furnace at Gladstone, Mich. Other producers of charcoal iron in Michigan are the Cadillac Furnace Co., Antrim Iron Co., Spring Lake Furnace Co., and East Jordan Furnace Co. These various "independents" have an annual capacity of close to a quarter of a million tons of iron, in addition to large quantities of chemical by-products.

Prospecting in the Dead River Valley, northwest from Negaunee, has been suspended for the winter, although it continues active in the Iron River district, where the most recent important discoveries in the Menominee range have been made. Two drills are in action in section 26, 43-34, owned by Wisconsin Land and Lumber Co. One drill is at work in section 20, 43-34 on the Waite farms. One drill in section 27, 43-35 for United States Steel Co.

After being idle since 1902, the Hilltop Mine, in the Crystal Falls district of the Menominee, is to be worked. The mine was not regarded with especial favor at the time of its suspension, but now, as a result of diamond-drill discoveries, it is expected to become an important producer. The matter of reopening the Cundy Mine at Quinnesec, Menominee range, is under consideration by the steel-corporation officials. The property has been idle almost a decade.

Rogers-Brown Co.'s Susquehanna Mine, at Hibbing, which for years operated as an underground proposition, is being converted into an open pit producer. The work of removing the overburden, estimated at 7,000,000 cubic yards, was awarded to Winston Brothers & Dear early last spring, and already in the neighborhood of 1,500,000 cubic yards have been stripped. Operations will be continued throughout the winter. Half a dozen steam shovels are in commission, many locomotives, and a large number of cars. The overburden is the thickest ever stripped on the Mesabi, its depth in places approximating 150 feet.

At its Kennedy Mine, on the new Cuyuna range, the Rogers-Brown Co. has completed the installation of a powerful new pump. The machine almost doubles the 2,200-gallon capacity of the pumps previously in position and assures that no trouble will be experienced with water in the underground workings.

The Cleveland-Cliffs Co. is increasing its holdings in Bates Township. It has recently started diamond drill work on the Kranz and Gustafson properties, in section 23, 43-34. Another crew of this company is located on the Sjoquist farm, in section 23, 43-34

Pickands, Mather & Co., which has been exploring the Spies lands, in section 24, 43–35, directly east of the James Mine, has suspended operations and it is likely the option will be surrendered.

Pickands, Mather & Co.'s Menominee mines, under C. E. Lawrence, of Iron Mountain, shipped 520,000 tons of ore last season. The shipments from the Florence Iron Co.'s Florence Mine were 208,000 tons, and those from Oglebay, Norton & Co.'s new Buckeye Mine, 89,000 tons. These two producers are the only Menominee range mines located in Wisconsin. The Menominee range shipments of Corrigan, McMinney & Co., which operates principally in the Crystal Falls district, were 630,000 tons.

The old Bird Mine at Crystal Falls has been taken under option by Joseph Croze, of Houghton, and will be given another test. It is said that $150,000 has been spent on the tract without finding ore in quantity.

It is reported that the Interstate Co., the Minnesota mining division of the Jones & Laughlin Steel Co., Pittsburg, is about to award a contract for stripping the Longyear Mine, 1 mile east of Hibbing, Mesabi range. It is estimated that the removal of 4,000,000 cubic yards of earth is necessary.

Preparations have been made to prospect a large tract of land in Keweenaw County by the Senter-Dupree Development Co., which has taken options on 1,520 acres near the middle of the district. Captain Thomas Hoatson, of Calumet, will be general manager, and Howard Wright, an engineer of experience, superintendent. The region to be explored is generally conceded to be worthy of a thorough test, as it is believed to carry several copper-bearing lodes. The property is from 2 to 3 miles due south of the Delaware station on the Keweenaw Central Railroad, and a short distance northeast of Gratiot Lake. There is over 2 miles of the strike of the formation on the Keweenaw Peninsula, and the property is from 1 to 1½ miles wide. The land lies close to the contact between the copper-bearing lodes and the eastern sandstone, and in a region which has received practically little attention. Diamond-drill contracts have been let to A. P. Silliman & Co., of Duluth, and Houghton; a road has been completed into the property; drills delivered, and several carloads of building material and fuel shipped.

On account of the low prices the Calumet & Hecla Mining Co. will report a materially lower production of refined copper for 1910 than for 1909. During the year the corporation has taken advantage of the situation to effect many economies, both in its own mines and at the properties of its subsidiaries, so that when production is increased copper will be produced cheaper than before. Although Osceola will show a reduction in output for 1910, the money made will be satisfactory to shareholders, and they will also have the satisfaction of knowing that their property is in better shape physically than ever. The South Kearsarge shafts command a highly mineralized formation; the North Kearsarge shafts have immense blocks of stoping ground, and in the Osceola proper there are thousands of feet of ground blocked out.

During the past year Ahmeek has given evidence of its coming greatness as a producer. This property is among the lowest cost producers of copper. Ahmeek, with the four-head stamp mill in operation, can produce 20,000,000 pounds of copper annually, which even at present prices, would give earnings of $1,000,000, or $20 per share. The daily capacity of the mill is approximately 3,000 tons. Ahmeek now has a market value of about $10,000,000, and the original investment was only $850,000, there being but $17 a share paid in on its 50,000 shares. The company has enjoyed the advantage of an excellent management from the start, and it is believed its copper will not cost more than 7½ cents per pound to produce.

In Belgium there must be a breathing appliance for every 200 underground workers in fiery mines of the second and third degree, with trained rescue brigades of not less than 4 men per set of apparatus. A leading company is organizing a well-equipped rescue station, staffed with 25 picked and trained men, who know every inch of the company's mines.—*United States Consular Report.*

BONANZA COPPER MINE, ALASKA

*Written for Mines and Minerals, by U. H. Wilhelm**

The Bonanza Copper Mine is the sole objective point of the Copper River & Northwestern Railroad, 200 miles in length, and costing approximately $22,000,000.

The railroad runs through an absolutely undeveloped district of no agricultural possibilities. The railroad is financed by the Morgan-Guggenheim syndicate, and will be soon advertised as a scenic marvel.

The first 40 miles of the railroad follows tide flats. At mile 50 is the Miles glacier bridge. Leaving this magnificent piece of engineering, the railroad is built in solid rockwork up the Copper River cañon. From mile 132 the railroad proceeds eastward paralleling the Chitina River at a distance of a few miles to the mouth of the Nizina. The Nizina is followed to the Kennecott, 4 miles from the mouth of which is the lower camp of the Bonanza mines.

The camp consists of the bunk house, mess house, ware-house, barn, assay office, and the saw mill, operated by steam. All the machinery and supplies have been freighted into the camp from Valdez, 180 miles distant, by means of horse sleds, at a minimum cost of 14 cents per pound. Mr. R. F. McClellan, who grub staked one of the original locators, is the superintendent, and Mr. Steven Birch is the general manager.

The lower camp is connected with the mines by a Bleichert tramway 15,000 feet in length, with a difference in elevation of 4,000 feet. The tramway has a maximum capacity of 300 tons in 24 hours, and cost $400,000, most of the cost being due to freight. The tram discharges at the lower end in ore bins, directly beneath which, on the hillside, a concentrator will be built, foundations of which are now being laid.

There are in all about 2,000 feet of mine workings, the highest tunnel being of the altitude of 6,200 feet; the lowest about 100 feet or less. The ores are chalcocite and azurite; the azurite appearing on the surface of the chalcocite.

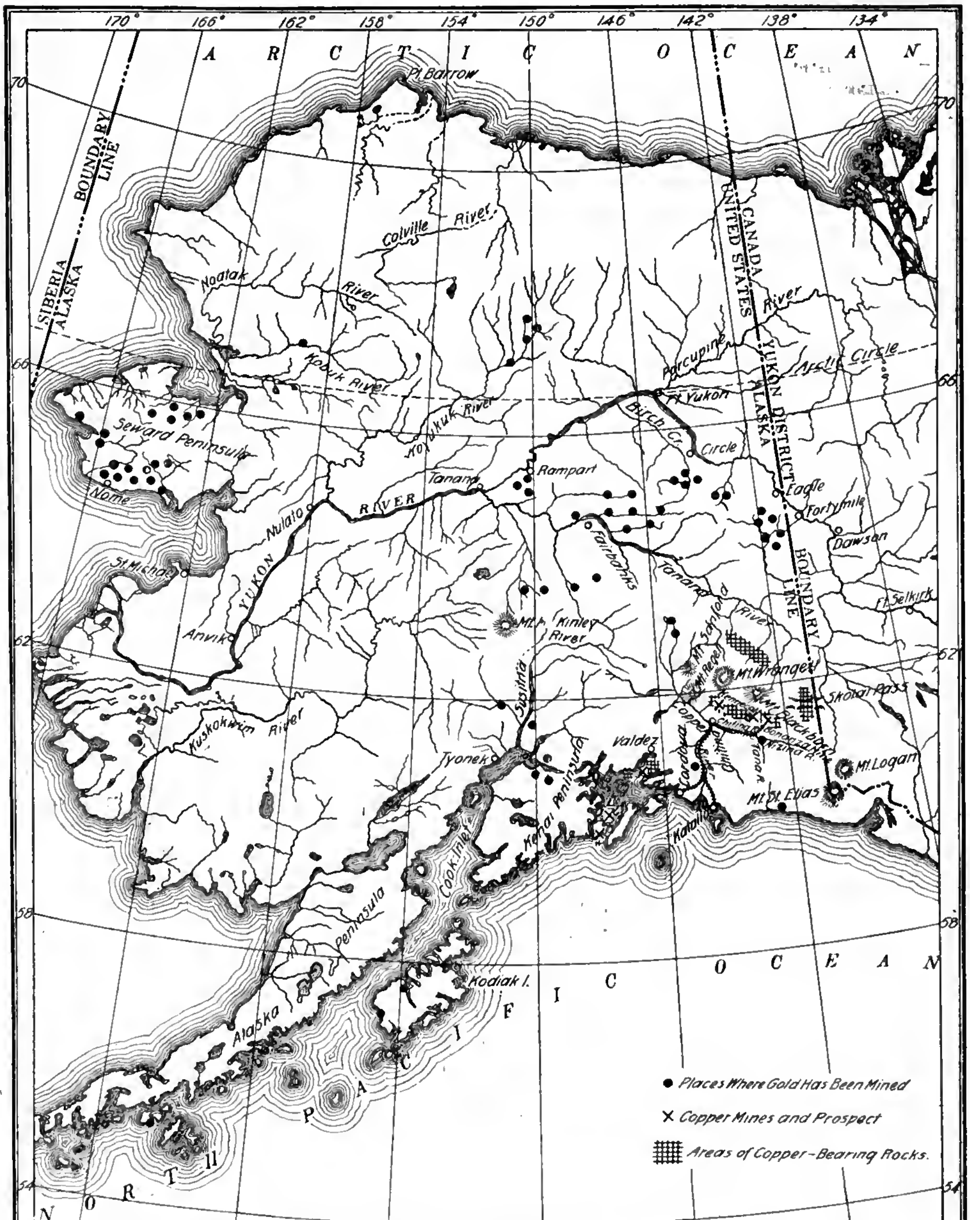
From the lower tunnel a raise passes through 40 feet of solid chalcocite, not a trace of limestone being visible. There is also a 235-foot tunnel running through the same ore, all walls showing solid chalcocite, with cross-cuts of 20 feet or less showing the same. At present but six men are working at the mine, though 30 men are working at the lower camp.

The track for the ore cars runs from the main tunnel to the upper ore bins over a landslide which averages 20 per cent. copper. This slide, or blow-out, contains individual boulders of chalcocite weighing as much at 200 pounds, and has been estimated to contain $8,000,000 in copper. The tramway and concentrator have been built to handle the ore from this slide, a switchback and main tunnel to tap the ore at depth being planned for the main ore body.

The main ore body is about 40 feet thick and of undetermined extent in other directions; it dips back and down so that the two original tunnels driven in at the outcrop run through it, and the tunnel 100 feet lower struck it at a distance of a little over 100 feet. The ridge of the mountain shows immense outcroppings along its entire length.

The same company owns the Jumbo Mine, said to be even richer property.

* Portland, Oregon.



Map of Alaska

OIL IN VENEZUELA

The eastern part of Venezuela and the delta of the Orinoco have been investigated and several tracts containing petroleum have been located. Geologists and mineralogists in the field under the direction of an expert mining engineer are at present exploring the regions around Lake Maracaibo. As this territory is especially rich in oil and asphalt lands, it is expected that the center of the company's operations will be in this locality and that exploitation will be commenced soon.

PETROLEUM MINING ENGINEERING

By Raymond S. Blatchley

Specialization has become a potent factor in modern progress, particularly in constructional work and development of great enterprises. Upon civil, mechanical, electrical, mining, and chemical engineers has fallen the evolution of great industries and the overcoming and harnessing of great forces of nature. These specialists are being turned out by hundreds annually to all quarters of America, where great railroad problems are being solved upon a methodical basis, where new machinery is being developed to minimize human toil and produce added power, where new resources of mineral wealth are being unearthed and converted into value, and where new industries with cheaper methods are being unfolded by the delving into latent mysteries of chemistry. Great results are apparent through the efforts of engineering, from which America has secured a world-wide reputation for energy and progressiveness. The future holds even greater promise to the advance of the nation along these same lines, in fields unexplored, and in many enterprises of the present day that have scarcely any specialization. In the latter class falls the petroleum industry.

Importance of the Oil Industry. Need of Special Knowledge for Successful Work

The petroleum industry, though but 50 years old, has presented a notable chapter in the world's commercial life, and particularly in America, where it has taken on its greatest activity, it has assumed such gigantic proportions in recent years that it wields a strong influence in modern life. The use of various oils, gasoline, and by-products of crude oil is universal and essential to modern progress, creating continuous demand for petroleum that will always be in excess of supply. Of the many branches of the industry, perhaps the most advanced is that of the manufacturing side. Chemists and physicists have made wonderful advance in creating new by-products, and especially in the utilization of waste materials. The future of this department of the industry is one of great opportunity to trained men, especially to chemists, for as yet the chemistry of petroleum is little known and varies widely for oils of different fields. A second and vital branch of the industry is that of the producing side. This offers greater opportunity to the trained man, in that it has little or no specialization, and certainly, through this lack, is in need of engineers to more thoroughly promote its many branches of technical work.

The present day does not warrant any worry over the lack of production, yet the inevitable decline of all of our present fields suggests a care for the future. In some near day production will need a new stimulus, and it seems that the proper way to create this is to develop a type of men peculiarly fitted to work out the problem of oil accumulation and to solve the many varied questions pertaining to its production. The object of this paper is the discussion of this new need.

The men who have developed the vast oil-producing areas of today have done the frontier work of a great industry. They are the pioneers who, through pure grit, costly practical experience, and an intense lure of the game, have made possible the present status of America's growth. Their patient toil and indifference to loss is significant of American success, yet, however profitable their operations may have been, it is easy to see that had they had a better knowledge of geological conditions their losses would have been greatly minimized. Their development of new fields, in practically all cases, dates back to wildcat discovery and to the gradual "feeling out" of pool limits. Often drilling was stimulated by oil seepage, either in outcropping or faulting of formations, in springs, or from mining of various types. Outside of these influences but little work scientifically has been done until within very recent years. Of late, government and state geologists have contributed to the development, and a gradual belief is arising that they are of service to the oil trade. These men are few in number in proportion to the enormous field. They are, for the most part, men trained in geological problems and are able to handle only certain phases of the development. They are not, as a rule, strictly trained petroleum engineers, because these are scarcely known in America, but they are trained geologists. Whatever benefit they have been able to render to the oil-producing business is of a geological nature. Their work has been practically limited to the vicinity of new proven areas, and the results accruing from the investigation of various fields is of immense value toward a broader interpretation of the work of the future petroleum engineer, especially in the search for new areas.

The questions now arise, is it possible to develop engineers of petroleum who can carry on work that will build up the producing side of the oil industry and put it on a scientific basis, as in other types of mining? Is it possible to go into new territory and be able to outline oil areas? The answer to the first question is "yes," and the method toward this end is to educate men along the lines of the petroleum business and at the same time bring them in touch with the chemical, physical, geological, technical, mechanical, and economic possibilities of the industry. The answer to the second question is, strictly speaking, "no," yet in a general way this is possible. The possibility lies in a close study of outcropping, dips, water saturation, and stratigraphy, the latter meaning the sequence of formations, and constructing therefrom a structural diagram showing the position of anticlinals, synclinals, terraces, and domes. The engineers, through the determination of rock structure and water conditions are reasonably assured of a working basis and an elimination of a goodly portion of the gambling nature of the business that oftentimes is astounding for its expense and impracticability. They are enabled to lead drilling to the most favorable conditions for the accumulation of oil and gas. Accompanying this phase of the work, as the advance is made into new territory, there arise problems of transportation, engineering, fuel supply, and other intricate portions of the business that can only be handled by the trained engineer.

Are there new fields to be opened up? As for this question it is sufficient to say that there undoubtedly exist many untapped fields in the United States, Canada, and Mexico. The fact that most of the fields of the world have been limited to the sedimentary rocks of varying age and that these are generally prevalent over the earth's crust is an answer in itself.

So far the discussion has been limited to the field for specially trained engineers. More systematic development of oil fields may be accomplished by including the operators and drillers themselves in a scheme of special training. The majority of the several hundred thousand persons connected with the oil and gas business in America are young men. Few of these have secured education that was of special benefit in their occupations. Why not educate the future generations with some of the technical training of petroleum engineers and thus provide them with better understanding of the scientific character of the oil business? At the same time that they are securing this they might receive the usual academic education and thus be equipped for the business of their choice. It is my opinion that the industry is ready for such action.

These few ideas are given merely to illustrate what the advantages would be to the industry as well as the individual. Whether these ideas have the favor of the oil trade is uncertain, since but little consideration has been given the subject. It is a large plan and an expression of approval or disapproval would mean much to those universities that have the establishment of such an engineering course in mind.

Some definitions and possibilities of petroleum mining are presented herewith. Petroleum mining is a branch of engineering. The term is as yet unfamiliar to the American oil industry, since it is more particularly a foreign expression, meaning in its strictest sense the development of oil properties and the winning of petroleum. The exploration for petroleum

is essentially mining, and it seems to fit no other classification. It is different from ordinary mining, however, in that it involves the laws applying to liquids rather than to those of solids. Moreover, the distribution and accumulation of petroleum is dependent on stratigraphic and structural features that do not apply directly to other minerals. Petroleum, accompanied usually by gas and salt water, is, to a certain extent, migratory and offers unsolved problems not found in any other type of mining. The underground manipulation in securing petroleum calls for peculiar machinery unlike that of ordinary mining, and thus introduces special mechanical problems.

Petroleum mining is closely related to the other branches of engineering and scientific work, such as civil and mechanical engineering, physics, chemistry, and geology, and necessarily borrows from them for the development of the engineer. In fact, there is occasion for specialization within the subject of petroleum mining and the development of petroleum mechanical engineers and petroleum chemical engineers becomes a part of the scheme. The possibilities to be gained under each subject are treated individually below.

Civil engineering offers training in constructional work of various kinds. The surveying and laying of pipe lines within the oil fields and from them to distant refineries requires accurate leveling, especially if extensive gravity systems are to be employed, similar to those of the Illinois fields. Some oil territories may require work in the construction and maintenance of wagon roads and light railways, such as are in use in several foreign fields. Overland pipe lines and light railways require possible rights-of-way. Future oil areas may lie close to large bodies of water and in event of this, docks or piers may be needed. The design and erection of power plants, field buildings, storage tanks, loading racks, and pumping stations require some training in civil engineering. This training is especially needed in order to determine well elevations for purposes of geological and structural study. Only in this way can one determine the dip and rise of various formations and the approximate limits of new and old areas.

The oil business has developed certain types of machines that are peculiar to its needs, and the possible development of additional useful tools and various mechanical devices opens up fields of wide opportunity to young men of an inventive turn of mind. Mechanical engineering offers a wide technical understanding of arrangement and use of machinery, and the incorporation of phases of this work in petroleum mining is desirable. The design and manufacture of special drilling tools for penetrating great depths of peculiar formations and for surmounting the many difficulties that overtake the driller is an important subject both for present knowledge and future investigation. The design of various pumping machinery for transporting viscous liquids, without blockade of movement, has a value of its own. The arrangement of power plants and pumping stations; the making, setting, repairing, and recovering of casing; the manufacture, assembling, and principles of steam boilers, steam economizing devices, steam, oil, and gas engines; the knowledge of steam, gas, and electric power; methods of excluding water by means of casing, packers, and use of cement; methods of sand pumping, bailing, and devices for inducing flow of oil, gas, or water, and many other detailed forms of mechanical work are useful, if not necessary, to the study of petroleum mining. Special opportunity is open to the petroleum mechanical engineer today in the use of various oil burners and oil-fuel apparatus in marine, railroad, and domestic application, especially since recent experiment has shown the practicability of oil as a source of cheap and efficient power. The condensing of portions of natural gas into gasoline and other similar volatile liquids at the gas well, without the loss of the gas, is commanding present attention. This field demands success because of the universal use of gasoline in motor power. Many other possibilities might be mentioned of the mechanical side of the industry, but the above are sufficient to show the need of specialists and also the general knowledge of the petroleum engineer.

The study of physics provides training to the petroleum engineer in various simple and everyday problems. The inequalities of temperature and their effect upon pipe lines, machinery, and even the product itself, is a subject of interest. The mechanics and laws of liquids, evaporation, congealing, pressure, equilibrium, weight, motion, etc., form the basis of mechanical engineering and its relation to petroleum mining.

The chemistry of petroleum is slightly known today except from its industrial side. It is a subject that has the earnest consideration of government officials and their efforts will pave the way to a wider investigation. The possibilities for successful research by chemists of petroleum are exceedingly promising. Aside from the scientific gain through research, new methods of analysis, fuel possibilities, new methods of distillation and refining, new by-products, more complete utilization of waste, products, etc., are open to investigation. An intimate study of the petroleum itself is needed. The problem of its origin is as yet not definitely solved, and new facts concerning its composition and organic relations may be of considerable aid in establishing clearer theories of its origin.

The knowledge of geology is perhaps one of the greatest aids toward the development of the petroleum engineer. In event that he will be called upon to do the bulk of outlining new fields, he must need a knowledge of the rocks of the area which he intends to investigate. An understanding of stratigraphy and geologic structure is indispensable. Some knowledge of paleontology will assist him in determining the character and classification of the oil formations, through various fossils of plants and animals. Mechanical means of portraying the structure of rocks is necessary, such as contouring, cross-section work, etc. The study of the dip relations of outcropping will materially assist him in his structure determinations. The principles of geology will aid the operators, drillers, and other men connected with the business in a systematic development of oil fields after the engineer has paved the way toward drilling.

The economics of petroleum would offer a valuable addition to the education of the petroleum engineer. The subject involves the discussion of necessary steps to successful handling of oil properties. Phases of leasing, choosing well sites, contracts for drilling, shooting of wells, taking the oil, power and property equipment, costs of the innumerable details of the business, costs of operating leases, oil investments, buying properties, gauging properties, geographical distribution of oil, and its transportation, storing the oil, keeping the records of samples of wells, statistics, legal phases of the business, etc., are various topics worthy of note.

The foregoing discussion of various subjects suggests the need of special training for the petroleum engineer. The list is long, yet by selection a good sound training can be gotten from them that will greatly aid the industry, as such training is not given at the present writing in any university in the world, though several foreign schools are considering the establishment of such a course and one American university has the plan in mind. The founding of petroleum mining as a university study will depend largely upon the attitude of those in the industry.

Some 15 years ago a mineral hitherto unknown to the scientific world was discovered in the Vermilion River district and was taken to Mr. Sperry of the Canadian Copper Co. to be assayed. He discovered it to be a diarsanide of platinum and the mineral was called after his name. Platinum is more valuable at the present time than gold and there is an active market for it, so that if the reports as to the amount and quantity of it are to be taken as reliable the discovery is of the greatest value.

EVOLUTION OF HOISTING

Written for Mines and Minerals, by E. B. W.

(Continued from January)

Owing to the first electrical engineers not understanding the conditions governing hoisting at mines, and in addition accepting entirely too many possibilities for motors, the first electric hoists were failures.

Methods of Calculating the Capacity of Electric Hoists and Output of Shafts

Most of the earlier motors used for hoisting were of the direct-current street-car type, geared to friction hoists. While direct-current motors are suitable for small hoisters situated near the generating power, they are not satisfactory when at a distance from the power, for at high voltage there is generally short circuiting at the commutator. The single-phase alternating-current dynamo can be made to generate a current of exceedingly high voltage; however, it is not suitable for hoisting machinery, because no single-phase alternating motor has been designed that is self-starting under load and capable of speed regulation.

The successful development of the multi-phase system has secured the advantages possessed by the direct and alternating currents, and aided in a large measure in meeting the requirements demanded of a mine hoister.

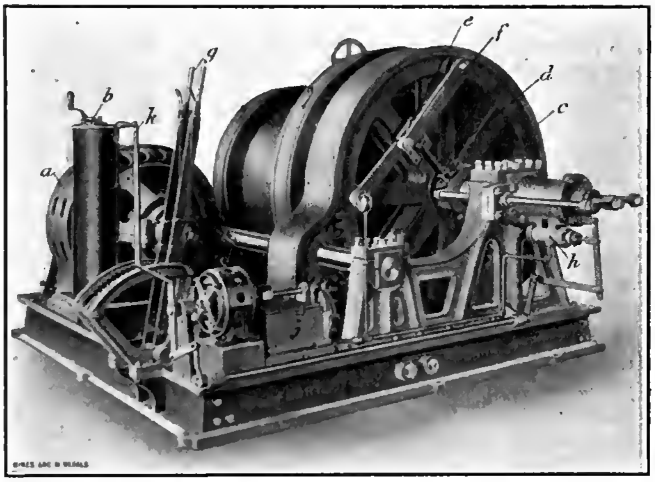


Fig. 52. Electric Hoist at Bliss Colliery

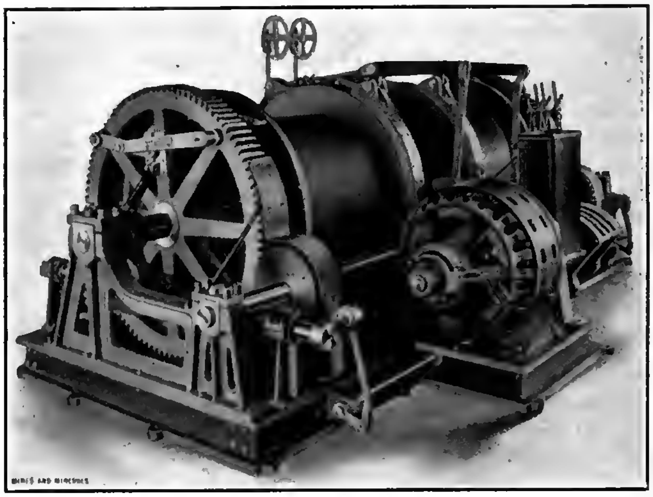

Fig. 53. Double Drum, Electric Hoist, Messina, Ala.

Frequently in the last few years electric hoisters have been described in technical journals; however, it is not to be taken for granted that all hoisters have been successful. At first glance it would seem that electric power would act the same as steam power in a hoister, but it must be understood that an electric motor will develop, for short periods, a torque equal to twice that which it can develop continuously. The steam engine is therefore better suited for an acceleration torque not much greater than the average, while the electric motor permits the acceleration torque to be about twice the equivalent of the horsepower it can continuously develop, that is, its rated horsepower.

Where an electric motor is driving a hoisting drum with variable load, the rated horsepower may be taken as being proportional to the square root of the mean square of the equivalent horsepower developed by the motor, taken over the time it is in motion, as the rating of a motor depends to a large extent on its capacity for dissipating heat, and the heat produced in the motor is proportional to the square of the equivalent horsepower exerted by the motor. If the depth of the shaft be S in feet, and s_1, s_2, s_3 feet be the distance described by either cage during acceleration, full speed, and deceleration, respectively, and the times $t_1 + t_2 + t_3$ be T seconds, the velocity in the shaft at full speed being V yards per minute, then the mean velocity over s_1 and s_3 will be $\frac{V}{2}$ feet per minute, and

$$V = \frac{120S}{t_1 + 2t_2 + t_3} \text{ ft. per min.}$$

The value of t_2 which gives the smallest motor under fixed winding conditions is $t_2 = T\left(1 - \frac{I}{I_c}\right)$ in which I is the total inertia of the winding engine, cages, etc., and I_c is the critical inertia of the motor obtained from the equation $I_c = \frac{1{,}220\ T^2 M}{120\ W}$ in which M is the load in pounds-feet, and W the number of revolutions made by the drum in completing one wind.*

A definition of this value would be: The critical inertia is that inertia which if existing in the hoisting motor under consideration would require the total time T seconds in order to run out from the speed attained, making the wind in T seconds with $t_2 = 0$.

Several calculations† having $\frac{I}{I_c}$ varying from .2 to .75, under various values of t_2 were made by Arthur Whitten Brown, in order to calculate the effect on the root-mean-square horsepower (R. M. S.). The curves from these calculations show that in every case the lowest R. M. S. horsepower is obtained when $t_2 = T\left(1 - \frac{I}{I_c}\right)$ and that at this point the equivalent horsepower during acceleration is about twice the R. M. S. horsepower.

The applications of this expression are many when considering the cylindrical-drum hoister, and it is seen that the more nearly $\frac{I}{I_c}$ approaches 1 the less practical will the winding become. Where possible the ratio should be between .4 and .65, the lower values giving the smaller motors and the lower power consumptions. The limit of output is probably reached with a ratio value of .7.

Similar expressions might be developed for other motor hoisters with cylindrical drums without balance ropes, or for conical drums, etc.

Starting with the assumption that the mineral load is G pounds, that the cars weigh $.5\,G$ pounds, and the cage and rope $1.5\,G$ pounds, a commercial value for the expression t_2 is found in an empirical formula. The total weight on the end of the rope is $3\,G$ pounds, and if the shaft be S yards deep the

* See November, 1910, Mines and Minerals, page 255.
† Arthur Whitten Brown, Trans. Manchester Geological and Mining Society.

weight of the rope per yard is found from the well-known formula $\frac{3G}{2{,}000-S}$, and the diameter of the rope $.45\sqrt{\frac{3G}{2{,}000-S}}$ inches. Taking x to represent the number of times that the rope diameter is contained in the drum diameter, then the drum diameter $=.45\,x\sqrt{\frac{3G}{2{,}000-S}}$ inches, or $.0375\,x\sqrt{\frac{3G}{2{,}000-S}}$ feet.

The torque due to the weight of the mineral would be $.01875\,x\,G\sqrt{\frac{3G}{2{,}000-S}}$ pounds-feet, but assuming the efficiency of the equipment is 85 per cent., then the total torque on the drum shaft becomes $.022\,x\,G\sqrt{\frac{3G}{2{,}000-S}}$ pounds-feet, and is the value of M. As a reduction gear is used between the motive power and the drum shaft, the efficiency must be reduced in order to cover losses in the gearing. The number of revolutions made by the drum to complete the hoisting is given by

$$W=\frac{S}{.04\,x\sqrt{\frac{3G}{2{,}000-S}}};$$

and assuming that the width of the drum is two and one-half times the width of W turns of closely packed rope, the width of the barrel is $\frac{28\,S}{x}$ inches.

The inertia of the drum has now to be considered, corresponding to weight in pounds × (diameter of gyration in feet)². The inertia of a straight drum may be taken as being equal to the inertia of an open cylinder equal in width to the drum, and having both its diameter and the diameter of gyration equal to the diameter of the drum. The thickness of the wall of the cylinder may be taken as 2½ inches. The inertia of such a cylinder, and therefore of the drum, would be as follows:

$$.45\sqrt{\frac{3G}{2{,}000-S}}\times\pi\times\frac{28\,S}{x}\times2\tfrac{1}{2}\times.28\times\left(.0375x\sqrt{\frac{3G}{2{,}000-S}}\right)^2$$

or,

$$.0388\,x^2\,S\left(\frac{3G}{2{,}000-S}\right)\sqrt{\frac{3G}{2{,}000-S}}\text{ pounds-feet}^2$$

This applies only to a single drum; a double drum would have greater inertia.

In a number of cases it was found that the inertia of all the moving parts in a hoisting equipment varied from three to four times the inertia of the drum. Taking three as a suitable factor, the total inertia I, becomes:

$$I=.117\,x^2\,S\left(\frac{3G}{2{,}000-S}\right)\sqrt{\frac{3G}{2{,}000-S}}\text{ pounds-feet}^2$$

From the definition of the critical inertia, I_c is equal to:

$$\frac{.00895\,x^2\,T^2\,G\left(\frac{3G}{2{,}000-S}\right)}{S}\text{ pounds-feet}^2$$

The ratio $\frac{I}{I_c}$ is then

$$R=\frac{13\,S^2\sqrt{\frac{3G}{2{,}000-S}}}{T^2\,G}$$

and from this is obtained the empirical formula

$$T=\sqrt{\frac{13\,S^2\sqrt{\frac{3G}{2{,}000-S}}}{R\,G}},\text{ or}\sqrt{\frac{22.5\,S^2}{R\sqrt{G}\sqrt{2{,}000-S}}}$$

One method of using this equation is in determining the cage loading for a given output of mineral from given depth. By reference to Fig. 54, which shows the winding time T seconds for any given output with any cage loading, based upon the assumption that the decking period is approximately 5 seconds + 5 seconds per ton. A table similar to the following is then prepared, calculated for an output of 100 tons per hour from a depth of 600 feet.

TABLE, SHOWING THE CAGE LOADING FOR A GIVEN OUTPUT OF MINERAL FROM A CERTAIN DEPTH

G	$\frac{3G}{2{,}000-S}$	$\sqrt{\frac{3G}{2{,}000-S}}$	T	T^2	T^2G	$13S^2$	$R=\frac{I}{I_c}$
2,240	3.74	1.930	26.0	676	1,520,000	520,000	.660
2,800	4.67	2.160	33.5	1,120	3,140,000	520,000	.355
3,360	5.60	2.365	41.5	1,720	5,800,000	520,000	.211
4,480	7.46	2.730	57.5	3,300	15,200,000	520,000	.093

From this it will be evident that a 1-ton load is practicable, but that the most suitable load would be 2,800 pounds.

If the decking period is inadequate any other value may be substituted from personal experience. The formula and data in the table will enable one to calculate approximately the maximum output of any shaft for any cage loading or to find the minimum practical cage loading for a given output. It is also of interest to note that R. M. S. horsepower is approximately $\frac{.0125\,Z\,G\,S}{(2-R)\,T}$, where Z is obtained from the chosen value of $\frac{I}{I_c}$. The equivalent brake horsepower during acceleration may be taken as twice R. M. S. horsepower, and the brake horsepower developed during the time t_2 is $\frac{.0125\,G\,S}{(2-R)\,T}$. These values do not make allowance for reduction gears.

In Fig. 52 is shown a mine hoist manufactured by S. Flory Co., which has several features that distinguish it from other

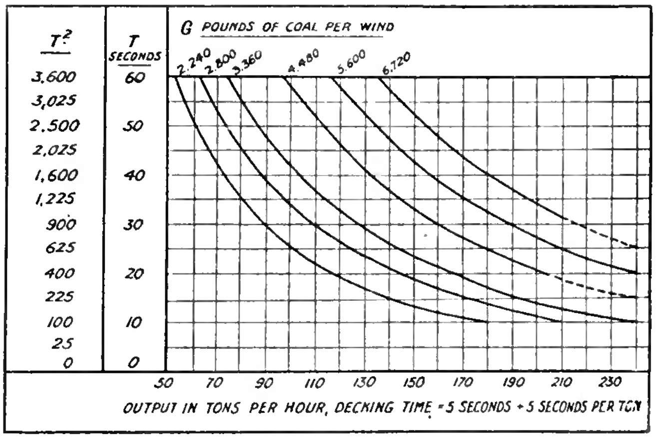

FIG. 54

electric hoists. This hoist was installed at the Bliss colliery of Delaware, Lackawanna & Western Co. It is a geared hoist supplied with a friction band, not shown, that operates on the inside cast-iron rim of the drum. The drum is 5 feet in diameter, 4 feet long between flanges, and capable of withstanding an 8,000-pound rope strain at a speed of 500 feet per minute. The hoist is operated by 150-horsepower Westinghouse alternating-current induction motor a suited for application where a strong starting effort is needed. The motor is governed by the single-handle, reversing drum controller b, which inserts resistance at the start and gradually cuts it out as the acceleration increases. The band friction which permits the rope to uncoil when it is free from the drum, or wind up when the drum is in motion, is known as the Werner band friction. It consists of a sleeve c, moved backwards and forwards on the drum shaft by a system of levers. The movement of this sleeve causes the spider arms d to move in slides e and force up or pull down the levers f which are keyed to rocker-shafts at their ends. The operation of the rocker-shaft tightens or loosens the friction band on the drum flanges. After the friction has been thrown in contact, it will remain in position until released. When the

friction is thrown out of contact, the drum is loose on the shaft and will permit the rope to pay out at high speed. The friction is thrown in or out of contact by the hand levers *g* or by a Westinghouse electric-railway air-cylinder *h* similar to that used on street-railway cars for setting brakes. The air compressor *i* and the air reservoir *j* are mounted on the base of the hoist. The reservoir is connected by pipes to the air cylinder at the end of the drum shaft, the latter being actuated by the lever *k*. The double-drum hoist shown in Fig. 53 is of the same type and was installed for the Bessemer Coal, Iron, and Land Co., Messina, Ala.

SUBMARINE DIVERS IN MINES

Written for Mines and Minerals, by George F. Duck

The use of divers is a comparative novelty in the West, therefore the following account from letters of Herbert A. Wilcox, superintendent of the Smuggler Mining Co., at Aspen, Colo., and W. J. Stevenson, manager of the Helena shaft, at Leadville, Colo., dealing with the work of two submarine divers in repairing submerged pumps at their respective operations, is of interest.

In describing the work at Aspen, Mr. Wilcox says that the collar of the Free Silver shaft, which is 1,196 feet deep, is 8,036 feet above sea level. The first connection underground is 848 feet below the collar and is with the ninth level of the Smuggler Mine. Below the ninth level, at intervals of 116 feet each, are the tenth, eleventh, and twelfth levels, the latter being at the bottom of the shaft. The mine below the ninth level has been under water for 12 years except for a few months in 1902 when it was unwatered to the eleventh level for exploration work.

At the lowest level, the shaft bottom, is a Jeanesville $32'' \times 14'' \times 48''$ duplex plunger pump, which, when the mine was allowed to fill 12 years ago, was left with connections arranged that it might be started under water with compressed air. This pump has not been in operation since that date except during the brief period of exploratory work in 1902.

When the present unwatering was contemplated it was found impossible to operate this pump, and its action led the management to believe that its packing had failed. As the inflow of water was great and the shaft small, it was found impracticable to unwater with sinking pumps. Although the flow of water at the eleventh level was at the rate of 1,500 gallons per minute it was lowered to this point by means of Pohle air lifts and Starrett air pumps delivering to the regular station pumps at the ninth level. As the mine equipment was insufficient to lower the water beyond the eleventh level, Messrs. Fred Johnson, diver, and George Peterson, tender, were called from New York, arriving in Aspen on October 17. On October 23, when the water was 103 feet deep, its surface being 6,943 feet above tide, the diver, after several attempts, reported his inability to work in this depth at the altitude, although at sea level he could work in 120 to 130 feet of water.

A station pump was then installed at the eleventh level and, with this and the Pohle and Starrett pumps in the shaft, the water was lowered to within 71 feet of the bottom by November 16, when the diver returned to work. During the next 10 days, while the diver was making the repairs, the water was held at a depth of from 71 to 65 feet. After the long submergence the packing in the water plungers was found to be in fairly good condition, but that in the steam end was entirely gone, and the piston rods were found to be very rough. By November 26 additional packing had been placed in the water end and all the glands tightened, the steam end had been repacked throughout, the rods smoothed, all nuts carefully gone over and tightened and jam nuts added where it was necessary.

The pump was started the next day on a mixture of steam and compressed air and has been running ever since with a piston speed of 120 to 136 feet per minute, with the exception of one shut-down of 4 days and several others of a few hours each, none of which, however, was due to any failure of the pump. The diver examined the pump on December 2, and again on the 14th, each time finding it advisable to add more packing to the steam end and to tighten the glands. At the date of Mr. Wilcox's letter, December 18, the pump was working nicely, and as there was but 10 feet of water in the station, he expected to recover the main pump in a few days.

Mr. Johnson had only been in Aspen 6 days when the preliminary trials were made. In diving in 103 feet of water he complained of shortness of breath, panting, and inability to exert himself without immediate and complete exhaustion, and described his sensations as being the same as when working at sea level at greater depths. Mr. Johnson estimated the effect of the altitude to be equivalent to that of about 27 feet of water at sea level. While the repairs were being made Mr. Johnson had no occasion to work under a greater pressure than 71 feet of water, and while not certain, does not believe he could work in mountain regions at as great depth as at sea level, even after becoming accustomed to the altitude.

Immediately after leaving Aspen, Messrs. Johnson and Peterson went to the Helena shaft, in Iowa Gulch, Leadville, the collar of which has an elevation of very nearly 11,000 feet, considerably above that of the Free Silver shaft at the former town. In describing the work at the Helena, Mr. W. J. Stevenson, the manager, says that when the mine was closed down some months ago the valves of the station pump at the 500-foot level were left closed and consequently had to be opened before the pump could be started and the lower portion of the shaft unwatered.

The Helena shaft consists of two $4' \times 8'$ compartments, in one of which are the pipe lines connected with the pumps, and which are supported by the stulls. Mr. Johnson at first attempted to lower himself in the pipe compartment, but was stopped by a pair of misplaced stulls just above the pump, and was unable to get between them and the side of the shaft. A second attempt was made to get down through the hoisting compartment, in which a Starrett air pump was working. This pump works entirely under water, and at the Helena shaft had been so placed that the exhaust took place about 2 feet above the top of the pump. This attempt also resulted in failure, as each time the diver got within about 4 feet of the exhaust he was blown back by the force of the air.

Unfortunately, a Cameron sinking pump had been wedged across the hoisting compartment, just below the station, so that ordinary sinking pumps could not be lowered. After several attempts, the pipes to give the necessary submergence for an ordinary air lift, were pushed past the obstructions, and when the water had been lowered to a depth of 50 feet Mr. Johnson was able to descend and open the valves in the station pump.

It will be noted that the surface of the water under which the diver worked was at Leadville 10,450 feet, and at Aspen 6,943 feet. This difference of 3,507 feet must have had some effect upon the ability of the diver to work, but Mr. Stevenson is of the opinion that the men labored under no greater disadvantage than would any one unaccustomed to the altitude.

While the work required of the diver at Aspen was much greater than at Leadville, in each instance most important service was rendered, and portions of the mine per force abandoned or only recoverable after long delay and great expense for new machinery, were cheaply made available for development. As Mr. Stevenson justly says, the remarkable feature is that the divers work entirely in the dark, guided only by their sense of touch and a thorough knowledge of their work.

RUSSIAN FAR EASTERN GOLD FIELD

Written for Mines and Minerals

The opinion of most geologists who have examined the Priamur Province is that the gold area is comparatively untouched and that up to the present only sands of the richest placers have been worked. Rock gold or quartz ore is found in every mining district, but scarcely any work has been done upon it excepting at four or five points. In the opinion of these geologists the alluvial gold in the Priamur district is most frequently found in the following primary combinations.

The Priamur Province With Its Mining and Labor Problems

In the Selemdzhinsk district it lies in a zone of granite and porphyry; in the Bureinsk system the deposit of gold is combined with gneiss and crystalline schist, but among the granites and porphyries there it never has been, and probably never will be, found. In the Amgun system the metal is found in connection with the clayey schist and schistose metamorphosed beds, and, finally, on the Ochot-Kamtchatka shore the alluvial sands are found associated with granite-syenite and gneiss, in hornblende schists.

In view of what is stated, if geological knowledge were wider and more detailed in the Priamur district, the gold industry might be on a firm footing and it might be developed for the future in a way more calculated to inspire confidence. Unfortunately, little geologically is known of the Far East, and the plans for working the area and of investigating it, as adopted by the geological committee, certainly suffer from a number of radical defects. After making an allowance of a fair sum per annum to the chief of the geological surveyors and their assistants, the committee is satisfied with their working from 2 to 3½ months, allowing them to pass the rest of the year in getting there and back, and living about 6 months in St. Petersburg. Notwithstanding this, the gold industry in the Priamur Province is gradually growing, as can be seen from the following statistical figures of the Irkutsk Mining Government:

	1905	1906	1907	1908
Gold produced, poods*	458	481	547½	478
Number of mines worked	251	237	278	297
Mines unworked	617	643	617	790
New claims	300	360	556	457

*A pood equals 36.07 pounds avoirdupois.

It is to be observed that the figures given for the production of gold are less than the actual figures, since with the free circulation of gold in Russia, part of it escapes registration, particularly since the greatly increased gold workings of recent times. To what extent the concealment of gold takes place can be seen from the fact that in 1905 M. Oparin and the Russo-Chinese bank bought at Blagoveschtchensk, 90 poods of gold. Of late years it has particularly been observed that the number of buyers has increased at all the mines. These deliver gold privately to the laboratories under the name of free gold producers, and partly get rid of their gold secretly and abroad. In this business the Chinese workman and the Japanese merchants have particularly distinguished themselves.

It is not uninteresting to observe that when measures began to be adopted against flooding the gold mines with Korean labor the number of Chinese workmen correspondingly increased on the gold workings, and along with this the movement of gold into China likewise increased. On the gold workings the average earnings of a Chinese come to about 50 kopecks (25 cents) per day but with the locally high cost of living he can hardly exist on this, whilst in the autumn every Chinaman takes hundreds of roubles to his home.

One may judge the dimensions and the growth of poaching by the quantity of free gold delivered at the Irkutsk gold smelting laboratory. In 1905 such gold was smelted to the extent of 86 poods and in 1908 to over 138 poods. The workmen at the mines constitute a particular type and are known generally under the name of miners. They are an uncommonly noisy and shifty people that can easily be recognized by their manners and customs. These characteristics—which have been produced by the severe conditions of the virgin forest and the gold fever, are obvious in each workman.

With such a contingent it is always difficult to get along, but recently there has been the addition of general strikes with which to contend, and concessions must be made to the workmen in view of a direct loss in business. The number of miners in the Priamur gold fields was, in 1905: Amur district, 955 Russians, 1,125 Chinese, 550 Koreans; Zea district, 2,187 Russians, 2,775 Chinese, and 1,156 Koreans; Primorsk, 1,700 Russians, 600 Chinese, and 700 Koreans; total, 4,842, 4,500, and 2,406, respectively. In 1908 the respective totals were 5,932, 7,483, and 2,492. It will be observed that while there has been a marked increase in the number of Russian gold miners, that of the Chinese has been much greater, while Korean figures remain about stationary.

There has been considerable agitation against Korean and Chinese labor, the Koreans particularly, because their government is not strong enough to make terms for them. The Russian insists on having Russian work done by Russian labor, and the particularly severe laws enacted to exclude foreign labor have forced the Koreans to resort to subterfuge in order to get back to their favorite work. One of the latest, which is attributed so frequently to another race, has been adopted by them. They are adopting the Russian orthodox faith, whereupon they are made Russian subjects and they become so, says a note from Kharbin, under the pretext of having subscribed to all that is required of a Russian, which entitles them to all a Russian's rights. It is not unlikely that when they have all they want they will revert to their old faith and return to their own country. Koreans are recognized as excellent miners, and were it not for that, the cheapness of their labor would not count much. In connection with the foregoing statement of laborers in the Priamur Province, particular attention is called to the fact that they stood firm in their numbers in spite of the exceptional measures taken against them.

During later years living conditions have considerably changed in the district, and the number of Russians arriving at the mines has increased. These are not entirely given over to gold mining, whereas the Chinese and the Koreans are engaged exclusively in the mines. The rate of pay for taking out a cubic sazhen (12⅔ cubic yards) varies between 2 roubles, 50 kopecks and 3 roubles, and the pay for the gold working is on the average 1½ to 2 roubles per zolotnik of gold produced. (A zolotnik equals 65.8 grains troy). At the same time the gold worker is obliged to give to the proprietor of the mine from 15 to 30 dolis per day (a doli equals .68 grain Troy or 2½ cents) according to the conditions, and dependent upon the richness of the alluvial. The gold produced by the gold workers over and above the quantity stipulated is considered as their own property and this attracts both Chinese and Koreans, who frequently sell some to the Bureau of Mines and take the remainder home to their own country.

The technique of mining is on a low level in the Far East, and seldom is there shown any desire to take advantage of modern improvements. Therefore, the industry is passing through a rather quiet time, and to a certain degree this is straining the owners. The use of the horse as power has outlived its period; and the application of steam and electricity is not everywhere introduced. Not long ago the introduction of excavators proved to be unsuccessful and unprofitable. Hope mostly rests on dredge working, although in the use of dredges one often sees a complete ignorance of the business. On account of the defective equipment of the owners and managers of the mines, many of them have gradually fallen into the hands

of more educated foreigners In order to show to the Russians the possibliity of taking advantage of the gold reserves, there must be better informed people, and for this it is not enough to have a mining school with 2 teachers and a budget of 30,000 roubles ($15,935) for the whole of the wide area of Eastern Siberia. The Irkutsk Mining Government might do more for the district and might win more in the opinion of society if it dropped the care of salt factories and mineral water and devoted attention to wider geological surveys and to the technical training of young people.

INDUCTION MOTOR RUNS UNDER WATER

The performance of apparatus under exceptional circumstances reveals its suitability for the service for which it has been installed. Due to the fact that reliable manufacturers design their apparatus with a large factor of safety, remarkable records are sometimes made.

A 20-horsepower, three-phase, 220-volt, standard induction

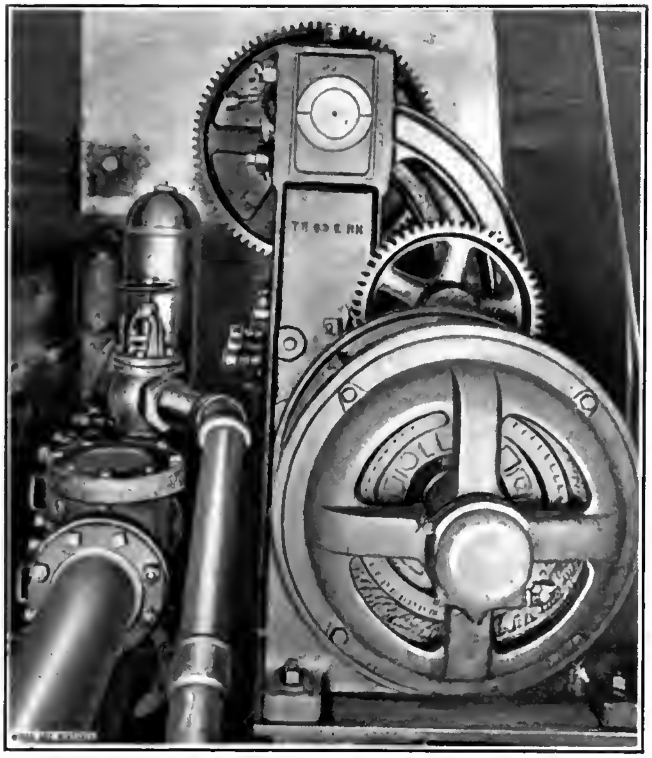

Fig. 1. Motor That Ran Under Water

motor, made by the General Electric Co., recently demonstrated the ability of their motors to operate successfully under the trying conditions met with in mines where the air is damp, without their being totally enclosed. This is of importance, as thorough ventilation of the motor is absolutely necessary due to the high temperatures which prevail if enclosed. This motor is geared to a mine pump at the bottom of the shaft at the mines of the Richmond Iron Works, Richmond Furnace, Mass., and is installed where the air is always damp, and moisture is continually dripping from the roof timbers. It is protected from this water by a piece of tarred paper tacked above it, so as to conduct the water away.

During a winter thaw the surface water broke in on one of the upper levels, and flooded the mine. The water rose so rapidly that the electric pump was soon under water, the top of the motor being 2 feet below the surface. Under such circumstances it was imperative that the pump should continue in operation so long as possible, and it was not shut down. It continued to operate perfectly, and at the end of 2 hours, during the whole of which time the motor was submerged under water, it had pumped itself clear of water. It was then stopped only long enough to clean the dirt and chips from around the rotor and put oil in the bearings, and then was started up again. This pump has been running about 20 hours a day ever since, and the motor has apparently suffered no injury from its unusual experience.

MINING IN THE MALAY STATES

The following from an engineer in charge of a mine in the Federated Malay States, gives color to the labor troubles in that Mohammedan country:

"Soon the Malays celebrate their great festival, lasting for three days, during which time eating, drinking, driving in carriages and rickshaws, constitute the program. This festival is a fitting end to the great fasting month during which no true Mohammedan is allowed to eat but twice in 24 hours, and that when dark, at 6:30 p. m. and 2 a. m. Between these hours they are allowed neither to eat nor drink, not even water, nor are they allowed to swallow their own saliva, but must expectorate. They fast 15 hours every day. The festival is a nuisance as the laborers are always getting sick and some become too weak to work as the days advance. It is fortunate that it only lasts one-twelfth of a year."

NEW INVENTIONS

Complete specifications and drawings for any of the following patents can be obtained from the Commissioner of Patents, Washington, D. C., at the following rates.

Single copies	5 cents each
Copies by subclasses	3 cents each
Copies by classes	2 cents each
At entire set of patents	1 cent each

PATENTS PERTAINING TO MINING ISSUED DECEMBER 6 TO DECEMBER 27, 1910, INCLUSIVE

No. 977,522. Coke-drawing machine, Howard Greer, Jr., Chicago, Ill.

No. 977,444. Apparatus for mining sulphur, Herman Frasch, New York, N. Y.

No. 977,956. Separator for lump material, Arthur Langerfeld, Scranton, Pa.

No. 977,955. Cutter head for tunneling machines, John Prue Karns, Boulder, Colo.

No. 978,321. Apparatus for handling mine cars, James McEvoy, Toronto, Ontario, Can.

No. 978,236. Process of utilizing coke breeze, Henry A. Tobelmann Warren, Ariz.

No. 978,659. Dynamite thawer, Sheridan S. Scholl, Roanoke, Va.

No. 978,642. Air reservoir for mines, Patrick Quinn, Forbes Road, Pa.

No. 978,586. Rock drill, Charles A. Hultquist, Bisbee, Ariz.

No. 979,086. Method of mining coal, Thomas Nichol, Glen Jean, W. Va.

No. 979,319. Mining starter bit, George G. Mayer and Reese Ashton, South Bethlehem, Pa.

No. 979,253. Operating mechanism for ore jigs, William Alma Bradley, Spokane, Wash.

No. 979,349. Furnace for roasting ores, Xavier de Spirlet, Brussels, Belgium.

No. 979,180. Method of treating ore, Thomas J. Lovett, Chicago, Ill.

No. 978,971. Process of treating fine ores, James N. Whiteman, Philadelphia, Pa.

No. 979,584. Coal washer, Newton A. Smith, Marion, Ill.

No. 980,004. Coke drawer, Andrew H. Reeder, Stonega, Va.

No. 979,597. Mining machine, Spencer Jay Teller, Unadilla, N. Y.

No. 979,857. Apparatus for ore concentration, Theodore Jesse Hoover, London, England.

No. 979,820. Flotation tank for ore dressing, Samuel K. Behrend, New York, N. Y.

No. 979,921. Ore furnace, Charles J. Best, Oakland, Cal.

Mines and Minerals

Vol. XXXI—No. 8. SCRANTON, PA.—MARCH, 1911—DENVER, COLO. Price, 25 Cents

EL COBRE MINES, CUBA

*Written for Mines and Minerals, by E. G. Tuttle**

The island of Cuba was discovered by Columbus on his first voyage of exploration, October 28, 1492. He landed at what is now called the Bay of Nuevitas and took possession of the island in the name of the King of Spain. The island has been called successively Juana, Santiago, Ave Marie, and finally regained its original Indian name Cuba. Diego Valesquez was appointed governor of the island in the year 1511, and to him fell the task of subduing the warlike and savage Caribs and Nahacs.

Old Shafts and Workings That Have Been Pumped Out and Valuable Ore Recovered

It was due to the importance of Havana that the French, Dutch, and British buccaneers during the sixteenth and seventeenth centuries attempted on several occasions to capture that port. While unsuccessful, they succeeded more than once in carrying off valuable booty. When Spain was at war with Great Britain and France, in the year 1762, a strong British army under Lord Albemarle captured Havana after a siege of 2 months. The British retained possession of the island until the following year, when by treaty it was restored to the Spanish authorities on June 6, 1763.

The numerous wars and insurrections which have occurred in Cuba have been a drawback to the development of her natural resources. The early Spaniards were good mine directors, when slaves did the work, even although they never developed their mineral resources in Cuba to any great extent. Copper occurs in many parts of Cuba, and openings have been made near Cienfuegos and Santa Clara, in Santa Clara Province, also in Pinar del Rio Province, but the principal mine is that of the El Cobre in Santiago Province, Fig. 1. The Oriente, as this end of the island is called, is rich in minerals. There are large deposits of manganese and iron oxides in addition to copper and gold. An east and west mineralized belt extends along the southern coast in which the El Cobre mine is located, about 12 miles to the west of the city of Santiago. The iron mines of the Spanish-American Iron Ore Co., near Daquairi, are some miles to the east of Santiago. The new mines of this company are almost directly north of the city of Santiago, at Mayari, near Nipe Bay, where iron ore said to contain 2 per cent. nickel is mined. El Cobre is connected by a railroad 9 miles long with Punta Sal, on the west side of Santiago harbor, nearly opposite Santiago city. It is necessary to cross the bay on a boat from Santiago to Punta Sal to reach the mines by rail, but there is a wagon road from Santiago to Cobre.

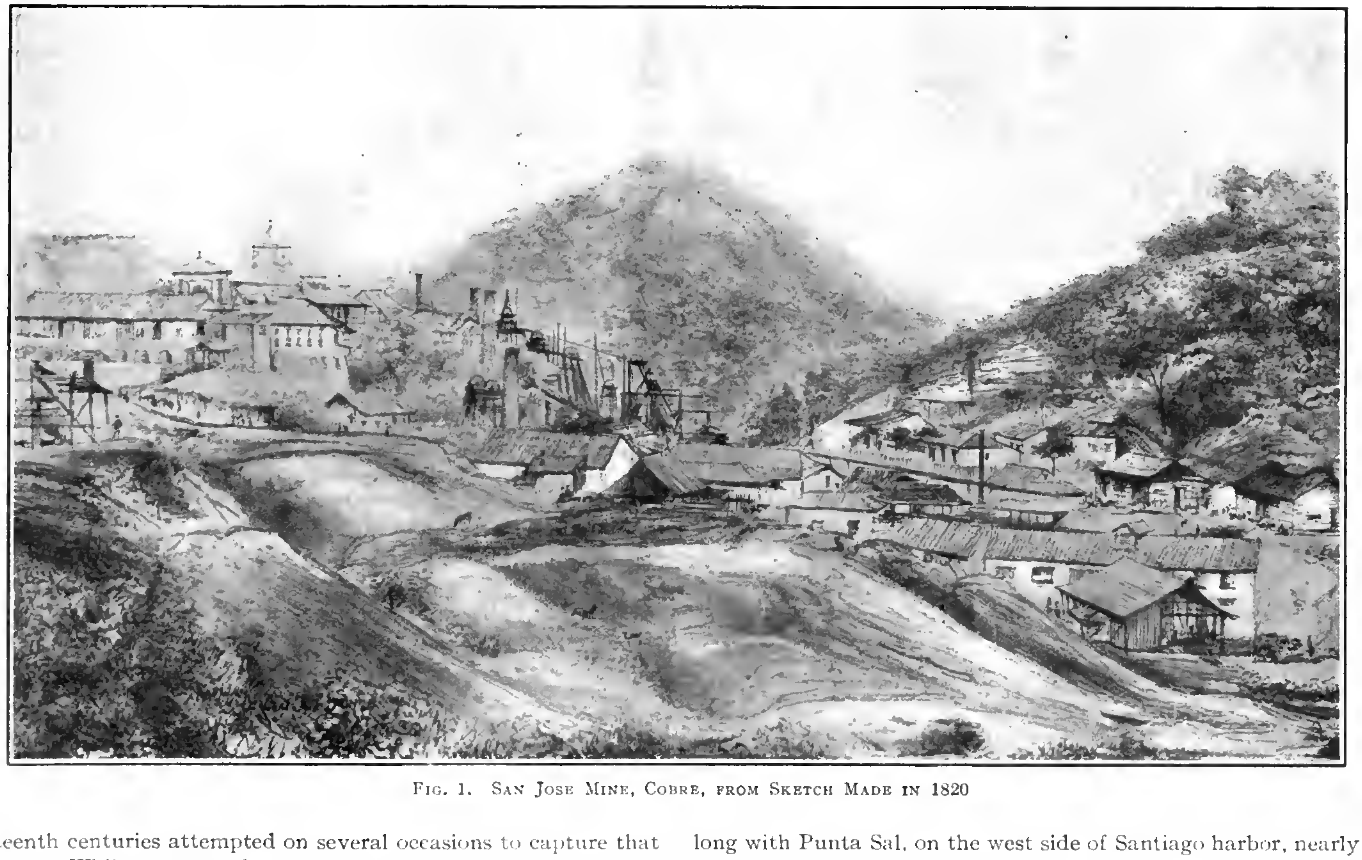

Fig. 1. San Jose Mine, Cobre, from Sketch Made in 1820

The first copper mining in the western continent, provided that of the aborigines is neglected, was done in the Province of Santiago in 1524. The mines at Cobre were worked irregularly from that time to 1832 or 1838. Previous to this time separate and individual property holdings were numerous, then there was a consolidation and several English and Spanish companies operated. In 1834 an English company bought and consolidated the principal properties of El Cobre, and operations increased

* E. M., 30 East Logan Street, Germantown, Philadelphia, Pa.

extensively. They began to assume some magnitude between the years 1840 and 1850 and continued to be prosperous until the beginning of the 10-year war, from 1868 to 1878, when operations ceased and most of the plant was destroyed by the insurgents in that rebellion. The slave insurrections in 1844, also the Lopez filibustering expedition of 1848 to 1852 probably influenced the steady operation of the mines. During the period of activity from 1834 to 1868 the annual average production of copper was about $1,000,000 yearly. The richest ores were shipped to Swansea, Wales, and this required that the ore contain more than 7 per cent. copper. The old records state that large bodies of 3 per cent. and 4 per cent. ore were left in the mines and that lower grades of ore produced in mining were either dumped in the stopes or outside the mine. From some of medium-grade ores matte was produced for shipment. It is stated that some of the shafts obtained depths of 1,200 feet and were equipped with Watt engines for hoisting, and Cornish pumps to remove water, as shown in Fig. 2. From an examination of the old machinery it was evident that it was built substantially and that also the boiler plants were well constructed. Flat hemp and flat wire ropes weie used for hoisting. The seepage water, and especially that during the rainy reason, filtered through the waste in the stopes and resulted in a considerable volume of acid water accumulating, which had to be removed by the pumps. This water attacked the cast-iron pipe columns and deposited copper and ochre to such an extent as to diminish the area of the column pipes. To prevent this as much as possible, long lines of precipitating troughs were constructed underground and filled with iron to precipitate the copper and reduce the acidity of the water. In addition to this, long lines of Californias, as such troughs are called, were constructed outside the mines, as shown in Fig. 3, to recover any copper in the water discharged from the pumps or flowing from the mine.

The concentrating mill was built below the mines for the treatment of some of the sulphide ores. Most of this is in ruins, but from the remains the plant apparently consisted of trip hammers similiar to that shown in Fig. 4, for crushers, and of jigs and buddles. From the arrangement of the plant it was evidently of small capacity and costly to operate, besides the tailing shows considerable loss. One or two attempts were made to reopen the mines after the 10-year war without success, and they practically remained idle from 1868 until 1902. When

Fig. 2. At Left, Watt Engine, Passenger Shaft; in Center What Remains of Old Cornish Pump

the property was acquired by the El Cobre Mines Co., an American concern, it consisted of about 800 acres. The mines were filled with water to within from 100 to 300 feet of the surface, and it was decided to use the Hardy shaft as the main pump shaft for unwatering the property. The old records and maps that were available did not furnish much information about the early surface workings, besides the entrances to them in many instances were caved and covered with thick tropical growth or obliterated by the wash of periodical rains through many years. The data available gave more information regarding the intermediate workings, and this information increased practically with the depth of the workings down to about 1,200 feet, or at the depth attained when operations ceased. Much of the data desired was not obtainable either because records had not been kept, or were misplaced and could not be found. It was also difficult to find the where-

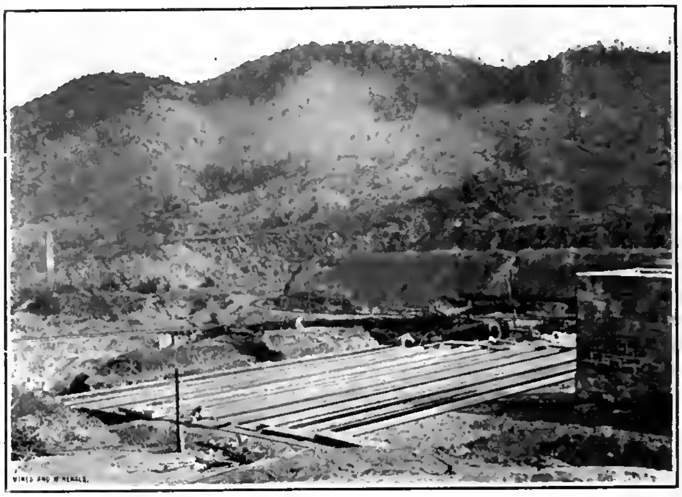

Fig. 3. "Californias" for Recovering Copper from Mine Waters

abouts of any old employes who were able to give verbal information concerning the old workings.

In the early days the ore in the veins was stoped down so far as water could be readily handled, and as the veins were leached from 100 to 300 feet below the surface, it was necessary to do considerable unwatering before any of the ore left in the old workings of moderate depth could be reached. Among the various difficulties encountered before starting up these old mines was the reconstruction of the railroad from Punta Sal to El Cobre. This road was built in the early days, down a valley as shown in Fig. 5, and operated by a Spanish company. Washouts were not infrequent along this railroad, and when the El Cobre Co. bought it many of the masonry bridges crossing the river were washed out. The river, which is apparently harmless most of the time, becomes a menace to the railroad and the mines during the rainy season. After the railroad had been put in working order a portion of it was washed out about a year afterwards and this retarded the work of development. Interruption at this time meant running short of coal at the mines, which in turn would interfere with the pumping which was the principal work in reopening; and most of the expense incurred for labor and material was directly or indirectly for the purpose of lowering the mine water. If the water gained on the pumps or the latter were out of order the work had to be done over again and greatly increased the cost. All efforts were at first concentrated on unwatering the mines to those levels where ore remained in the old stopes, and to this end an expert diver was employed to attend to submerged pumps needing repairs and the removal of obstructions from shafts ahead of the pumps. Another difficulty at the start was in pumping acid waters. Some of the shafts were timbered through old stopes, and the water seeping in these shafts through old fills was very acid, requiring pumps with bronze water cylinders and lead-lined water columns to be installed. The seepage was particulary heavy after the rainy season began, and therefore care was required to prevent the acid waters from corroding the wire ropes, cages, and cars.

Another difficulty which the American company encountered was in determining locations where the ground was sufficiently firm to place foundations for power plants, engines, etc., in other words where it had not been dangerously undermined. In cases it was necessary to proceed without this knowledge

except so far as it could be determined from surface indications, consequently some of the locations proved so insecure later on that parts of the plant had to be rebuilt in other places.

Good progress was made in unwatering the mines, and in about 1 year the shallow workings could be explored, and some new openings were made on ore deposits that were near the surface. During the year 1904 the old workings were unwatered to a depth of about 600 feet and the mud which had accumulated in most all of them, sometimes nearly filling them to the roof, was cleaned out. Explorations were also carried on in new ground which resulted in finding ore. Some large bodies of silicious sulphides containing from 2 to 4 per cent. copper were discovered in the old workings, and were developed in the walls

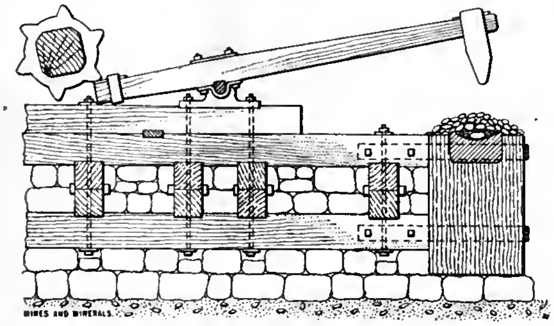

Fig. 4. Ancient Trip Hammer for Breaking Ore

of the stoped veins. Many blocks of higher grade ore were also found in various parts of the mine, besides some parallel veins to the southeast were explored which looked favorable as ore producers.

The high-grade ore taken from new openings and in exploration, beginning in 1903, was shipped to the United States. This averaged from 1,500 to 1,800 tons of 8 to 10 per cent. copper per month. Late in 1905 a depth of about 800 feet was attained at the Hardy shaft where a permanent pump station was installed on the ninth level. This was equipped with 18 in.×28 in. and 14 in.×13 in.×24 in. triple expansion Prescott pumps capable of lifting 1,500 gallons of water per minute. This arrangement of pumps drained the water from all the shafts that were being opened along the vein system to the east and west as shown in profile, Fig. 6.

In 1903 it was decided to build a smelting plant at Punta Sal for the treatment of El Cobre ore. This was completed and put in operation toward the end of 1904. It consisted of a 600-ton concentrating mill capable of enlargement, a briquet plant, and two 200-ton shaft furnaces. The low-grade sulphide ores were concentrated to a ratio of 4 to 1. The mines were equipped so that they could furnish about 750 tons of ore daily, which was to be composed of about 100 tons of 7 to 8 per cent. copper, 100 tons of 5 to 6 per cent. copper, and 550 or more tons of 2 to 4 per cent. copper. By concentrating the third-class ore and some of the second-class ore and mixing them with some of the first-class ore to obtain in all about 200 tons for the smelter charge, a surplus of the first-class ore was left for shipment if desired. It was found necessary to make some improvements to the concentrating mill after starting up. The furnace slag was disposed of at first by dumping it in the water along the shore at Punta Sal as shown in Fig. 7. This plan however was changed and the slag was granulated and hoisted for slacking in piles.

The production of the furnace for January, 1905, was 307 tons of matte containing 39½ per cent. copper; and in February of the same year the furnace produced 271 tons of matte, containing 34.12 per cent. copper.

The vein systems at El Cobre have a nearly east and west strike. The main workings are on what are known as the middle and the north veins shown in the plan, Fig. 8. Near the outcrop, these veins are about 350 feet apart and from 15 to 25 feet in width and occasionally wider. The north vein has a dip of about 55 degrees to the south and approaches the middle vein with depth, as shown in Figs. 9 and 10, which are sections through *A B* and *C D*, Fig. 8. A nearly north and south fault displaces the vein system so that on the east side this system is thrown about 200 feet to the north. The ores are mainly copper sulphide and contain little gold or silver. There are several other parallel veins on which recent developments to the south would suggest that they were of considerable importance.

The geological formations in the vicinity of the mines are for the most part tertiary eruptive andesite, although slates also occur, and exposures of porous calcareous formations are occasionally seen flanking the country rock. Associated with the deposits are large intrusions of quartz porphyry, which where exposed at the outcrop shows extensive weathering, decomposition, and leaching. The ore seems to have been developed near and in the porphyry. To the south there are some very promising copper croppings in a region of slate formation.

The first important opening on the easterly part of the property is the Pozo Verde shaft. Then proceeding westerly, see Fig. 6, the openings are as follows on the south slope of the hill:

Shaft No. 1, Hardy shaft; shaft No. 4; Arrieta shaft, not shown; Richards shaft; Passenger shaft; San Juan shaft; San Jose shaft; and on the north slope of the hill and beyond is the Mina Blanca and other openings. The Trevence shaft is to the south of the San Jose shaft, and is shown on plan, Fig. 8, as are the several tunnels 1, 2, 4, 5, opened on the north side of the hill and driven southerly to the veins. Through these the ores mined near the surface in the early days were trammed.

The Mahon shaft is an old important opening on the north side of the hill near tunnel 5. Some distance to the south of the first-mentioned line of opening and on the northern slope of the mountain is the Santiago mine, and some distance to the west of this is Jueves Santo mine.

Pozo Verde is an old mine of considerable depth. It was reopened to some distance below the fourth level which is 216 feet below the surface, as shown in the profile, Fig. 6. By pumping at the Hardy shaft the water lowered so that from the

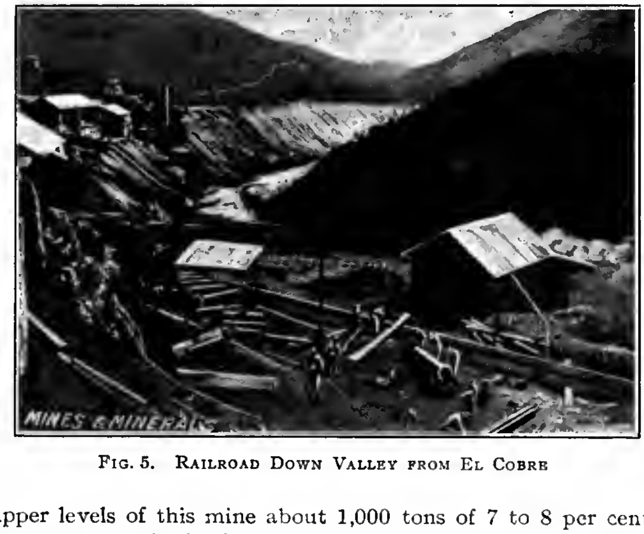

Fig. 5. Railroad Down Valley from El Cobre

upper levels of this mine about 1,000 tons of 7 to 8 per cent. copper was obtained per month. Considerable low-grade sulphide ore was found in the old stopes and faces. It is probable that this mine is on the same vein system as the Hardy mine.

No. 1 shaft is a new opening on a body of oxidized ore that was uncovered by the recent development work, near the surface. The opening was 144 feet deep and dry, as it is in a continuation of one of the Hardy mine veins. About 300 tons

per month of from 11 to 13 per cent. copper ore was obtained from this opening.

During the time of the old operations pumping plants were at the Pozo Verde, Hardy, Richards, San Juan, Santiago, and other shafts. The Richards shaft was equipped with a heavy Cornish pump the ruins of which are shown in Fig. 11.

Through the Hardy shaft the veins on the east of the fault were reopened. What apparently here corresponds to the middle vein is associated with two other veins, see Fig. 8. Considerable 3 per cent. to 6½ per cent. copper ore was found in the mine from the fifth level down. Some of it was in pillars and some in the solid. Above this the veins were extensively stoped. The lower levels connecting with the Richards shaft in a roundabout way also showed good ore remaining near the fault. On the sixth level a rock tunnel was driven toward the Santiago mine. Several of the Hardy mine levels extended to the north vein. On the ninth and tenth levels openings to the north vein showed considerable ore assaying 5 per cent. to 9 per cent. copper; 10 per cent. to 17 per cent. iron; 17 per cent. sulphur, and from 6 per cent. to 13 per cent. lime. The ore produced from this shaft in exploration and mining amounted to about 400 tons of 6½ per cent. copper and 600 tons of 3 per cent. copper per month. The north vein approached closely to the middle vein on the lower levels, as shown in Figs. 9 and 10. Cross-cut tunnels to the north vein were opened at several places, and disclosed that the vein had been extensively mined and filled. Some stopes were open and heavily timbered, and good ore remained in occasional pillars or along the walls.

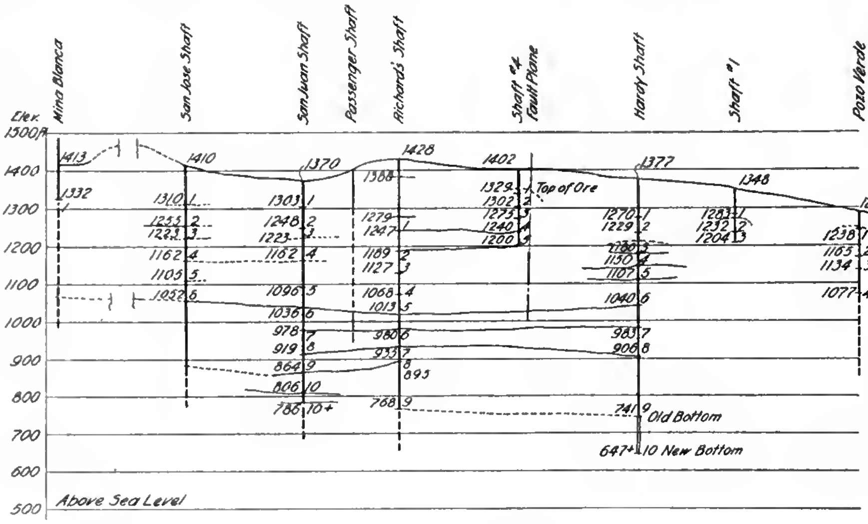

Fig. 6. Profile of Mine Shafts

No. 4 shaft was a new opening on a body of ore near the fault. This shaft is 200 feet deep and is connected with the north vein on the west side of the fault. The mine was dry and the best of the ore came from above the fourth level. The monthly output from here was about 1,600 tons of from 7 per cent. to 7½ per cent. ore and 700 tons of 3 per cent. ore.

The Richards shaft was equipped for hoisting some of the ore from the Hardy and San Juan workings as well as its own. The lower levels of this mine developed the north vein which was very close to the middle vein at this depth. Thick bodies of ore had been extensively mined in the past in the vicinity of this shaft and there was still considerable ore remaining. Some of the stopes were heavily timbered and others were filled.

The Arrieta shaft was not reopened but some of the levels of the Richards shaft extended in its direction. This was once an important mine as large bodies of ore had been stoped. It is located near the intersection of the north vein and the fault. A cave occurred here during the reopening which took in a large area of the surface near the stream and one of the buildings and the lumber in the yard, leaving a deep pit.

San Juan shaft was sunk in the early days on the middle vein, and as in the other cases mentioned, the ore was stoped pretty thoroughly in the upper workings. Good ore remained in the pillars in the lower levels, and high-grade ore was developed in the pillars in the lower levels, and high-grade ore was developed in new explorations. A large body of low-grade quartz sulphide ore was cross-cut in driving in the wall north of the vein on the lower level. This deposit lies between the middle and north veins and is developed for considerable distances to the east and west, and from 200 to 300 feet in height. This deposit was blocked out and as soon as it was removed the space excavated was timbered with square sets. The San Juan shaft was very wet and the water very acid. The monthly output was from 200 to 400 tons of from 9 to 11 per cent. copper ore, and a large tonnage of low-grade ore carrying up to 4 per cent. copper.

The exploration of the San Jose shaft workings was mostly carried on through the San Juan workings. The lower levels were reopened beyond the San Jose shaft toward the Mina Blanca shaft, and the vein was found to have been extensively mined in this direction. A quantity of good ore remained in the stopes and there was a satisfactory amount of unworked ground. Considerable cement copper was found in old Californias at this mine. The old operations, of which there are several on a continuation of these veins to the westward, were

Fig. 7. Punta Sal Smelter, Cuba

not reopened to any extent. The ores in this direction, according to old reports, are said to contain considerable zinc and gold.

The Trevence shaft, which is about 600 feet south of the San Jose shaft, was reopened a short distance and slightly explored. It is on a vein to the south of the middle vein, and cross-cuts were driven from the San Juan shaft in the direction of these workings.

The Jueves Santos mine is an old one some distance to the south on another vein system of some promise. It was reopened through an old drift where there had been some old shafts worked. A small amount of ore was produced here in the exploration of comparatively new ground.

The Santiago mine, which is on a parallel vein a short distance to the southeast of the Hardy shaft, was worked in the early days but probably not steadily toward the last. There was water in some of the workings which may have been difficult to handle. A few parts of what was then a new Cornish pump, Fig. 12, are lying on the ground ready for installation, apparently indicating an intent to further develop the property. A considerable amount of good ore has been obtained from some of these workings. In removing the pump columns from the Richards shaft and elsewhere, some cement copper was obtained where the acid water had attacked the pipe and precipitated copper thereon. Frequently old iron pipe and wire rope were found in the mines which had almost completely turned to copper. The result of the reopening to a depth of 800 feet continued to prove satisfactory, as the deeper and remote workings were penetrated and explored. As stated, the greatest depth attained by the old workings is reported to be 1,200 feet and further reports state that large bodies of low-grade ore, or mundic, as it is referred to, are said to have been opened up at this depth. The north vein is also said to unite with the middle vein and form large ore bodies. The shafts that attain a depth of 1,200 feet are probably the Richards, San Juan, and possibly some others. Among the fairly deep shafts are the Pozo Verde, Pozo Viejo, Hardy, Arrieto, Mahon, Richards, Påssenger, San Juan, San Jose, Mina Blanca, and some others to the west; also the Trevence and Santiago.

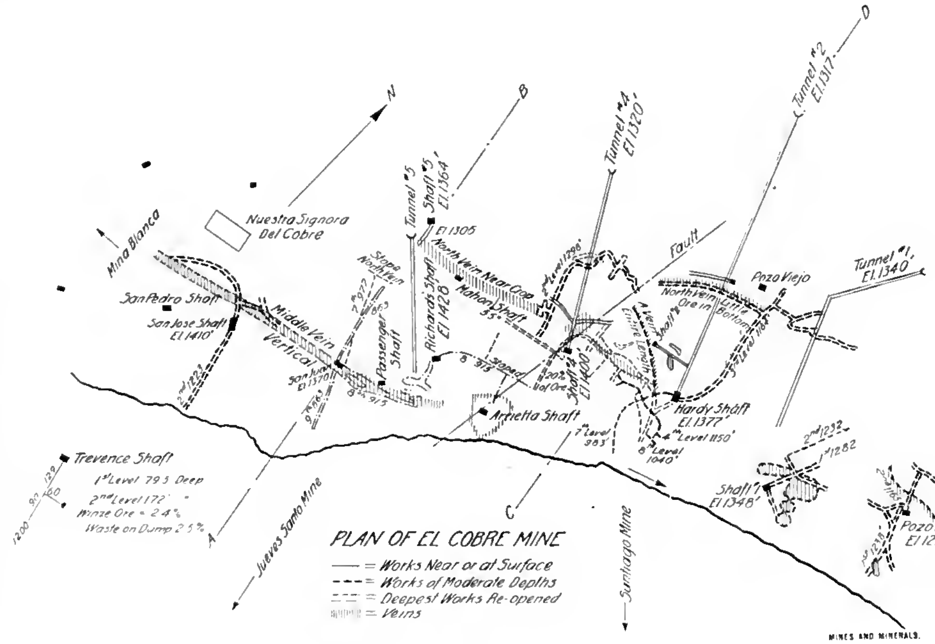

Fig. 8. Plan of El Cobre Mine

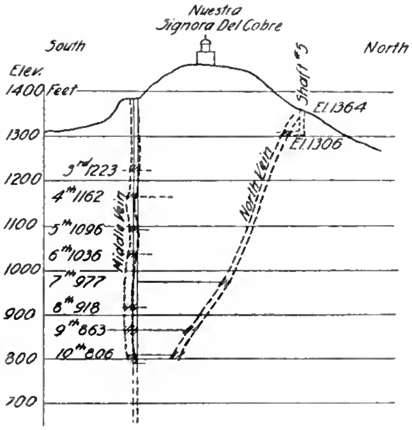

Fig. 9. Section on A-B, Fig. 8

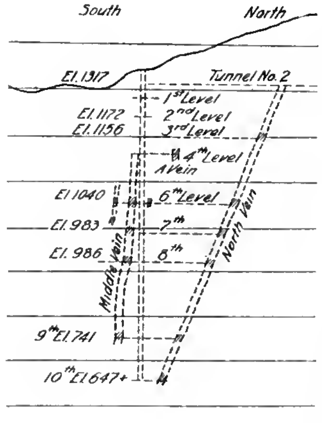

Fig. 10. Section on C-D, Fig 8

Operations were steadily improving when late in the year 1906 a cave-in of old workings occurred between the Hardy and the San Juan shafts. The cave extended from the lower levels to the surface and affected the shafts so that all mining work in this area was closed down and smelting operations at Punta Sal suspended. The extensively mined stopes in the old workings had become weakened through age, and the lowering of the water after so many years' standing probably had some effect thereon. Many of the stopes were opened for wide areas. Several of those that were filled caved during the period of reopening. The country is subject to frequent earthquakes and these occurrences have at times caused the stopes to cave. The explorations of the veins to the south of the old workings resulted in obtaining a large amount of ore for shipment after the old works caved in. Some very good ore is being obtained near or from the Santiago workings, so that the shipment of quite a large tonnage to the United States is kept up. The development in this section may result in some large operations in the future. It is probable that any exploration of the old workings would be better carried on in a shaft sunk in more secure ground to one side of the old veins, or at some distance to the east or west near or on the vein. In the event of such an undertaking it would be preferable to sink deep enough to reach the solid ore below the bottom of the old workings. Cross-cuts might be driven from such a shaft to any of the levels of the old workings if such was warranted.

A most interesting feature of El Cobre and one that has made it widely known throughout the world, is the Sanctuary of the Virgin of Cobre. This stands upon the very apex of the Cobre vein, and its pink dome and square blue towers may be seen from any point in the mountains for miles around. The incident of its erection forms a part of the history of the mine.

Alonzo Ojeda, from San Domingo, wrecked upon the shores of Cuba early in the fifteenth century, was saved from death by an Indian chief, Cacique by name. Ojeda had with him an image of the Virgin, and, in fulfilment of a vow conditional on saving of his life, built a chapel to her in the town of Cuieba. This was the first christian chapel in the island of Cuba. The Indian chief, however, stole the image to try the Lady's charm against his enemies, and it is said that so great was her power that he never lost a battle while he had the image in his possession

In 1660, so legend has it, Juan de Joyos and Rodrigo de Joyos, Indians, and Juan Moreno, a negro, found the image floating in the bay. On a board upon the image was written: "Yo soy la Virgin de la Caridad"—"I am Our Lady of Charity." These three men took the image to Hato, where the mayor erected an altar for her, at the same time notifying the manager of the Royal Mines at El Cobre, Don Francisco Sanchez de Moya, that he had done so. Francisco built a chapel for the Virgin, first at Hato, and afterwards she was brought to Cobre, and a chapel was built for her in the town. As the mine prospered, Our Lady of Caridad became, as it were, the patron saint of the mine, and the sanctuary was built for her protection on the present site. It is a handsome building, 150 ft. × 90 ft., supported by massive columns, and is reached by 430 steps from the village below. Up these steps on their knees the pilgrims passed in thousands to pay their "promesas" to the Mother of Charity, and many wonderful cures of the sick are mentioned. Back of the chancel is a pile of crutches and canes, testifying to the fact that cripples had left the sanctuary without these aids to locomotion.

Fig. 11. Old Cornish Pump—El Cobre

Heroic figures of the saints stood on either side of the entrance to guard the Virgin, who, in her cloth of gold, stood on the altar under the great dome. The figure is about the size of a child's doll and holds a small image of the Holy Infant in her left hand who in turn holds a sphere symbolizing the world. The right hand of the image is raised in benediction.

This celebrated shrine was on the ground that caved in 1906, and while the sanctuary still stands Nuestra Signora del Cobre has been placed in the El Cobre railway station.

The following table gives the average analysis and kinds of ore obtained in the various openings of El Cobre:

Name of Mine	Kind of Ore	Analyses			
		Cu Per Cent.	*FeO* Per Cent.	*SeO*² Per Cent	*S* Per Cent.
Pozo Verde	Sulphides	8.00	22.00	42.80	17.40
Shaft No. 1	Oxides	13.80	11.10	67.70	2.50
Hardy shaft	Sulphides	6.45	15.40	58.50	13.70
	Sulphides, 3d class	3.16	11.60	69.70	8.60
Shaft No. 4	Sulphides	7.50	10.85	63.30	11.00
	Sulphides, 3d class	3.28	11.00	72.40	5.50

Tunnel No 2	Oxides				

PHOSPHATE IN OCEANIA

The island of Makatea, which is situated in the extreme northwestern part of the extensive Tuamotu Archipelago, has an area of about 10 square miles, one-fifth of which is covered with deposits of phosphate estimated at 10,000,000 tons, of an average grade of 82 per cent. So far as is known here nothing further has been done to develop the phosphate discovered on Henderson (or Elizabeth) Island, a British possession lying east of the Society Islands. As that island is of an elevated coralliferous limestone formation like Makatea, Ocean, Pleasant and Angaur, it is highly probable that further investigations will show conclusively that the deposits on Henderson are large and valuable.

The world's annual production of phosphate rock is about 5,000,000 tons, the United States being the largest producer, with an annual output of more than 2,000,000 tons. Tunis, which ranks second, produced phosphate of a rather low grade to the amount of $6,117,000 in 1908. In 1909 the great Gafsa Company, which owns its own railroad, mined 907,000 metric tons (metric ton = 2,204.6 pounds). It pays a large dividend on its capital of $7,750,000, as is shown by the fact that the stock of this Tunisian company is selling in Paris at a premium of more than 600 per cent. The Pacific Phosphate Co., of London, which owns deposits of 50,000,000 tons of high-grade phosphate on Ocean and Pleasant islands, is mining some 250,000 long tons a year at a profit of more than 50 per cent. on its capital stock of $1,216,600. A German company has recently begun to mine phosphate to a considerable extent on the island of Angaur, which lies in the western part of the Carolines at no great distance from the Philippines.—*United States Consular Report.*

ACTION OF *CO* AND *H*, OR CO_2 AND *H*, ON IRON OXIDES

A mixture of three volumes of *CO* and one volume *H* was passed at 300° C. over ferroso-ferric oxide. The product contained about 7 per cent. carbon, the remaining 93 per cent. being about one-half ferrous oxide and one-half iron carbide. When steam was passed over this at 400° C., a gas was obtained containing 96 per cent. *H* and 4 per cent. CH_4. If two volumes CO_2 and 1 volume *H* were passed over iron at 1250° C. the issuing gas consisted of 23 per cent. *CO*, 76 per cent. *H* and .15 per cent. CH_4. A mixture of equal volumes of *CO* and *H*, saturated with H_2O vapor was passed over Fe_2O_3 at 250° – 300° C. and the resulting gas was heated to 500° or 600° C. Besides permanent gases a small proportion of a substance condensible to a jelly-like solid, like vaseline, was obtained. These experiments may have a bearing on the geological formation of hydrocarbon gases and petroleum. A. Gautier and P. Clausman. (Comptes rendus, cli, 355.)

CANADIAN IRON ORE INDUSTRY

Written for Mines and Minerals

A Description of the Principal Iron Deposits of the Province of Ontario

The Canadian Department of Mines, under the direction of Eugene Haanel, Ph. D., issues from time to time advanced chapters of the Annual Report of the Bureau of Mines. Bulletin No. 79, by John McLeish, B. A., chief of the Division of Mineral Resources and Statistics, contains much interesting information for those engaged in the iron and steel industry as well as for laymen. The information in the following article has been abstracted from the Annual Report of the Bureau of Mines, Ontario, and from Bulletin No. 79.

Although iron ores are of wide occurrence throughout Canada, their development has not kept pace with the growth of the manufacture of pig iron and steel, a feature of which reminds one of putting the cart before the horse, were it not that the transportation facilities in Canada must be considered before conclusions are reached. In 1909 the iron mines of Canada produced 268,043 net tons of iron ore, of which number 21,956 tons were exported, and during the same period 1,235,000 tons or 83 per cent. of the ore used in making was imported.

Most of the imported ore came from Newfoundland and the south shore of Lake Superior, although it is probable that the Thunder Bay district in the vicinity of Lake Nipigon is abundantly supplied with iron ores. Heretofore Nova Scotia has been the chief pig-iron producer of the Dominion, but in 1909 Ontario took the lead.

The Oranian iron range is 23 miles northeast from Humbolt Bay in Lake Nipigon.* According to E. S. Moore, the iron formation extends east and west in two bands about 2 miles apart. The iron ore deposits in this district are lean magnetites of the following average analysis taken from specimens: Metallic iron, 50.52 per cent.; ferrous iron, 17.06 per cent.; silica, 26.85 per cent.

The Lake Savant iron range is northwest from Lake Nipigon, and although extensive has had no pay ore located up to this time. The ore is a lean magnetite that contains from 35 to 40 per cent. iron when free from schist.

The Moose Mountain mine is located 25 miles north of Sudbury, in Hutton township. The ore occurs in the lowest Pre-Cambrian rocks termed "Keewatin," which consist of banded iron formation, greywacke and fine-grained gray gneiss, rhyolites, quartz-porphyries, greenstones and green schists. The ore is fine-grained magnetite, hard but comparatively easy to crush. The property is known to contain four different deposits, with probably different analyses, as is usual in such magmas; however, No. 1 deposit is the one at present worked.

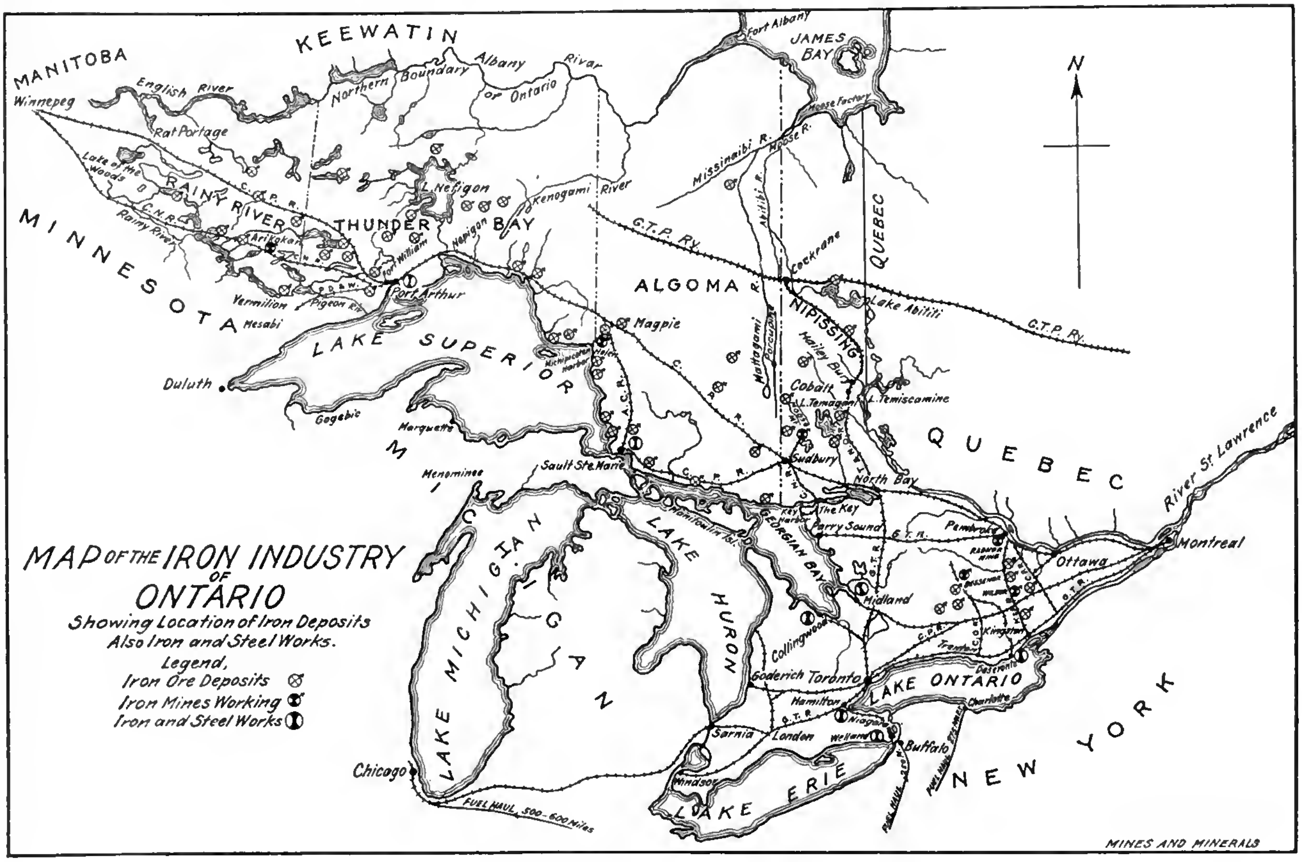

Fig. 1. Map of Ontario, Canada

Nos. 3 and 4 are said to be equally as good although not so well known, while No. 2 is low grade and will require concentration. No. 1 deposit, which is 500 feet long by 150 feet wide, is 210 feet horizontally and 140 feet vertically above the railroad track, as shown in Fig. 2. The ore is mined open-cut, consequently no shipments are made during the freezing months; in the warmer months the ore is shipped 80 miles over the Canadian Northern Railway to docks at Key Harbor, on Georgian Bay. As the ore is broken from the 65-foot stope it falls to the level, where it is loaded in mine cars, trammed to a 30-degree pocket chute *a* and dumped. From the large pocket the ore is fed to the large gyratory crusher *b*, which reduces the pieces to 6-inch diameter and passes it on to the 48″ × 12″ rotary screen *c* having ½-inch perforations. All ore that passes through the screen falls to the elevator boot *d*, but all ore that passes over the screen is fed to the gyratory crusher *e* and is reduced to 1-inch diameter before discharging in the boot. The elevator *f* raises

* Eighteenth Bureau Mines Report, page 196.

the ore in 14″×30″ buckets to the storage bin *g* of 250 tons capacity, from which it is loaded into drop-bottom steel railroad cars and transported to the ore docks at Key Harbor. At the docks the cars are dumped from a trestle on a stock pile, underneath which and in center line of the trestle there is a tunnel through which a 42-inch traveling belt moves and conveys the ore to a similar belt at the docks.

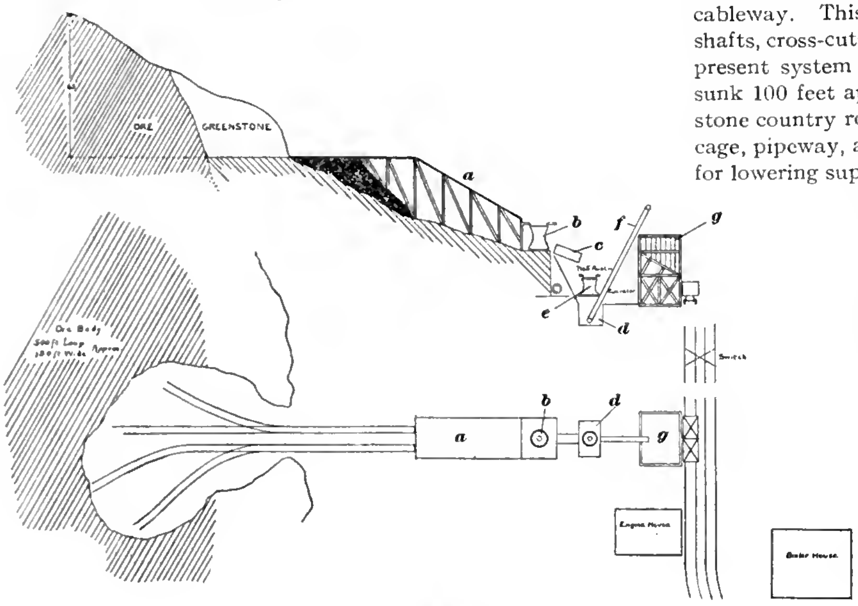

Fig. 2. Moose Mountain Mine

The second belt elevates the ore to the dock trestle 60 feet above water level, but before the ore is tripped off the belt into the ore pockets it is automatically weighed. It is expected that the belts will have a capacity of 800 tons per hour, and also that from the pockets, which have 8,000 tons capacity, ore can be loaded into the holds of vessels at the same rate. As stated, the ore is magnetite, and it may be added that it is of non-Bessemer standard, it being sold on the following guaranteed analysis: Iron, 55.50; silica, 13.29; alumina, 1.21; phosphorus, .10; manganese, .02; lime, 3.60; magnesia, 3.15; sulphur, .011; moisture, 1.

Another producing Canadian iron mine, known as the Helen, is situated 12 miles from Michipicoten Harbor and is connected with that shipping point by a branch line of the Algoma & Hudson Bay Railway. This is the largest iron mine in Canada, as it is capable of producing 1,000 tons of hematite and limonite daily. The first grade ore is a hard, compact, red hematite, 60 per cent. iron or over; the second grade is a porous but hard brown limonite, 57 to 58 per cent. iron; the third grade is a soft brown limonite, 53 to 54 per cent. iron. Samples of the ore taken from the stock pile at a furnace and said to be representative, gave the following analysis: Iron, 57.100; silica, 5.270; alumina, 1.040; phosphorus, .128; manganese, .038; lime, .200; magnesia, .100; sulphur, .053; moisture, 3.410.

Were it not that the presence of phosphorus exceeded the Bessemer limit, which in this ore is $\left(\frac{57.10}{1,000}=\right).057$, the ore could be classed with the best of Lake Superior ores as it is of such composition as to admit of rapid reduction in the blast furnace. The iron formation of the Michipicoten district in which the Helen mine is situated consists of ferruginous cherts, banded cherts and iron ore, and cherty siderites, which contain the iron ore proper. The formation, which is 1¾ miles long and 900 feet wide, strikes east and west and lies in greenish or brownish schists belonging mostly to the lower Huronian. The main ore body extends 1,400 feet eastward from the eastern end of Boyer Lake and has an average width of 400 feet. The highest point at which the ore is found is 100 feet above the lake, and as drill holes have proved the ore to a depth of 188 feet below the lake level, the total thickness is approximately 288 feet.

During early mining the ore was worked as an open cut, broken down by heavy blasts, loaded with steam shovel, and where inaccessible to the latter it was handled by a Lidgerwood cableway. This system of mining was abandoned in favor of shafts, cross-cuts, and stopes. In Fig. 3 is shown a plan of the present system of working. The shafts No. 1 and No. 2 are sunk 100 feet apart, to the south of the ore body in the greenstone country rock. No. 1 is a double-compartment shaft with cage, pipeway, and ladderway. It is used mostly for a manway; for lowering supplies and for hoisting waste rock. It is 450 feet deep. No. 2 shaft has two compartments that are used exclusively for hoisting ore. Both shafts are connected at the bottom by a drift 100 feet long, and from the bottom of the No. 2 shaft a cross-cut *a* is driven 150 feet and continued through the deposit to the northern boundary of merchantable ore, and hence 500 feet a main drift *b* follows the ore to its eastern boundary. From the main drift the levels *c*, *d*, *e*, *f*, etc. are branched out every 50 feet, running to the boundaries of the deposit in each case. Risers are made in these levels every 40 feet and are driven to within 20 feet of the corresponding level above, after which chutes are put in the bottom of each riser as shown in Fig. 4.

The stopes, which are not more than 60 feet high, are worked overhand from the boundaries of the ore body back toward the main level. Boyer Lake is pumped out adjacent to the mine to prevent the water seeping into the workings and necessitating its being pumped to the surface; however, it requires five pumps inside to keep the mine free from water.

Ore is raised in 4-ton skips and dumped directly into a large gyratory crusher capable of breaking 2,500 tons per day to a diameter of 6 inches. When navigation closes, the development work is carried on underground; for instance, new levels will be driven at greater depth and whatever ore is stoped is raised to higher worked-out levels, where it accumulates without freezing and can be drawn off as soon as navigation opens.

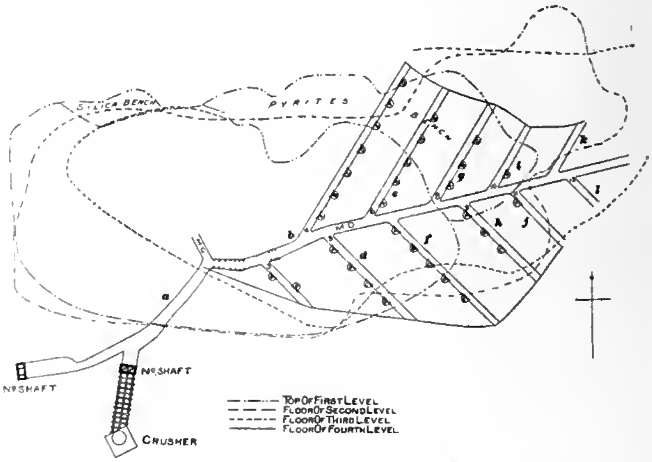

Fig. 3. Plan of Helen Iron Mine

In one instance, a drift run on the third level through a dike found a body of good Bessemer ore; in another case, a drift from the easterly limit of the ore on the fifth level encountered a large body of pyrite, and a large tonnage of this ore has been blocked out for future shipments.

The surface plant at the Helen mine is driven by electric power from the Algoma Power Co., at High Falls, on the Michipicoten

River. An 80-horsepower motor drives No. 1 hoister; a 150-horsepower motor drives No. 2 shaft hoister; a 200-horsepower motor drives a 12-drill compressor; a 100-horsepower motor drives a turbine pump having a capacity of 500 gallons per minute against a head of 400 feet; and an 80-horsepower motor drives the ore crusher. The power is brought to the mines under a pressure of 10,000 volts and is stepped down at the transformer house at the mine to 550 volts. The steam plant is kept in reserve in case there is a break in the power plant. The Lake Superior Power Co., of Sault Ste. Marie, Ont., which owns the Helen mine, is also developing a mine called the "Magpie," 15 miles northeast on the Algoma Central Railroad.

The iron-ore industry in Canada has been encouraged by a bounty and so much as $1.70 per ton was paid for pig iron manufactured from Canadian ores. In the table following the production of iron ores in net tons for 1909 is given:

Kind of Ore	Net Tons 2,000 pounds	Total Value Dollars	Value Per Ton Dollars
Magnetite Fe_3O_4........	74,240	$162,280	$2.19
Hematite Fe_2O_3........	190,473	492,348	2.58
Limonite $Fe_2O_3.3H_2O$..	3,330	4,688	1.41
Totals...............	268,043	$659,316	$2.46

The Atikokan Iron Co., Ltd., of Port Arthur, owns an iron mine 132 miles to the west, near the Canadian Northern Railway. The ores occur in a ridge of chloritic schist striking east and west across a swamp for a distance of 4,000 feet. Parallel bodies of magnetite standing almost vertical can be traced along this ridge.

The ore carries 60 per cent. metallic iron, but is unfortunately mixed with pyrrhotite and pyrite to such an extent that the run-of-mine ore will average 2.5 per cent. sulphur. Like most magnetic iron magmas, the ore carries phosphorus to such an extent it is non-Bessemer; in this case $\left(\frac{62.14}{1,000}=\right).062$ per cent. phosphorus is the limit, whereas from the analysis of the run-of-mine ore given below it carries .12 per cent. phosphorus. Analysis of the Atikokan run-of-mine ore: Iron, 62.14; silica, 7.64; alumina, .75; sulphur, 1.40; phosphorus, .12; manganese, .09; magnesia, 2.18; lime, 2.54. In 1909, 150 tons of ore were shipped daily from this mine to Port Arthur, where it was

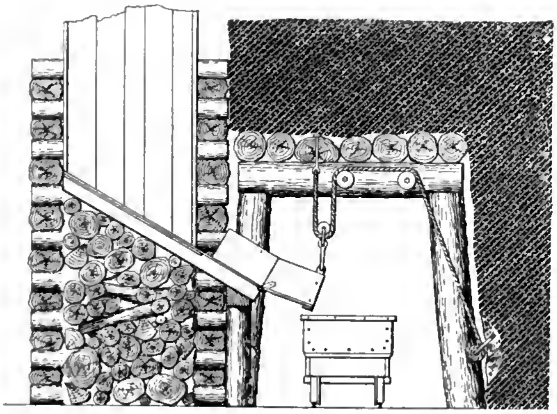

FIG. 4. LOADING CHUTE AT BOTTOM OF RISER

roasted by the waste gases from the blast furnaces of the same company. The ore bodies, three in number, are cross-cut by a tunnel 6 feet to 12 feet wide driven through the hill. The deposit *a*, Fig. 5, is 40 feet wide; deposit *b*, 10 feet wide; and deposit *c*, 16 feet wide. Deposit *a*, the only one worked at present, is developed by "risers," started 85 feet to the east from the tunnel and 65 feet to the west, the object being to understope the ore back toward the tunnel after the risers are holed through to the surface. When ore is broken it is trammed out of the tunnel and fed to a gyratory crusher having a capacity of 50 tons per hour. After crushing, the ore is delivered to 12″×18″ elevator buckets that raise it to a sufficient height to fall by gravity into 50-ton drop-bottom steel cars. No storage pockets are used, but a string of empty cars are kept spotted on the mine siding and allowed to run by gravity to the elevator as required.

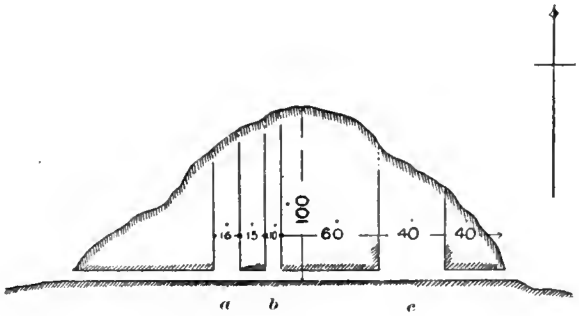

FIG. 5. CROSS SECTION OF ATIKOKAN IRON MINE

In Eastern Ontario several magnetite mines are opened. The Canada Iron Corporation, Ltd., of Montreal, operates the Mayo mines, at Bessemer, in Hastings County, 5½ miles east from L'Amable station on the Central Ontario Railway,

There are five ore deposits opened at Bessemer, which strike northeast and southwest, the usual strike of New York state, and New Jersey magnetites. They dip 60 degrees to the south, and lie in diorite schists and greenstones with one or two intrusions of gneissoid granite with crystalline limestone on the foot-wall. In this respect they differ from the New York and New Jersey magnetites, which are in gneissoid granite with no limestone nearby. The Franklinite deposit of New Jersey is in white crystalline limestone, but with this exception there is probably no other location where magnetite is associated with calcite in the states mentioned. The ore at the Mayo mines is fine grained and will, if cobbed, average 60 per cent. iron. Phosphorus is below the Bessemer limit and the sulphur, which occurs in small stringers of iron pyrite, can be separated by hand picking. An average analysis of the shipping ore from No. 4 opening is as follows: Iron, 54.29; silica, 9.84; alumina, 2.02; phosphorus, .019; manganese, .38; lime, 6.86; magnesia, 1.35; sulphur, .062.

At No. 3 mine the open cut is 36 feet deep and 80 feet square in an ore body approximately 300 feet deep and 800 feet long. The ore from this pit is not all high grade, the proportion being 35 tons high grade to 50 tons low grade. No. 4 open cut, shown in Fig. 6, is 55 feet deep and 500 feet long. At the west end of this cut an 8′×14′ incline follows the dip of the ore. The shaft house shown in Fig. 7 is placed near the shaft collar to receive the ore from the hoisting skip. In order to make a uniform product for the blast furnace the ore is crushed before loading on the cars. It has been found from experience that magnetite is somewhat more difficult to smelt than hematite; however, the No. 4 ore should be more readily smelted than hematite. Magnetite produces less flue dust in the blast furnace than hematite and the best results will be obtained by a mixture of the two ores. The No. 4 ore body has been traced 1,800 feet on the surface and is supposed to be 55 feet wide, between walls. Forty feet of the width is high in iron, the remaining 15 feet is lower in iron and high in sulphur. In this ore bed the pyrite is not spangled through the ore, but is found in fairly large masses, and along the contact of the ore with the country rock.

At the Child's mine 2½ miles east of Bessemer there is an immense body of low-grade magnetite averaging 40 per cent. iron, with both phosphorus and sulphur within Bessemer limits. The gangue of this ore consists of hornblende and calcite with a varying proportion of silica.

The Radnor mine, in Grattan Township, Renfrew County, has been one of the most important iron-ore producers in Eastern Ontario. The ore, which is a coarse crystallized magnetite, occurs in beds from 4 to 10 feet wide, that strike northwest and southeast, with an average dip of 34 degrees. Assorted ore from this deposit carries about 50 per cent. metallic iron, the tailing about 30 per cent.

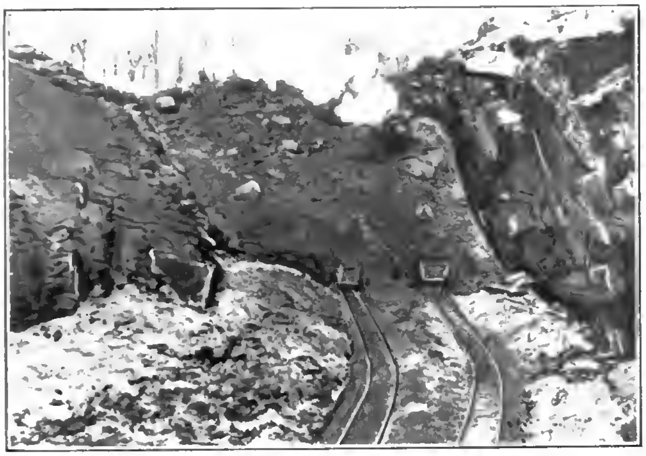

Fig. 6. Open Pit, Mayo Iron Mine No. 4

Another mine in Renfrew County is in Lavant Township, about 60 miles north of Kingston, on the Kingston & Pembroke Railway. This deposit of magnetite, known as the Wilbur mine, is found in detached masses at the contact of crystalline limestone and gneissoid granite, the limestone being invariably in the foot-wall. The strike is a little east of north, with the ore dipping at an angle of 27 degrees to the east. One peculiarity of this deposit is that while the run-of-mine ore carries 50 per cent. iron, the ore is seamed with chlorite and calcite, making it evidently a deposit of second concentration. An analysis of the shipping ore is given as follows: Iron, 55.490; insoluble, 3.450; sulphur, .040; phosphorus, .022.

There are eight openings on the property, the most important being where the ore is mined and hoisted through inclined shafts. Other ore deposits along the Kingston & Pembroke Railway that have been worked intermittently are the Calabogie, Robertsville, and Glendower. In the vicinity of the Central Ontario Railway there are, besides the mines at Bessemer and Mayo, the Belmont, Blairton, and Coe Hill mines.

AN ACCIDENTAL TAYLOR AIR COMPRESSOR

In a recent number of *Science*, E. H. Sellards describes a "Spouting Well" which is of interest as showing how there has been unintentionally constructed what is practically a Taylor air compressor, similar in principle to the large plant at Ragged Chutes, Canada, described in the October, 1910, number of Mines and Minerals. A similar "blowing" of the compressor is there described and a photograph shown. The following is a description of the well:

In parts of Central Florida bored wells are somewhat extensively used for drainage purposes. The wells are drilled through the superficial material and as a rule enter the Vicksburg limestone of Oligocene age, although other porous limestones may serve the same purpose. Many of the wells terminate in cavities in the limestone, while others reach layers of shell or other porous material. Surface water entering the wells is carried into the limestone formation. In some localities in the central part of the state these wells have been found efficient in carrying off surface water and in draining small marsh areas.

One of these drainage wells near Orlando, in Orange County, recently developed the unusual phenomenon of spouting. The well was drilled, in 1907, near the edge of a small lake. It is 12 inches in diameter, has a total depth of 260 feet, is cased 60 feet, and terminates in a cavity in the limestone. The level of permanent underground water at this locality is 33 feet from the surface. The well is intended, by carrying off the surplus water, to prevent the lake from rising above a given level, since to do so would flood the farming land.

When first seen by the writer the water of the lake stood a few inches above the level of the top of the pipe, and the well was receiving water at much less than its full capacity. At intervals of a few minutes the well would reverse itself and spout, throwing a column of water into the air. The spouting comes on gradually. First, the well ceases to receive water and begins bubbling; the column of water follows, rising with considerable force to a height of 20 feet or more above the surface, the spout occurring with tolerable regularity at intervals of 4 minutes. The manager of the farm states, however, that the interval between spouts varies from 2 to 15 minutes.

Although drilled 3 years ago and receiving water more or less continuously during that time, the phenomenon of spouting developed for the first time in September, 1910. The well continued spouting without interruption for a little more than a week and until shut off by the owner.

At this stage of the lake the well is receiving water at less than its full carrying capacity and as the water enters the vertical pipe it forms a suction, carrying a large amount of air into the well, which doubtless collects in a chamber or cavity along the side or at the bottom of the well. As the well continues receiving water the air accumulates under pressure in this chamber until ultimately the pressure under which the air is confined is sufficient to overcome the weight of the overlying water plus the inertia of movement and hence rushes out with considerable force, carrying the column of water with it. The fact that the well when first drilled did not spout and afterwards began spouting indicates that the essential conditions were subsequently developed either by caving or by other changes in the underground conditions.

GRAHAMITE, A SOLID NATIVE BITUMEN

Grahamite was discovered in West Virginia, in about 1860, but there is considerable confusion in literature as to its

Fig. 7. Mineral Range Iron Mining Co., Shaft and Crusher House

distinction from albertite and gilsonite and to a certain extent from manjak. It may be described as a brittle, solid native bitumen, generally pure, but at times mixed with adventitious mineral matter, characterized when pure by a peculiar schistose fracture, known as "hackly." It does not melt, but intumesces; it is soluble in carbon bisulphide and to a small extent in light naptha and yields a high percentage of coke. It closely resembles the "asphaltenes."

TRANSVAAL DRILL COMPETITION, 1909*

During the last 15 years there have been several attempts made on the Rand to determine the efficiency of rock drilling machines, in order to decide their relative merits, to establish the actual cost of machine drilling and compare the costs of of machine drilling with those of hand drilling.

Report of the Committee On the Results Attained by the Competing Drills

In February, 1898, Major L. I. Seymour conducted a test with 31 reciprocating machines varying from $2\frac{1}{2}$ inches to $3\frac{5}{8}$ inches in diameter, averaging 30.9 machines of $3\frac{1}{4}$ inches diameter. On ordinary work they averaged 26 feet 10.4 inches per machine in 6 hours, or .9 inch per minute. The volume of free air used per minute per $3\frac{1}{4}$-inch diameter machine was 81.08 cubic feet, compressed to 69.83 pounds per square inch. The test was for 6 hours; the number of feet of holes drilled by one machine 51 feet 9 inches (9 holes); average, 1.72 inches per minute. The free air used per inch of hole, 90.5 cubic feet, or 1,086 cubic feet per foot drilled.

The next trial was made in 1904 by Messrs. Goffe, Carper, and Docharty. The holes were drilled vertically and great care taken to ascertain the quantity of air consumed by different makes and sizes of air drills.

In these tests there was 105.2 cubic feet of free air required at 70-pound pressure to run a $3\frac{1}{4}$-inch drill 1 minute; 95.6 cubic feet for a 3-inch drill; 88.1 cubic feet for a $2\frac{3}{4}$-inch drill; and 68.2 cubic feet for a $2\frac{1}{4}$-inch drill.

These tests indicated that a small machine $2\frac{3}{4}$ inches in diameter using $3\frac{1}{16}$-inch bit drilled more hole per cubic foot of free air than a larger drill; and also that the cubic feet of free air used per inch drilled was fairly constant at all temperatures.

In 1907 the *South African Mining Journal* inaugurated a competition to test the relative merits of small machines for stoping purposes.

The trials were made on the surface and underground. A report of this test appears in Volume 6, No. 7, of the Journal of the Transvaal Institute of Mechanical Engineers, part of which was abstracted and printed in Volume 30, page 385, Mines and Minerals. At the surface, the Gordon hammer drill with 50 pounds of air pressure per square inch, drilled 1.42 inches per minute of total time, or 1.62 inches per minute of actual drilling time. At 60 pounds pressure 1.8 inches per minute were drilled in the total time and 2.13 inches per minute in the actual drilling time. Underground the Gordon hammer drill, which won the competition, drilled dry holes at the rate of 1.74 inches per minute of total time and wet holes at the rate of 1.82 inches per minute. This drill weighed $72\frac{3}{4}$ pounds, was $1\frac{13}{16}$ inches in diameter, and had a 10-inch stroke. The benefit to be derived by using high air pressure was evident from this trial. Following the trials, the Gordon drill in actual service underground was found to be unreliable. The pistons and anvil blocks had but a short life and the drill used frequently broke or stuck in the holes, and the machine entirely failed to fulfil the expectations of its promoters. As the mining industry on the Rand was expanding and the supply of unskilled labor for hand drilling did not keep pace, the necessity for a good stoping drill was as evident as before.

* Published by Committee, Johannesburg, 1910. Price, 7s 6d.

In February, 1908, the Chamber of Mines and the Transvaal Government jointly offered a prize amounting to £7,500 for the best drilling machine that could be produced for mine work on the Witwatersrand. There were 23 entries for this prize, 19 of which started in the competition.

In the elimination trials, which were carried out on the surface at the Transvaal University College and underground at the Ferreira Deep, Ltd., nine drills were eliminated and 10 entered for the competition of 300 shifts. These were the Holman $2\frac{1}{8}$ inch, Holman $2\frac{3}{4}$ inch, Siskol, Climax Imperial, New Century 00, Konomax, Chersen, Waugh, Murphy, Westfalia.

In the surface elimination test the most rapid rate of drilling was accomplished by the Westfalia machines; namely, 4.996 inches per minute of actual drilling time. The largest air consumption recorded was that of one of the Konomax machines; namely, 125.9 cubic feet of free air per foot drilled.

Fig. 1. Little Holman Drill in 18-inch Slope]!

In the underground elimination air trials the quickest drilling speeds were attained by the Chersen and Holman $2\frac{3}{4}$-inch machines. The former drilled 1.81 inches per minute over drilling and changing time and 1.56 inches per minute over total time, which consisted of three 8-hour shifts. The figures recorded for the Holman $2\frac{3}{4}$-inch machine on this trial were 1.94 and 1.47 inches per minute, respectively.

As the competition proceeded the following machines withdrew: Climax Imperial, Konomax, Murphy, Waugh, and Westfalia. It was the intention to run 300 shifts, but owing to lack of air pressure, 215 shifts were run. The stopes drilled in were 24 to 45 inches wide. The number of feet drilled by each pair of the four leading competing machines were as follows: Holman $2\frac{1}{8}$-inch, 12,779 feet; Siskol, 14,083 feet; Holman $2\frac{3}{4}$-inch, 11,744 feet; Chersen, 11,781 feet. This was drilled in 215 shifts of 8 hours each.

The drilling speeds attained over total times by the four machines are as follows:

Holman, $2\frac{1}{8}$ inches	.742 inch per minute
Siskol	.818 inch per minute
Holman, $2\frac{3}{4}$ inches	.682 inch per minute
Chersen	.684 inch per minute

At the surface elimination trials the average rate of drilling of each pair of machines was as follows:

Machine	Total Time Inches Per Minute	Actual Drilling Time Inches Per Minute
Holman $2\frac{1}{8}$ inches	1.566	2.393
Siskol	2.058	4.337
Holman $2\frac{3}{4}$ inches	1.988	3.110
Chersen	2.515	4.110

The cost of drilling per foot with these four leading machines amounted to: Holman $2\frac{1}{8}$-inch, 9.77d.; Siskol, 9.90d.; Holman $2\frac{3}{4}$-inch, 10.91d.; Chersen, 11.94d. These figures compare favorably with the cost of hand drilling on the Rand.

At the underground elimination trials the rate of drilling was as follows:

Machine	Total Time Inches Per Minute	Over Drilling and Changing Time Inches Per Minute
Holman 2⅛ inches	1.24	1.79
Siskol	.89	1.28
Holman 2¾ inches	1.47	1.94
Chersen	1.56	1.81

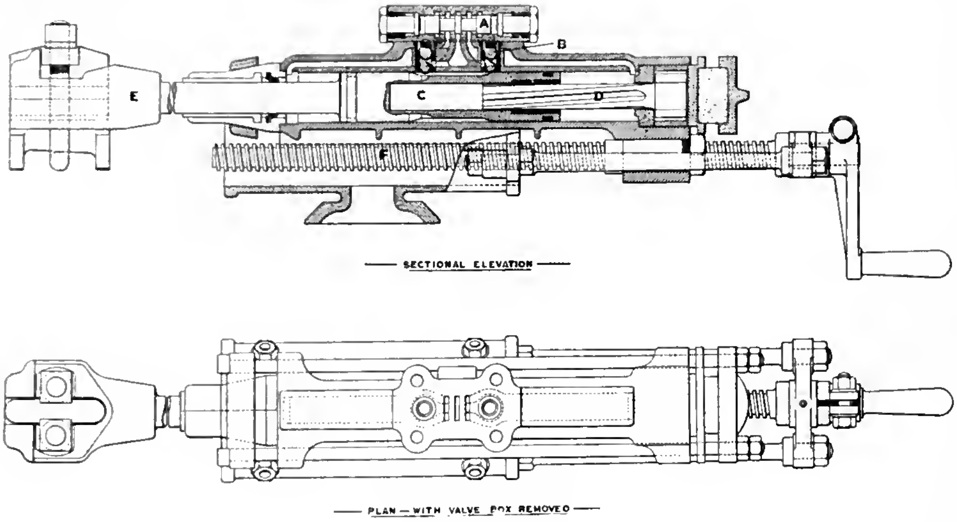

Fig. 2. The Holman 2⅛-in. Stoping Air-Valve Drill

The points to be noted in connection with the four machines are as follows:

The Holman 2⅛-inch seemed a little too small, but it drilled well, was easy to handle, and its maintenance was the lowest of any machine, which fact largely assisted in keeping it in the leading position. This machine, shown in Fig. 2, has a working stroke of 4½ inches. The piston valve is air thrown and is operated by the four steel balls *B* acting as auxiliary valves. The lower ball of each pair is worked by the piston and this actuates the upper pair. The machine worked consistently throughout the trials. Its maintenance cost was low, but its drilling speed was not so high as the Siskol. If the diameter of the cylinder and the length of the piston stroke had been rather more, there is no doubt but that this machine would have exceeded its performance. The miners liked the machine and found that their boys could handle it with ease. Fairly good deep holes could be drilled with it and good arrangements were made for cradle adjustments.

The Siskol machine is shown in Fig. 3. This machine is of the reciprocating type; the diameter of the cylinder is 2⅝ inches, and the stroke of the piston is 7 inches, but its total working stroke probably averages about 6 inches. The valve *A* is of the piston type, operated by air from the main cylinder. The valve chest is fitted on the top of the cylinder and is easily removable. The rotation gear is of the ordinary type. This machine was hampered by the excessive cost of duplicate parts in the earlier stages of the competition, due chiefly to the fact that certain parts, for instance the chuck and its details and part of the front head, were manufactured locally at a much greater cost than if they had been imported. The water in the original design passed through passages *H*, *J*, and *K*. This arrangement was found to be unsuitable for local conditions, and therefore was not used after the underground elimination trials. The details of the front head bushings, designed for water connections in conjunction with hollow steel, were retained because the conditions of the competition did not allow of alterations being made during the competition. The cradle of the machine is faulty in design, in that no allowance is made for adjustment to compensate for wear and tear. During the trial the wear in the cradle had to be taken up by the primitive method of heating and closing by hammering from time to time. The feednuts and screws are on the light side and show considerable wear, thus causing expense for renewals. The valve *A*, which is of the piston type, has not shown undue wear, nor caused much cost for upkeep. The drilling speed of this machine was higher than any other in the competition, showing that both in diameter and stroke it is well proportioned for a machine weighing 100 pounds or under, but if it were made slightly heavier it would be greatly improved.

The Holman 2¾-inch does not drill well in awkward ground and it is liable to fitcher and stick, thus giving considerable trouble. As the travel of its valve is very small it is easily interfered with by dirt. The machine is shown in Fig. 4 as being of the reciprocating type. The diameter of the cylinder is 2¾ inches, the length of the piston stroke 6½ inches. The valve is not of the ordinary operated class, but consists of a hinged flap moving backwards and forwards when the cushioning pressure exceeds the compressed air supply. Valves of this class did not succeed during the competition. The machine was otherwise of the old and well-tried pattern. The cylinder was fitted with a movable steel liner *F* for renewal in case of the wear of the cylinder or piston. This proved a useful feature.

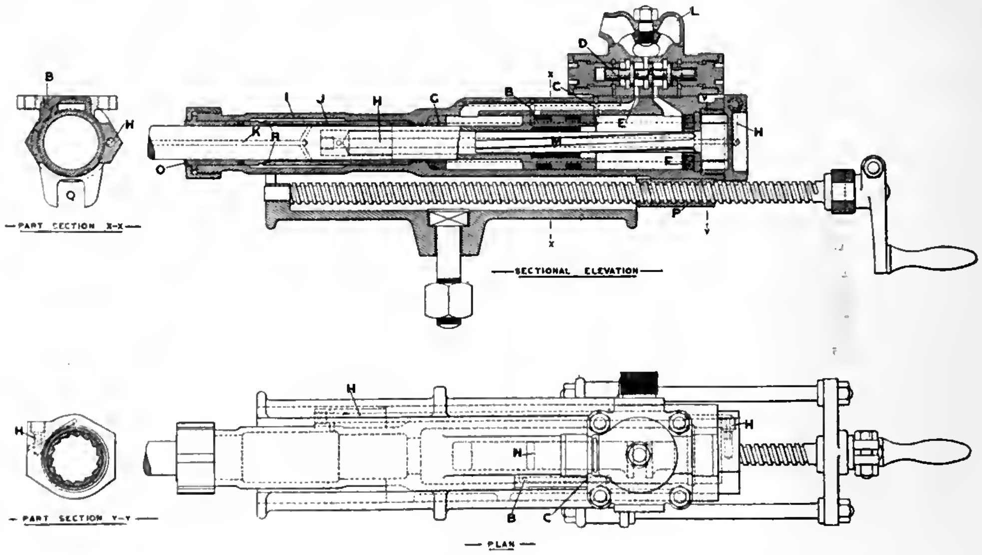

Fig. 3. The Siskol Stope Drill

The Chersen drill, Fig. 5, had a small travel to its valve and was easily interfered with by dirt. This drill did not act well in awkward ground and was liable to fitcher and give trouble. The cut of this drill shows that it is of the reciprocating-piston type, with a piston diameter of 2¾ inches and a

stroke of 6 inches. Compressed air is admitted through the spool valve *A*. It passes through ports *B* and *C* and exhausts through ports *D* and *E*. The motion of the valve *A* on its spindle is caused by compression at each end of the stroke of the piston and is only $\frac{15}{1000}$ of an inch. It was found in practice that unless this travel was kept correct the machine did not drill at its best. Particles of dust or grit easily stopped the proper movement of the valve and temporarily laid up the machine. Considerable trouble was also found in fitchering owing to the want of elasticity in the stroke of the machine. High costs were incurred by piston breakages. The rotation is of the ordinary rifle bar and ratchet type.

The performance of the Chersen was very satisfactory. It suffered, however, from high maintenance cost owing to certain defects in design easily remedied. The only piston drill using water through the machine was the Konomax, and in this case it was found that water leakage could not be prevented internally. Continual trouble in stoppages was thus caused, and finally this machine was withdrawn.

It is interesting to note in these trials, which were carried on for about a year, that the hammer type of machine has not come to the fore, and that the reciprocating type which has been commonly used on these fields has held its position and gained both the prizes. In all cases of hammer-type machines trouble was given by the hollow drills, which crystallized and broke continually. Another trouble was that they frequently stuck in the holes after drilling a certain distance; this being due to the fact that the borings became jammed in a cement-like mass between the drill and the

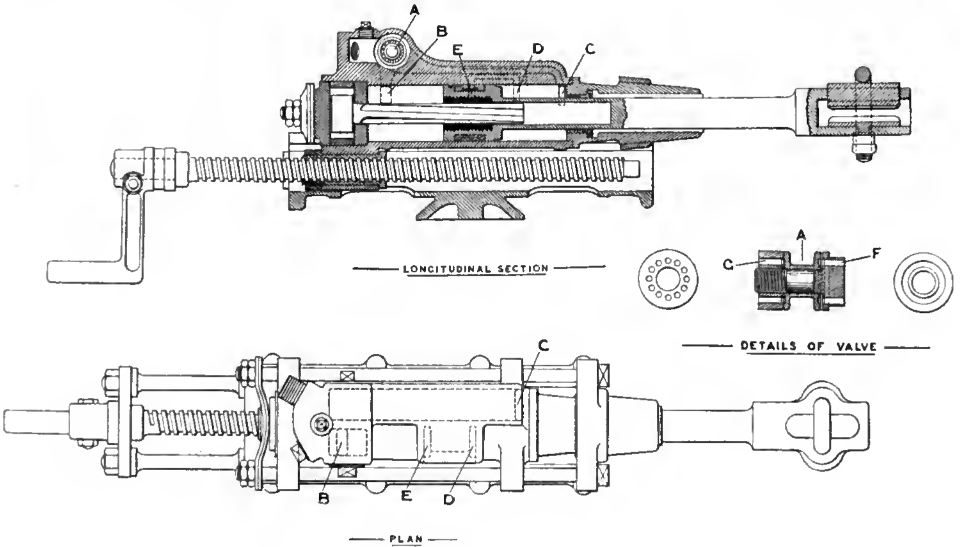

FIG. 5. THE CHERSEN ROCK DRILL

hole. In these cases the holes were lost and fresh holes had to be drilled alongside.

The general deductions made from observations and the results of competition are:

1. That hammer drills are not at present suitable for the general stoping conditions which prevail in the Transvaal fields, that is to say, for putting down holes the reciprocating drill has proved its superiority and there is very little back stoping carried on here.

2. That hollow steel is not at present recommended, the class of material used in its manufacture not being suitable. It is a high-priced article but it appeared to crystallize more rapidly than the cheaper solid steel and gave more difficulty in tempering; which process, it should be stated, was carried out by blacksmiths accustomed to the cheaper solid steel ordinarily used.

3. That no new type of gear was shown to be efficient.

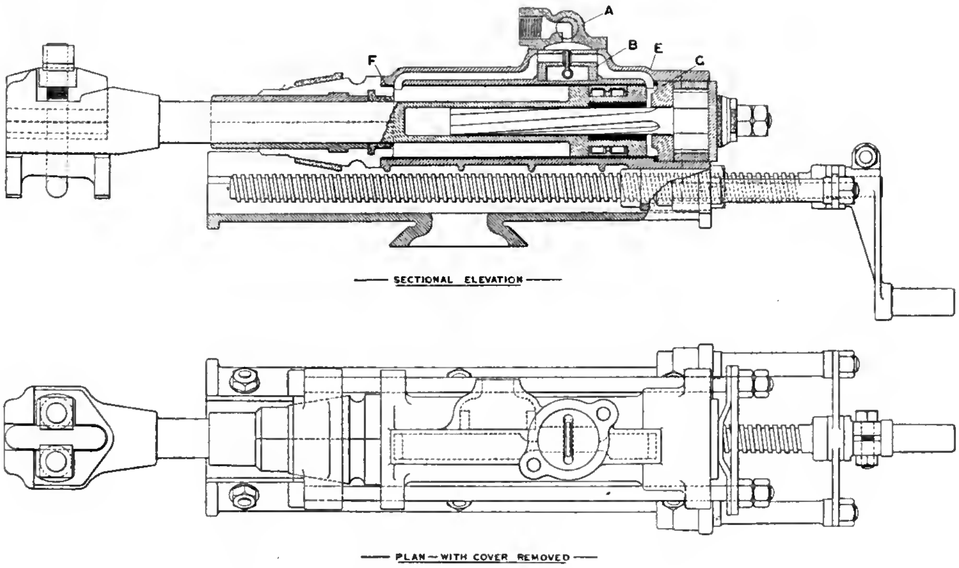

FIG. 4. THE HOLMAN $2\frac{3}{4}$-IN. STOPING AIR-VALVE DRILL

All the finishing machines used the well-known type of jack bar and screw with arms, usually of the Holman type.

4. That any capable miner can supervise efficiently more than two small machines, to which number he was restricted by the rules of the competition.

5. That no two machines finishing in the competition could be efficiently run unless the miner had five native assistants.

6. That it is essential that the arrangements made for the supplying of drills, stores, etc. to the miner should be good, as a short supply of drills often causes the loss of half a shift.

7. That seeing that five boys for two machines weighing 100 pounds are necessary, it would be better to strengthen the machines, adding slightly to their weights but greatly to their durability. Two boys can handle a machine weighing 125 pounds as quickly as one weighing 100 pounds.

8. That under suitable conditions, both as regards mining and efficient working, it is possible to break ground as cheaply and keep stopes as narrow as required with small machines as with hand hammers.

9. That the machines entered in the trials have shown that valve gears operating with a very short stroke are not so efficient as those with a longer stroke, as the longer motion gives more clearance and therefore is less liable to become choked by small particles of dirt passing through the air pipe. This point has been proved by the difficulties that occurred with valves of the type used in the Chersen and Holman $2\frac{3}{4}$-inch machines.

10. That the machines with longer piston stroke have proved themselves in advance of those of shorter strokes in that they have been able to work in broken ground more easily and have also been able to drill deeper holes.

11. That provision for a feed of not less than 18 inches in length appears very desirable.

In the competition, two sets of machines, the Holman 2½-inch and the Siskol have cost approximately 8.3d. per foot drilled plus the cost of steel and drill sharpening, which would come to, at the most, 1.5d. per foot, making 9.8d. per foot. But it has taken 1.282 mine shifts to make one 8-hour shift, therefore the wage cost must be increased in that ratio. Further, instead of assuming 10s. per shift for two machines as the white wage, 25s. per shift were taken for four machines. This alteration means an increase of ½d. per foot drilled, making the total cost per foot of these two sets of machines practically 11.8d. per foot. This is as near as one can get to the actual cost per foot for 28,528 feet drilled by these machines. This cost of 11.8d. per foot compares favorably with the cost per foot by native labor, for which 1s. 1d. per foot would be an exceedingly low figure. The tonnage broken should be as 6 to 5 in favor of the machines. The cost of explosives would be as 6 to 5 in favor of native labor. The tendency is for native wages and cost to increase and this is the heavy item, 10d. per foot, in hammer work, but a much smaller item, only 3d. per foot in machinery. With a proper size of bit a hole 4 feet 8 inches or 5 feet deep is much better as regards tonnage than the ordinary hand-drill hole, for it will carry more explosives and so a greater burden.

THE INGERSOLL-RAND-CAMERON COMBINATION

One of the strongest connections of two kindred, yet dissimilar, industries, is the alliance of the Ingersoll-Rand Co., and the Cameron Steam Pump Works. The alliance was effected by the Ingersoll-Rand Co. purchasing a controlling interest in the Cameron Steam Pump Works. The combination is in no sense a consolidation, for each concern will be operated separately and under separate management. The titles of both companies will also be unchanged. For the present the Cameron Steam Pump Works will remain at the foot of East 23d St., New York, but a new and more commodious plant at some other place is in contemplation.

Under the new arrangement, Mr. Geo. W. Fuller, who entered the employ of the Cameron Works in 1883 as office manager, and who has been general manager since 1899, continues as general manager with the additional title and authority of vice-president.

Nearly 50 years ago both companies had their origin and both carried on their operations under the same roof. Later the Ingersoll-Rand Co., through their representatives both in America and in foreign lands, sold Cameron pumps, and the Cameron Pump Works made the castings for Ingersoll compressors, until the Ingersoll-Rand Co. built its own foundry. In this alliance there was only one of friendship and mutual business interests. Both companies were separate and distinct organizations without any financial interest in each other. Naturally when a time arrived that the Ingersoll-Rand Co. could, in a friendly and amicable manner, purchase a controlling interest in a company whose products they had justly indorsed for many many years, the purchase was made. That the high standard of Cameron pumps will be maintained, and if possible improved on, is doubly assured by this combination. Mr. Fuller, as all who have ever met him know, is imbued with the one idea, and that is that in steam pumps, as in human character, the Cameron slogan, "Character is the Grandest Thing," must apply. That he will be supported in this high ideal by the influence of the officials of the Ingersoll-Rand Co. now in the directorate of the Cameron Pump Works, is evidenced by the high character of the products of the former company.

MAGNETIC SEPARATION OF WOLFRAMITE

Written for Mines and Minerals

Although the mining industry of Great Britain is chiefly devoted to coal, the extraction of other minerals is also extensively carried on and an interesting example of the use of electricity in connection with ore dressing is the use of the magnetic separator in connection with the ores mined from the North Tincroft mine of the Carn Brea and Tincroft Mines, Ltd. Here a Wetherill magnetic separator has been installed by the British Humboldt Engineering Co., Ltd., and as this separator is representative of the latest means of separating wolframite, arsenic, copper, and sulphur pyrite from tin ore, green sand from zinc blend, titaniferous iron from diamonds, and copper pyrites from silica, a brief description of its construction and use may be of interest. The material uniformly spread over a belt is conveyed under a magnetic edge, which extracts the magnetic material, and this is conducted out of the field by a cross-belt running under the magnet to the hoppers at the side. A very clean separation is effected through this lifting out and for this reason this separator is very largely used for valuable minerals and ores. It has also been discovered that for ores whose metallic particles are very small and which therefore necessitate fine crushing, this separator gives excellent results.

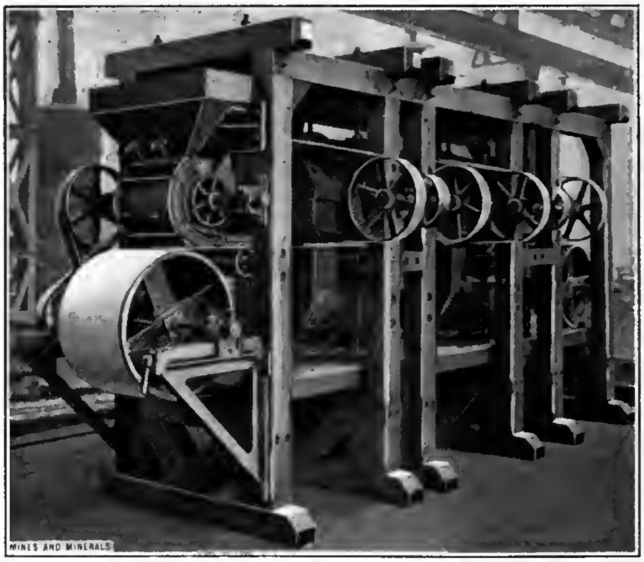

Fig. 2. Six-Pole Magnetic Separator

Owing to the edge shape of the magnets a high concentration of the field is attained, so that this separator can be used for feebly magnetic ores.

The Wetherill separator is built as a two-, four-, and six-poled machine, according to the purpose for which it is required. If only one constituent of an ore is to be separated or the quantity to be treated is small, so that by altering the strength of the

field the material can be retreated, then the two-poled machine (see Fig. 1) is ample. The six-pole machine (Fig. 2) is only considered when four products of different permeability are required. These differences of permeability may be due to the material being ingrained; for example, the six-poled machine is used for enriching slightly roasted copper pyrites. Six different copper products are obtained, that at the first pole being the best, that at the last most ingrained. The last product can thus be further reduced and treated again in order to enrich it. Magnetic separation is especially adapted to copper ores, for wet handling introduces considerable losses due to floating.

For the separation of tin and wolfram minerals the cross-belt is extensively used; the first pair of magnets generally eliminates the feebly magnetic iron, while the second and third pairs extract wolfram. If there is not much wolfram in the crude ore the four-poled machine is sufficient to remove it. These separators are built in two sizes, that is to say with poles 360 and 450 millimeters in width. The latter machine is of much stronger construction, so that the magnetic strength is also greater, the consequence being that both the capacity and efficiency are increased.

The wear of the belts is small; changing can be quickly carried out and the small cost of the belts is soon made up by the increased profits due to the excellent separation. Fig. 3 shows another view of the six-poled machine, and is the type of plant used at the North Tincroft mine.

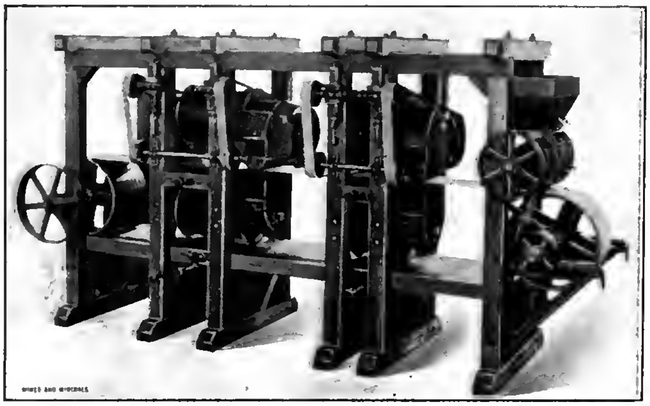

Fig. 3. Six-Pole Magnetic Separator Used at North Tincroft Mines

Personals

H. C. George, B. S. E. M., who for the past 3 years has been Director of the Wisconsin State Mining Trade School, has resigned to become mining engineer for the Wisconsin Zinc Co.

Edward G. Locke, formerly with the United States Geological Survey, has been placed in charge of the mines of the Davis Coal and Coke Co.

H. W. Shields, land agent, and Thos. H. Clagett, chief engineer, will be located in the annex to Norfolk & Western Railway Co.'s office building, at Bluefield, W. Va., instead of at Bramwell, W. Va., after February 1, 1911.

Henry F. De Bardeleben will occupy the position of vice-president of the Alabama Fuel and Iron Co., made vacant by the death of his father.

Miss Kathryn McGough is president of the Phyllis Mining Co., with headquarters at Monongahela City, Pa.

H. C. Parker, of Logan, Utah, is with the Nevada-Utah Co., at Pioche, Nev.

David Cole, formerly assistant general manager of the Green-Cananea Co., is now associated with the Ray Consolidated Copper Co.

Walter Harvey Weed, of the firm of Weed & Probert, has finished his examination of the Butte-Balaklava properties, at Butte, Mont.

Dr. H. G. Torrey, who was chief assayer at the United States Assay Office, in Wall Street, has opened an assay and metallurgical office at 99 John St., New York.

Frank H. Probert, of Los Angeles, recently examined the Ray Central mine at Ray, Ariz.

YUKON TERRITORY OF CANADA

What is known as the Klondike placer mining district, has produced $150,000,000 in gold since 1898, and mining experts estimate the amount yet to be mined equal to that already produced However, as the remaining gravel is of a lower grade, the work must be done by machinery, and for this purpose 20 dredges are in operation this season, as well as a number of hydraulic plants. There are 10 large mining companies operating here, the principal one having 10 dredges and a large hydraulic plant, and it has invested over $17,000,000 in the district. There are also 6 incorporated companies operating for quartz in the district, but little has been milled, although some high-grade ore has been found.

The gold production of the district for 1909 was $3,595,985, an increase over 1908 of $307,321, and the indications are that the production in 1910 will exceed that of 1909. This gold, with the exception of a small quantity sent to the new Canadian mint, was all shipped to the United States, principally by registered mail.

Rich deposits of copper ore have been discovered in the southern part of the district, which is being worked and shipped to a smelter at Tacoma, Wash. The richer ore seems to be on the White River at the Alaska-Canadian line, but this is not mined because of the lack of shipping facilities. The ore extends over a large territory and is claimed to be the richest in the world. A good grade of bituminous coal is found in various localities. An English concern engaged in mining coal is constructing a 10,000-horsepower electric plant for the purpose of supplying Dawson and other towns with heat and light, as well as furnishing power to dredges, etc., within a radius of 75 to 100 miles of the plant.

All but two of the dredges mentioned were manufactured in the United States, as well as three-fourths of the tools used here for mining purposes. Two-thirds of the mining companies are American concerns and four-fifths of the capital invested in mining is American.—*United States Consular Report.*

Obituary

Charles Francis Shelby

Charles Francis Shelby, who went to Peru in 1910 to become general superintendent of the Cerro de Pasco Mining Co.'s smelting plant, was killed January 25 by a railroad automobile jumping the track and striking an iron telegraph pole. Mr. Shelby was a graduate of the International Correspondence School of Metallurgy, having taken up the course while at Aguascalientes, Mex., where he was a chemist. Soon after, he became assistant superintendent, then superintendent of the Old Dominion Copper Co., at Globe. In 1906 he went to Cananea, Mex., and in 1910 to Peru.

Mr. Shelby's aim was to become the best in his line, and in this he did not fall far short. Unlike most metallurgists, he was alway ready to impart as well as to absorb knowledge, as the readers of Mines and Minerals and the *Engineering and Mining Journal* can testify. Mr. Shelby will be buried in Cleveland, Ohio, so soon as Mrs. Shelby and baby can reach that city.

THE PHILIPPINE GOLD MINES

Written for Mines and Minerals, by Monroe Woolley

Recent discoveries of gold in the South Camarines, Province of Luzon, have brought the mineral possibilities of the Philippine Islands into prominence. Probably the richest gold deposits (at least so far as known) are in the vicinity of Paracale, although there are other deposits, as shown on the map, Fig. 1.

Regions and Formations in Which Gold Has Been Found. Conditions Affecting Development

According to Warren D. Smith, Chief of the Division of Mines in the Philippine Islands, the Paracale-Mambulao gold field was recorded in 1571. The Chinese and natives washed gold in a crude way until the Spaniards taught them the use of the arrastra a few years previous to the American occupation.

Native women wash the streams where gold is to be found, being adepts in the use of the pan and batea. A group of women gold washers is shown in Fig. 2, who are partly civilized and who live in the vicinity of Penaranda, where gold washing has been carried on for centuries. The natives at this place resent so strongly the American invasion that constables are required to protect prospectors. The Igorotes and Negritos, uncivilized mountain tribes of the islands who never come down into towns, have been taking gold from their mountains for perhaps centuries. What little they obtained was devoted to ornamental purposes, and it is only recently that they have commenced to sell it to white people. Mindoro, or island of gold mines, has never been systematically prospected or the geology of its interior studied. Placer deposits have been found on the west and north coasts where a few Americans have claims. However, little, if any work has been done on them. From a glance at the map it will be seen that the Paracale mines are not far from Manila, and that between Paracale and Mambulao Bay there is an almost continuous mineralized zone. The Paracale mines were worked in a crude way by Spanish and English, who completely abandoned them. Americans acquired them shortly after the occupation by our troops, and at present new companies have been formed to exploit and prospect these gold deposits in a systematic way. Ore from one mine in this vicinity was shipped to Manila that carried $147.60, and contained besides gold, silver, copper, and zinc. At the present time most of the gold obtained in the immediate vicinity of Paracale is from dredging operations in the rich bottoms of the Paracale and Malaguit rivers. Most of the dredging ground has been staked out on these rivers, although but one dredge is working on the Malaguit, while three are at work on the Paracale, and another is about constructed. Two of the dredges are of the New Zealand type and are manned by New Zealanders; while three are of the Postelthwaite type. The essential difference between these dredges is the absence of a tailing distributor and the rotary screen and side tables on the New Zealand dredges.

Fig. 1. Map of the Philippine Islands

Lode deposits are not receiving so much attention in the vicinity of Paracale as to the west toward Mambulao, nevertheless, development work is being carried forward on several properties in the foot-hills. As the roads and conveniences are not favorable for moving heavy machinery, considerable difficulty is experienced in transporting it to the mines, as may be seen by a glance at Fig. 3. The heavy wagon is pulled up the incline by means of blocks and falls, and the use of a capstan, shown in Fig. 4. Before the machinery is in operation capstans are used to hoist rocks from the shaft.

To the west of the Paracale, near Mambulao, are the ancient workings of the natives and of the Philippine Mineral Syndicate that was composed of Spaniards and Englishmen. Recently two companies—the Tumbaga and San Manricio—have been preparing for immediate operation.

Tumbaga lies 2½ kilometers south of the town of Mambulao.* The ore body is in a brecciated zone between impure sandstone and andesite. The strike of the ore deposit is northeast and southwest. In it there is considerable shattered slate which has been cemented by calcite carrying free gold. Although the mineralized zone reaches a width of 35 feet, the calcite stringers do not all carry gold, consequently the gold is not constant in quantity. Over 100 meters of drifts and crosscuts have been opened in this lenticular ore body, and the ore treated as follows:

Crushing coarse; grinding in a Huntington mill having a capacity of about 21 tons per day; amalgamating on outside plates, and concentrating the pulp that passes over the plates on two tables.

The mines on the island of Masbate, at Aroroy, are not so extensive or so rich as those in the Camarines. However, perhaps a dozen companies are now installing mining machinery. †"In all probability mining was carried on in the Aroroy district before the Spanish conquest." "Old open cuts showing the use of fire in breaking rock, and stone mortars for crushing the ore are indications of the ancient native miners." "The natives say that about 100 years ago an arrastra was worked by a Spaniard and Englishman, and in several places there are underground workings that cannot date back very far."

* Mineral Resources of the Philippine Islands, 1910, page 10.

† H. G. Ferguson, Geologist, Philippine Bureau of Mines.

Near Baguio, the summer capital north of Manila, several Americans and some aliens hold paying claims known as the Benguet mines. A lone prospector of the Benguet country sold his claims to a Hongkong, China, syndicate, for $20,000 cash. A bar of gold weighing 233 ounces, valued at $4,000, was shortly afterwards sent to Manila from these mines, and this, with a smaller one, represented the clean-up of free-milling ore for 1 month. American miners, according to Frank T. Eddingfield,‡ have been prospecting in Benguet for 10 years, "but only in the past 3 years has successful mining been carried on by organized companies; previous to this the veins had been worked by Igorotes, Filipinos from other provinces, and Chinamen." "Some of these old workings are quite extensive, and have been a great help to prospectors in locating veins." "When driving a drift an old stope was found in which the waste rock was cemented as hard as wall rock. There are four mills, 12 mining companies, and four prospecting companies reported in this district from which 279,600 pesos were taken in 1908 and 243,500 in 1909. These figures, while showing the mining activity of the district, do not give an idea of the development work and prospecting which is being done on some 300 claims. The principal producers are the Benguet Consolidated and the Bua. The latter is working two veins, one of quartz .3 to 1 meter wide, the other a rhodochrosite vein 1 to 2 meters wide.

FIG. 2. WOMEN WASHING GOLD

The ore is mined by overhead stoping, the excavation being filled with waste broken during mining. The ore is dumped in a bin at the mouth of the adit, from which it is trammed for a distance of about 1 kilometer to a second bin which feeds into a two-bucket gravity aerial tramway, stretching across the Antamok Valley to the mill. The mill, which is run by water power, consists of six stamps with two amalgamating plates; the tailing from these is cyanided and then discarded. A custom mill designed to treat the ore in this district is greatly needed. Igorotes are used for surface laborers and cutting timbers, Filipinos from other provinces as miners and mill men, as they are steadier and better workmen; Japanese are used as timbermen and carpenters because of their greater strength and adaptability.

‡ Mining Engineer, Bureau of Mines, Philippine Islands.

A number of men from Manila formed a company and tested the placer ground in the vicinity of Penaranda with a drilling machine. The drill tests were reported as showing 33 centavos per cubic yard; while pan tests in other places gave gold varying from 50 centavos to 1 peso per cubic yard. One of the interesting features in connection with this Nueva Ecija district is the presence of platinum in the placers. The natives who have been washing for gold in this district for ages, ignorant of the value of platinum, threw it away. The only other place in the Philippines where platinum has been found is 40 miles south from Penaranda.

According to Mr. Eddingfield gold has been found on Catanduanes Island with evidences of placers having been worked by Spaniards or natives. Old Spanish reports of 1877 speak of placer mines in Mindanao.

Filling Stopes

In large veins ore is sometimes lost by settling upon the timbers of the first few sets above the sill floor. The weight of the ore crushes the timbers and forces them out of line to such an extent that cars can no longer be trammed through the levels. When this occurs, bulkheading and filling must be quickly done to prevent collapse.

When a case of this kind, occurred some time ago at the Anaconda Mine, Butte, Mont., and the timbers on the sill floor were forced out of line, the stope was filled with waste and timber as rapidly as possible and the level abandoned. A lateral drift was then run in the foot-wall 60 feet from the vein; and from it at distances of 60 feet and directly opposite the chutes in the abandoned stope a square set was placed. At each such station a raise was put in and carried up on an incline to the ore body above the filled stope. The drift was in solid granite, but as the raises approached the vein the rock was found decomposed, and required careful timbering. The raises were timbered with square sets, though had the foot-wall been solid no timber would have been required. Through these raises nearly all the ore lost by settling was recovered.

GEOLOGY OF THE LA VETA COAL FIEI D

Written for Mines and Minerals, by Arthur Lakes

The difference between the geological conditions surrounding the coal fields of the Rocky Mountains and those of the Eastern States is very marked.

An Illustration of Volcanic Action Upon the Quality and Location of Coal Seams

In the East the coals are mostly of the Carboniferous period of the Paleozoic system and found in the Appalachian system of mountains and to the west of them. In the Rocky Mountains, taking Colorado as a type, the merchantable coals belong to the Mesozoic system and are mainly of Cretaceous period. There are a few inferior and unimportant Tertiary coals, and none workable of Carboniferous period.

The western coals underlie the horizontal plains for an unknown distance or occur between horizontal strata of lofty tablelands bordering on the mountains, or lie in a highly tilted position in the sandstones of the foot-hills, or within the parks of the granitic ranges. The coal measures may be capped with flows of lava, or intruded by horizontal sheets and vertical dikes of igneous rock emanating like the tentacles of an octopus from some center of eruption, such as from an old volcanic neck or a laccolite, as shown in Fig. 1.

Eastern coals are mostly of the bituminous, semibituminous, or anthracite type. Western coals grade from brown lignite to black lignite, to lignitic-bituminous, to full and coking bituminous, and locally to anthracite.

Some of the eastern coals are of the coking variety, others are anthracized by metamorphic heat connected with the mechanical folding up of the mountains.

Western coals are locally coking, sometimes over considerable area and occasionally anthracized more locally and on a smaller scale; both conditions and qualities are due to their proximity to igneous rocks.

A striking example of the characteristic geological conditions in the West is shown in that part of the great Trinidad coal field of Southern Colorado, which is dominated by the Spanish Peaks as a volcanic center, with La Veta and Walsen-

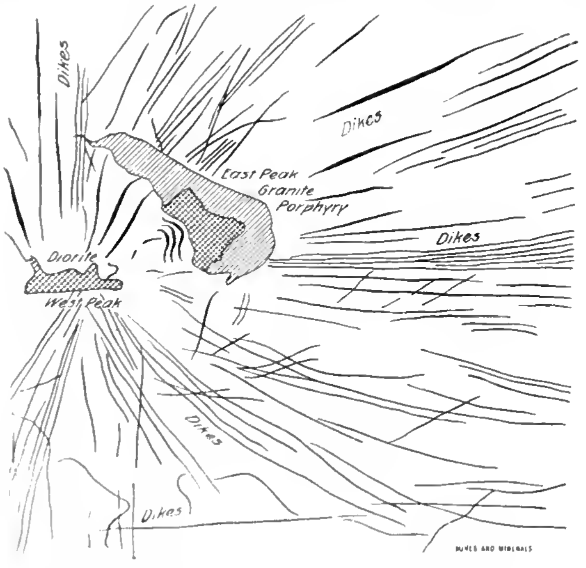

Fig. 1. Spanish Peaks, Showing Plan of Dikes

burg as the principal railroad coal towns. Here in the heart and center of the coal fields, and greatly influencing the character and quality of the surrounding coals is the most extraordinary volcanic eruption in the Tertiary period of the Rocky Mountains, the monuments of which are two isolated lofty and prominent mountains called the Spanish Peaks, rising from the prairie and foot-hill zone to a height of 13,623 feet above sea level, a few miles east of the main Sangre de Cristo Range. These symmetrical peaks represent the center of a series of eruptions which for a long time affected the southern part of the state for hundreds of miles. From this center emanated a system of dikes radiating from the central peaks like the arms of a cuttlefish. The singular dike walls, Fig. 2, can be followed across the foot-hills and over the prairie for many miles, giving

Fig. 2. La Veta Region, Showing Dikes

rise to such names as Crestone, Stonewall Park, Muralla Wall, or Dyke Mountain and the like. The entire region is traversed in every direction by a network of dikes and "sills," and it would seem as if the country at the time of these eruptions must have literally sweated igneous matter.

The traveler can wander amongst these dike walls, rising at times in the vicinity of the peaks a hundred or more feet above him like ancient fortifications, pierced here and there by natural embrasures, or eroded into battlemented forms. The walls are occasionally utilized by stockmen as shelter for their flocks and herds, or as forming convenient sides for corrals. The faces of these cliff-like walls betray their igneous origin in rounded outlines, suggestive of molten matter retaining the form of the soft shale mold in which it was cast and through fissures in which it ascended and was congealed in the form of dikes. Fragments of shale altered by heat into slaty hardness still cling to the walls.

As the sedimentaries approach the central cores of eruption against which they are tipped, they show the evidence of heat in being metamorphosed.

The influence of these centers of igneous intrusion has been on the whole beneficial to the surrounding coal field, changing the lignitic-bituminous coal, characteristic of the more northern fields of Colorado, into a coking bituminous coal. The destructive effects on the coal have been local. Intrusive horizontal sheets have locally changed the coal into a worthless species of natural coke or graphite, Fig. 3. The effect of the dikes passing through coal seams has generally been confined to a width commensurate with the thickness of the dike. Dikes and intrusions, if numerous, are sometimes annoying, but not insurmountable obstacles in the development of a coal mine, as they can be readily cut through.

Despite the geological disturbances to which the La Veta region has been subjected, faults of importance are singularly few in the coal measures. Along the eastern border from Walsenburg north to the Huerfano River, the coal plateau is abruptly terminated by erosion, displaying a line of low sandstone cliffs containing several workable coal seams dipping gently southwest into the plateau, which here is in the form of a broad synclinal fold, which further west, near Oakdale, is followed by an anticlinal, and that in turn by another synclinal whose western limb highly tilted against the Sangre de Cristo Range, raises the coal to verticality. Here, at the Occidental mine there are two seams 8 and 4 feet thick.

The intervening country of Huerfano Park, between the Sangre de Cristo and La Veta Mountains is doubtless underlaid by coal whose outcrops are obscured by a large overlying deposit

of Eocene-Tertiary lake beds, 1,000 to 2,000 feet thick. These coarse sandstones and conglomerates were deposited in a lake occupying one of the great trough-like folds parallel with the Sangre de Cristo and Greenhorn Mountain ranges.

For a detailed account of the eruptions of this interesting region we are indebted to the researches of R. C. Hills.*

The prominent feature connected with the overflows of lava covering the Raton hills in Southern Colorado, is that they

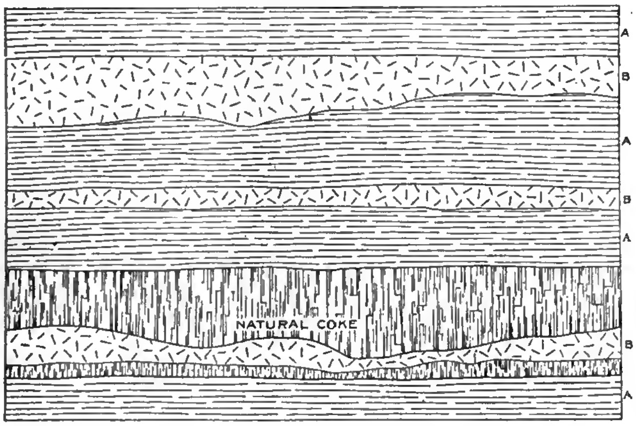

FIG 3. NATURAL COKE AND SILLS OF IGNEOUS ROCK
A, Shale; *B*, Igneous Rock

contain most of the coking coal of this part of the state. The dikes, radiating throughout the region, and the Veta, Silver, and Black Buttes mountains, are northward prolongations of the eruptions of the saddle-shaped twin mountains known as the Spanish Peaks.

The Spanish Peaks and Silver Mountain, Fig. 4, are a similar and connected eruption, as shown by their component rocks, and they are directly connected with the great system of diverging dikes. The upheavals are due to intrusions of igneous rock into the Cretaceous shales. The intrusions were upwards of 2,000 feet thick and extended in wedge-like form along the shales 8 to 12 miles. The sedimentary rocks overlying these intrusions were arched and fissured, allowing molten lava to ascend from the main igneous reservoir through these vents, giving rise to two systems of dikes.

Dikes radiating from the West Spanish Peak are most numerous and cut through the sedimentaries lying on the upper flanks of the mountain.

The laccolitic masses of the Spanish Peaks are composed of a succession of consecutive intrusions of different varieties of lava.

At Silver Mountain the upheaval was greatest immediately under the crest of the mountain, which is the focus of intersecting and diverging dikes, so numerous as to exclude all other rock matter. These dikes do not descend below the laccolitic horizon in the Colorado shales.

The igneous material composing the La Veta, Black Buttes, and Silver Mountain is from one magma. Another system of intrusions and dikes having no connection with the former appears in the Colorado shales from the state line to the Huerfano River, 50 miles. These intrusions produced in the overlying coal measures a system of fissures through which lava exuded. All these dike systems were formed from the reservoirs of molten rock underlying the region and from which on the surface these dikes were the manifestations.

In the South Veta and Sheep Mountain is a second group of laccolites unconnected with any corresponding system of dikes. Five intrusive bodies belong to this group in the northwest portion of the area between Cuchara and the Huerfano River. The Veta Mountains consist of two distinct eruptions of equal size forming North and South Veta peaks. North Veta belongs to the Silver Mountain and Black Buttes systems.

* United States Geological Survey, U. S. Folio, No. 71, 1901.

South Veta is of hard white porphyry, unlike the coarse, hornblendic lavas of Silver Mountain and the Spanish Peaks. Veta Mountain is of later eruption than Silver Mountain.

Upheaval was followed by subsidence due to the extravasation of so much molten matter and its ascending into fissures caused by upheaval and in them solidifying as dikes. Each lava injection was a pulsating movement giving rise to independent systems of dikes.

The alteration effects on the coals, changing dry coal to coking, was due to radiation of heat through the medium of water.* More pronounced alterations, such as to natural coke, semianthracite, or graphite were due to the direct contact or action of steam or very hot water.

At the close of the Laramie coal-making period general upheavals accompanied by folding formed long trough-like depressions parallel to the main ranges that formed the basins of subsequent Tertiary fresh-water lakes. Less pronounced folds eastward also formed minor lake basins.

One of these greatest trough-like depressions received the Tertiary lake deposits, known as the "Poison Cañon" series. This lake covered the depression between the Greenhorn Mountains and the Sangre de Cristo, receiving sediments washed down from the neighboring highlands. The thickness of this series of rock beds is between 1,000 and 2,000 feet, and it covers an area of 250 square miles. These beds are folded and metamorphosed against the West Peak. Among the carnivora and rodents that once inhabited the shores of this semitropical lake was one the size of a little black bear, termed "Tillotherium," whose jaws were armed with enormous incisors; another has been called "Coryphodon." Bones of the diminutive Tertiary horse, or Pliohippus, have been found; also the huge carapace of gigantic turtles.

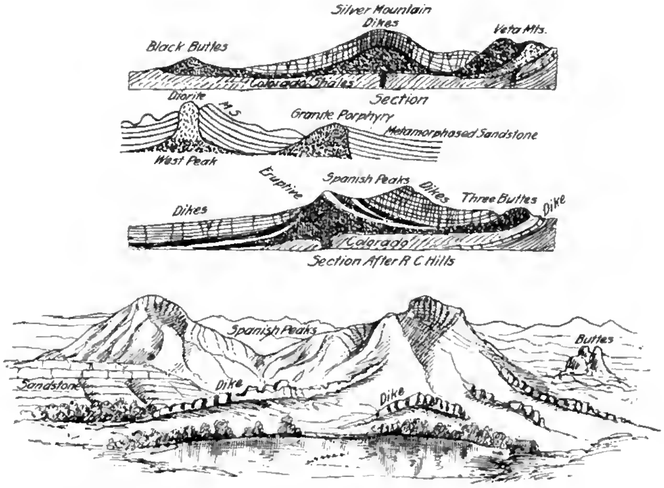

FIG. 4. SPANISH PEAKS AND SILVER MOUNTAIN

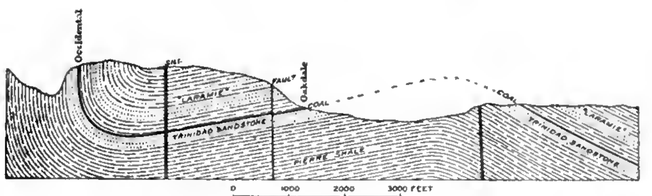

FIG. 5. SECTION OF STRATA NORTHWEST OF LA VETA, COLO.

Previous to the last eruption the sedimentaries of the West Peak were riven in an east-west direction, and a mass of igneous rock ½ mile wide, was forced up into the vent. At the same time another portion of the igneous mass was intruded in lenticular form beneath the sedimentaries of East Peak. At a later date final eruption was initiated by the production of a U-shaped fracture, a prolongation of the old vent across the base

* The editor was not there, and is unable to disapprove these two sentences.

of East Peak, and thence to the West Peak. This was accompanied by displacement of strata along the line of fracture as much as 5,000 feet. Sediments included between the **U**-like arms were upturned in a spoon-shaped trough. The effect of this eruption on the previously formed trough was the production in its bottom of a great upward bulge, rent and faulted at the summit, warped by the intrusion of huge masses of igneous rock and ribbed by a system of dikes.

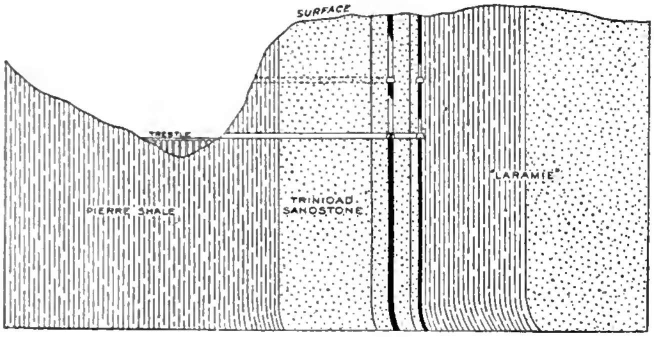

FIG. 6. SECTION AT OCCIDENTAL MINE

The igneous rocks of this region, identified by R. C. Hills, are: Monzonite porphyry; early lamprophyre; late monzonite porphyry; late lamprophyre; augite diorite; augite granite porphyry; granite felsophyre; basalt. Eruptions continued intermittently nearly up to the present time; the varieties of rocks observed may be due to differentiation from one common magma.

Coal Seams of the La Veta-Walsenburg Area.—The Walsenburg area embraces the coal beds and outcrops on the northeastern extremity of the Trinidad field. The coal plateau here terminates in abrupt cliffs of yellow Trinidad sandstone facing the prairie. Below this, in Colorado, well-known bedrock of coal, are the non-coal-bearing Cretaceous shales, which largely underlie the eastern prairie. Above the sandstone, within the first 200 feet, are usually two to three workable coal seams. The cliffs represent the upper limit of a synclinal and the commencement of a broad anticlinal stretching toward the prairie. The crest and remainder of the anticlinal has been entirely eroded on the east, so that there is no more coal east to the Kansas boundary of Colorado. The coal outcrops are very clearly seen along the cliffs, and several small mines and openings are on them. Near Black Buttes, on the north, the Laramie coal-bearing series is overlapped by the "Poison Cañon" Tertiary beds. Along the eastern margin the coal dips gently inward to the plateau southwest and becomes almost horizontal in the bottom of the succeeding synclinal trough. Only the lower group of the Trinidad coal-field series is worked at Walsenburg, principally three prominent parallel beds locally known as the Cameron, Walsen, and Robinson. The coal beds in this field cannot be persistently correlated or identified over large areas, the coal horizons changing.

A prominent feature of the Walsenburg area is a great dike extending east and west for many miles. It cuts through the coal about a mile northwest of Walsenburg. The Maitland and Pictou mines have long been worked on these seams. North of Maitland is the Pinon, and still further north along the D. & R. G. R. R., the Tioga and Sunnyside. South of Tioga are horizontal intrusions of igneous rock, and the position and character of the coal should be tested by drilling. Between the Big Four and the Oakdale mines, on opposite sides of the synclinal basin, the coal outcrops are obscured by Tertiary beds. It is probable that the coal measures extend beneath this basin to Huerfano Park. The depth and thickness of the coal should here be tested by drilling.

The La Veta district includes the area contiguous to the coal outcrop along the northwestern margin of the Trinidad coal field. In the center and southern part of this basin the continuity of the coal is interrupted by those great igneous intrusions already mentioned. The coal measures in this area dip northeast from 10 to 65 degrees. At northwest end the rocks are folded into anticlinals and synclinals. The Laramie formation is overlain for a considerable area by the Poison Cañon Tertiary formation. This Veta field offers an inviting area for investigation by drilling. It has not been thoroughly prospected, largely owing to the local covering of Tertiary rocks. Only the lower group of coal seams have so far been found and worked.

In the subsidiary basin north of the Denver & Rio Grande Railroad, there has been considerable development work. Here coal is cut off at the north end by the intrusion of the Veta Mountains, Fig. 5. On the west side of the basin the coal stands vertical; on the east side the dip is 15 degrees and to the southwest.

The Occidental mine is connected with the Rio Grande Railroad by a long tramway, and the coal is reached by tunnel 300 feet long (Fig. 6). The coal is in two seams 45 feet apart, one 4 feet, the other 8 feet thick.

The Oakdale mine, on the east limb of the synclinal, was working in 1908 on a 7-foot seam.

Outcrops of narrow coal seams occur along the main west margin of the Spanish Peaks syncline west of La Veta, but are rarely of workable size.*

THE MAIKOP OIL FIELD

The Maikop oil field is situated in the Kuban Province, in Southern Russia, on the western fringe of the Caucasian Mountains. As at present known, it has a total length from east to west of approximately 25 miles, while its greatest width from north to south is about 20 miles.

The field only came into prominence during the latter part of 1909, owing to the sinking of a 240-foot well, which is stated to have thrown upward of 30,000 tons of petroleum in 6 days, and after defying all attempts at control for weeks continued to discharge oil in large quantities. This marked the commencement of the commercial history of petroleum in the district, for although the region has been known for centuries to be oil bearing, no serious attempt had previously been made to test the territory by means of boring.

It is the most favored petroleum-producing region in Europe, being only about 50 miles from Tuapse, on the Black Sea, with which export point it will in time be connected by both railway and pipe line.

At many points, particularly on the hillsides, large outcrops of impregnated oil sands have been noticed, and in other places exudations of petroleum are very frequently encountered. To the east of Khadijinskaya is an asphalt mountain, from almost every spot of which oil oozes, which, after losing its volatile constituents, leaves a tarry residue spread over the surface. To the southwest of Nephtanaya, indications of the petroleum deposits have been evident from time immemorial. It was here the Black Sea Co.'s spouters were struck and not only are the most prolific oil sands encountered at shallow depths, but exploration generally can be conducted at considerably less cost than in the Baku region.—*United States Consular Report.*

RULE FOR FIGURING CAPACITY OF ROLLS

By Charles F. Spaulding

Let S equal speed of roll stull in feet per minute; F equal face of roll stull in feet per minute; O equal opening of rolls in feet; C equal factor for irregular feeding (usually 2 to 4).

$$\text{Tons per hour} = \frac{S \times F \times O \times 60}{C\ (2\ \text{to}\ 4) \times \text{cu. ft. in ton}}$$

Taking $C=3$ for average work, and 20 cubic feet to a ton, the above equation becomes:

$$\text{Tons per hour} = S \times F \times O$$

* For further information on this district, see U. S. Folio Map 71, and G. B. Richardson's Report, Bulletin 381 of the United States Geological Survey.

Amphibole and Chrysotile. Sources of Supply and Uses to Which Asbestos May Be Applied

Take a certain kind of glass, soften it by heat, draw it out into fine, flexible thread, weave it with care into a fabric incorruptible as to decay and the action of most acids, but not as to heat, and you have approached the limit of man's effort to produce a mineral fiber. Nature makes a shrinkage crack in a rock, fills it with water, dissolves a little of the rock in the water, and crystallizes the whole crack full of threads which are much finer, more flexible, and stronger than the glass fiber, and in addition thereto capable of withstanding a temperature of 2,000° to 3,000° F. Remembering that the water combined in these fibers runs as high as 14 per cent. of the whole weight, one is forced to the conclusion that some of nature's processes are "past finding out."

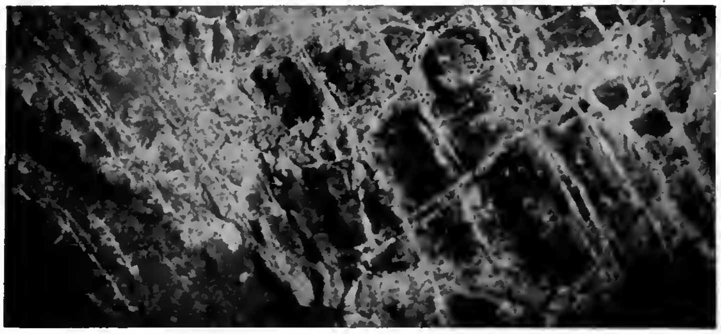

Fig. 1. View Showing Asbestos in Walls of Drift in Bell Mine

The Greeks named this fiber "asbestos" (unquenchable, unconsumable); the Romans made cremation robes of it, and Charlemange astounded his gaping courtiers by casting his soiled table cloth into the fire and withdrawing it clean and white for another feast. Nor has it been many years since an otherwise respectable and industrious lumberman was accused of witchcraft and run out of a camp in the Canadian woods because he persisted in washing his socks in the stove instead of by more conventional methods.

Because of shrinkage, the outer surface of the earth has become wrinkled and cracked, folded, and broken, worn and torn, and the fissures filled by rock from within. In the vicinity of Thetford, Province of Quebec, one of these intrusions of rock occurs. It is, more correctly, a series of rocks, including peridotite, pyroxenite, gabbro, diabase, and others. The peridotite when altered by hydrating is called serpentine. During the cooling of this peridotite it is supposed that fissures formed and that the hydrating process which caused the rock to take water into its structure widened these fissures. During the hydrating action the water carrying some of the serpentine in solution collected in these cracks, and eventually the dissolved mineral formed thread-like crystals, usually building up from opposite walls of the crack and meeting or forcing past each other at the center. The cracks are generally straight, and do not occur in parallel planes, but cross each other in all directions.

Broadly, asbestos may be classified as amphibole or hornblende and chrysotile, or serpentine asbestos. The amphibole, hornblende asbestos, does not possess the fineness of fiber, the tensile strength, the elasticity, or the flexibility of the chrysotile, although it has approximately the same heat-resisting qualities. Amphibole differs from chrysotile chemically in having lime combined with its magnesia, and while the chrysotile, a silicate of magnesia, is always hydrated, amphibole is frequently anhydrous.

*Reprinted from *The Electric Journal.*

It will be noted in Table I that the composition of chrysotile is practically identical with that of the serpentine rock from which it is formed.

Table I. Typical Analyses of Rock and Fiber

Chemical Constituents	Serpentine Rock	Italian Chrysotile Fiber	Canadian Chrysotile Fiber	Amphibole Fiber
Silica	40.34	40.30	41.90	61.82
Magnesia	43.32	43.37	42.50	23.98
Alumina	1.32	2.27	.89	1.12
Ferrous Oxide	1.23	.87	.69	6.55
Lime				1.63
Water	14.17	13.72	14.05	5.45

There can be little doubt but that there is a definite relation between the softness of the fiber and the quantity of water contained therein; 14.38 per cent. of water has been found in very silky fiber, while a harsh, brittle sample showed only 11.7 per cent. This possibly accounts for the extreme brittleness of amphibole asbestos, one sample of which, as indicated in the table, contained 5.45 per cent. of water. The effect of high temperatures on very soft fiber also demonstrates this fact. When part of the combined water has been driven off by excessive heat, the fiber loses its flexibility and becomes harsh and brittle, and the variations in strength and silkiness in various deposits of the mineral are best explained by assuming that the water content was originally nearly the same in all cases, and that the movement of associated rocks or the injection of igneous rock have furnished sufficient heat to drive off part of the water.

Physically, chrysotile has some interesting properties. In the absence of reliable data as to the diameter of its fiber, some microscopic observations were attempted. At about 90 diameters the subdivisions of the fibers appeared to be unlimited. The bundles broke up and branched off into numberless finer collections of lines. At 900 diameters magnification, fibers appeared which were barely discernible and which were estimated to be five one-millionths of an inch in diameter. There was, however, nothing to indicate that these were not capable of still further subdivisions, and, as suggested by A. Kingsbury, who very kindly made this examination, it would not require much elasticity of imagination to believe that the ultimate asbestos fiber is just one molecule in diameter. This seems reasonable, moreover, as in the case of mica, the cleavage is such that specimens have been split to a thickness equal to one-half wave length of distinctly violet light.

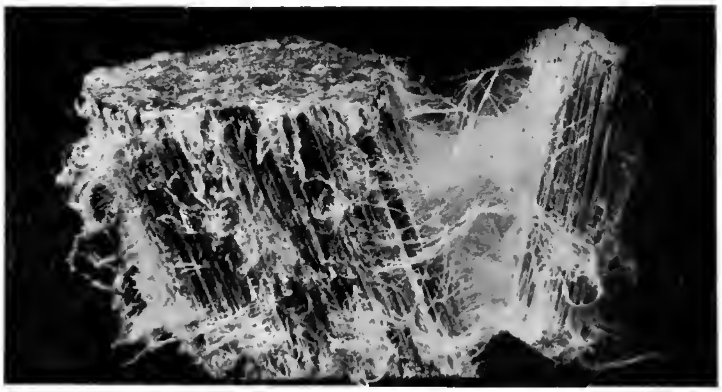

Fig. 2. Asbestos from Bell Asbestos Mines

Wool, cotton, silk, and other fibers, all have rough surfaces, and when spun into a thread this roughness aids in holding the mass together. While its fibers are almost infinitely finer than these, chrysotile has an absolutely smooth, glossy surface, that for a long time prevented the successful spinning of what was otherwise an ideal fiber. The overcoming of this difficulty

has made possible the spinning of a fairly strong thread weighing approximately an ounce per hundred yards of length.

Chrysotile has the following tints: Pure white, yellow, pale green, grass green, blackish green, blue, gray, brown, salmon, greenish blue, and lavender blue. When fiberized the color generally disappears, in most cases the flossy crystals appearing entirely white.

As a material in engineering, asbestos is unique. Soapstone has great heat resisting qualities and is a good electric insulator, but it can only be used where massiveness is permitted. Mica also withstands heat and provides excellent dielectric resistance. Its brittleness bars it from use as an insulator in many cases. Asbestos is to mica and soapstone what the line is to the plane and solid, and later references to its use will bring out this fact more in detail.

At least 75 per cent. of the world's supply of chrysotile is mined in the eastern townships of Quebec. The asbestos-bearing serpentine is scattered through a relatively narrow belt running nearly northeast from the boundary of Vermont to within about 40 miles south of Quebec.

On account of the general distribution of serpentine rock throughout the world, it is not surprising that deposits of chrysotile should be discovered in widely distant places. If the quality were always good, the available useful supply would be much greater than it is. Unfortunately, most of the fiber is dead and not suitable for spinning and weaving. The United States has many deposits, but they are generally of inferior quality. The largest supply of usable asbestos has come from the Sall Mountain district in White County, Ga.; Dalton, Mass.; New Hartford, Conn.; Pinto Creek and Grand Cañon, Ariz.; Polk, Mitchell, Wilkes, and Yancey counties, N. C.; Stevens Point, Wis.; Gaspar, Wyo., and Orleans and Lamoille counties, Vt., have all produced more or less of the fiber. The deposits in Vermont form a part of the great serpentine region extending across the Province of Quebec.

Fig. 3. Carded Asbestos, No. 1 Quality

Newfoundland, in the vicinity of Port au Port Bay, has large and promising deposits, but is prevented by its inaccessibility from participating in the rapid development now in progress in the Canadian field.

Italy, up to 1877, produced practically all the asbestos, but its use was made almost prohibitive by the high prices charged. So soon as the Canadian product was exploited the Italian industry received a decided set-back; nor is it surprising, because Canada has a much greater percentage of good fiber that is more easily spun and woven than the Italian mineral.

There are extensive deposits in the Ural Mountains of Russia. At Ekaterinburg chrysotile of fine and silky fiber is found, which is valuable for spinning on account of its tensile strength. The work in these mines is done by Russian peasants, who receive for their labor from 33 to 38 cents per day, together with free sleeping quarters.

Mongolia, Siberia, Finland, Queensland, South Australia, New South Wales, and New Zealand, have deposits which have not as yet been extensively worked. A lavender-blue fiber is mined in South Africa, which differs from other varieties, not only in color but in specific gravity, which is lower. This fiber has great strength and other good qualities and is becoming a strong competitor of the Canadian product.

The production of Russian chrysotile has been pushed forward at even a greater rate than the African fiber. In 1902, 45 tons were shipped from the South African mines, and in 1909, 2,000 tons were exported, at an estimated value of $135,000. In 1907 the Russian mines produced over 10,000 tons, as compared with 1,000 tons in 1900, and they are rapidly increasing their annual output. The startling growth of shipments from these two sources of supply is furnishing food for thought on the part of the Canadian producers, whose annual deliveries have only about trebled in 8 years.

According to a recent estimate, the world's annual consumption is not over 100,000 tons of all grades of chrysotile. Since 1877, when the Canadian industry was founded, the Province of Quebec has supplied at least 75 per cent. of this, and asbestos mining is without doubt the most important mineral industry in the province. To within a very short time, the mines have been owned and operated by a considerable number of separate concerns. Recently the Amalgamated Asbestos Corporation, Ltd., has drawn together a large majority of these concerns, and with a capitalization of $25,000,000 controls from 50 to 70 per cent. of the world's supply of asbestos. In the opinion of H. Mortimer Lamb,* this merger has grossly overcapitalized a fine industry. The rapid growth in foreign fields is cited as an indication that the Canadian producers may not always enjoy their recent monopoly.

The immediate result of the merger has been unprecedented activity, and the opening of new mines and the erection of new plants is going rapidly forward. Some of the larger mines are working 24 hours daily, using electric searchlights for illumination at night. An Asbestos Bureau has been instituted, its object being to keep the public advised of the new uses for asbestos, and to report the development of asbestos properties the world over.

Excepting a few underground workings, asbestos is mined in open pits. When consistent with thorough work, the barren rock is left standing and the fiber-bearing rock removed. In many cases, however, the useless rock is carried to the dump and the pit left unobstructed. While tunneling work can be continued throughout the year, regardless of weather, it is not well adapted to asbestos mining on account of the irregularities of the deposits and the amount of waste made necessary in order to have suitable pillars and supports. The beginning of an asbestos mine is no small undertaking, it sometimes being necessary to remove a layer of soil 15 to 25 feet deep before actual quarrying can be started. In some cases the steam shovel is furnishing excellent results as to speed. It may also be suggested that an opportunity is offered for the use of electrically operated shovels where electric power is available or may be developed. In quarrying, the serpentine is attacked with air or steam-driven drills, that make holes from 8 to 15 feet deep. About ½ pound of dynamite is used for each foot depth of hole. Three cents worth of explosive brings down about 1 ton of rock. Electric batteries are used for firing the shots. The broken rock is next sorted and lifted from the pit in boxes and placed in cars, the barren rock going to the dump and the fiber and "fines" to the mills for further treatment.

* In the *Canadian Mining Journal* of January 15, 1910.

To convey some idea of dimensions, a typical mine might be referred to. This mine is 700 feet long, 200 feet wide, and 165 feet maximum depth. Cable derricks are placed along one side, and the transport boxes of rock are hoisted and carried to the side of the mines by these derricks.

The dressing of asbestos consists in removing the adhering rock, by cobbing the long fiber, and machine treatment of the shorter stuff. No. 1 crude chrysotile fiber measures over three-quarters of an inch in length, and is worked up by men using 6- to 7-pound hammers. The sorting work is usually done by girls, who break and pick out the fiber.

Putting chrysotile fiber into suitable condition for spinning is by no means an easy problem. To find methods of separating each fiber from its neighbor and from the small pieces of rock has taxed the ingenuity of asbestos engineers. A number of plants were failures because complete fiberization was not accomplished. Successful extraction of fiber from the ore dates back barely 15 years, and now the greater quantity of Canadian asbestos is fiberized at the mines.

As a preliminary step the ore is heated sufficiently to expel all water adhering to the fiber. When dry, the mineral passes through crushers which break and grind the bundles of fibers until they are pulled apart. These crushers are, essentially, magnified coffee mills. For still finer separation the fiber passes between rolls giving direct pressure to the bunches of fiber which at this stage are rarely more than three-quarters of an inch in size. After these crushing operations, the fiber is mostly in the form of small lumps, which must be further broken up and put into a flossy, feather-like condition. This is accomplished either by cylindrical beaters or "cyclones." The beaters have rapidly revolving arms with teeth at their ends mounted within a cylinder. The rapidly moving teeth tear the fiber apart and the finished floss is passed out of the cylinder at an opening opposite its entrance point. The cyclones have propeller-like beaters placed opposite each other and revolve at 2,000 to 2,500 revolutions per minute. The lumps of fibers are fed in so as to strike these beaters, and are hurled against each other with sufficient force to be torn apart and fiberized almost immediately. An exhaust fan draws out the fibers and carries them to a shaking screen, which takes out the remaining lumps. Suction fans carry the finished fiber to collectors and settling chambers. It is sometimes found desirable to pass the crushed ore under magnets to extract small particles of iron.

Materials of a fibrous nature enter very largely into the useful arts. As organic fibers, generally used for such purposes, must be kept at a safe distance from fire, it is natural that intensive engineering should welcome asbestos which assists in space economy and in fuel economy as well. Probably the most striking example of its value is the use of boiler and steam pipe coverings made from asbestos and plaster. A conservative estimate places the fuel saving resulting from this protection at 25 per cent.

The modern fire fighter can accomplish very much more than was formerly possible, because of his fireproof equipment. His garments, boots, gloves, helmet, mask and respirator (all asbestos), permit him to remain in direct contact with the flame for a considerable time. Asbestos theater curtains have become a necessity, and asbestos rope makes possible the saving of property and oftentimes life as well.

Rubber sheeting, strengthened by a web of asbestos, makes ideal steam packing, while for the insulation of cold storage chambers and ammonia pipes, asbestos felt, both plain and corrugated, is used. For general heat insulation around stoves and furnaces, asbestos mill board is available. This is made by one manufacturer as follows: Asbestos fiber is placed in beating engines, with water, where it is thoroughly worked up with a suitable binding cement, and stored in tanks, from which it is fed to the paper machines. These machines have cylinders of fine wire gauze, upon which the pulp is collected, excess water pressing through the gauze. The thin coating of pulp passes from the gauze cylinder on to another drum, and when a sufficient thickness has collected it is cut across and removed. This moist square of mill board is pressed by hydraulic machinery and dried.

Asbestos enters into many materials of architecture. Fireproof brick, wall plaster, floor tiling, shingles, roofing felt, and so-called fireproof paints all have asbestos in their composition, while gas grates are faced with clear asbestos fiber.

In the field of electrical insulation, asbestos gives the fireproof fiber necessary to hold together certain other insulating materials. The gums, such as asphalt, rubber, shellac, and Bakelite, are molded with asbestos, and the fiber adds strength to what would otherwise be too brittle for practical use. Asbestos wood or lumber is being used for switch bases and small switchboards. When properly waterproofed by impregnation with asphalt, this material is entirely suitable for these purposes. The unimpregnated lumber has remarkable arc-resisting qualities, and gives excellent satisfaction when used in switch boxes.

In addition to its use in molded insulating pieces, asbestos is used to insulate copper conductors in coils where the temperatures are relatively high. Field coils for railway and other motors have their life decidedly increased in this way, as a greater temperature rise may be allowed than is permissible when ordinary cotton insulation is used. For this purpose round wire is wound with cement, which makes a fairly homogeneous covering. This wire and flat ribbon similarly insulated are used to some extent for armature windings. Field coils made from edgewise or flat wound copper straps are insulated by winding strips of asbestos paper between turns of the bare conductor.

FIG. 4. SPINNING DEPARTMENT, THE UNITED ASBESTOS COMPANY'S WORKS, LONDON, ENGLAND

The fire underwriters require the employment of asbestos as a non-inflammable covering for conductor cords used as leads for electric-heating apparatus. Copper cable is loosely insulated with asbestos thread and one or more strands thus protected are encased in a cotton sleeve. The destruction of this outer sleeve would not in any way damage the insulating qualities of the asbestos.

Notwithstanding the uses just indicated, it must be said that asbestos has very serious limitations as an all-around insulating material. Asbestos fiber is not as strong mechanically as other fibers ordinarily used for insulating purposes. It cannot be used as an outside covering when it will be subject to abrasion. Mass for mass, the insulating value of asbestos is relatively low compared with the best insulating materials, such as mica or

varnish-treated cloths. It is also true that molded insulating materials containing asbestos do not compare favorably in dielectric strength with those which are made without it. A possible explanation lies in the fact that the relative conductivity of asbestos is greater than that of other fibers. Another explanation is that a compound of two materials having a wider divergence in specific inductivity capacity will not be as good an insulator as a compound of two materials having capacities more nearly coincident. Asbestos fiber is more likely to collect moisture than the other fibers, thus reducing the resistance of the mass of which it forms a part. It is probable that all three of these conditions combine in making asbestos a less valuable electrical insulator than many other materials used for such purposes.

Fig. 5. Process of Drawing, Doubling, and Combing Asbestos, Mill of Keasbey & Mattison, Ambler, Pa.

Notwithstanding its limitation as an insulating material where high voltages are in question, asbestos will continue to be used to advantage for moderate voltages. In the application of asbestos to electrical work as well as in its common application as a heat insulator, great progress has been made in the last few years, and without doubt new needs will continue to develop and the demand for this valuable mineral will be greatly increased during the next few years.

EARTH COLORS OF SARDINIA

Earth colors are mined in Sardinia, at Capo Rosso, Capo Becco, and Cola Figu. The annual production of red oxide, both light and dark, ranges from 3,000 to 4,000 long tons. The selling price of the light variety is $7.72, while the dark-red oxide sells for $9.65 per long ton f. o. b. Carloforte. These prices are for shipments not exceeding 100 long tons, when sold in bulk. The price is higher when the earth is packed in sacks. The chief exportation of these red oxides is to England, though some small quantity finds its way to Germany.

Thousands of tons of dark yellow and light yellow oxides are also mined every year and sell at the same price and on the same conditions as the red oxides. These yellow oxides when treated with calcium are said to give a fine quality of red. The same mines yield a jasper that has the same color as yellow, red, and violet ocher, and is, at times, extracted in blocks that measure a cubic yard. Violet ocher is also mined, the selling price of this at times reaching $77.20 per long ton. Manganese is also obtained from the mines at Capo Rosso and Capo Becco, to the extent of 3,000 long tons per annum. This product contains from 35 to 45 per cent. of metals, 10 to 12 per cent. of silica, and 10 to 12 per cent. of iron.—*United States Consular Report.*

JOPLIN ZINC ORE NOTES

Three concentrating plants, each having a capacity of 500 tons per day, are under course of construction in the Granby, Newton County, Mo., camp, and considering the large amount of development being done in that camp, the production of zinc blende, calamine, and lead ores should be materially increased during the ensuing year. Two of these large mills are being built by an eastern company, represented in this district by Axel Ulhorn, who closed a deal recently whereby the Mascot and the Homestake mines were bought from Neosho, Mo., bankers, for $75,000 cash. This was the largest deal of many months in the Joplin district. Both of these mines are large producers of zinc and lead ores, despite the fact that they have been equipped with mills of only 100 tons capacity per day. The Mascot is on a 30-acre lease of the Granby Mining and Smelting Co.'s land, while the Homestake is on a 30-acre lease of the Davis land adjoining. Operations are conducted at a depth of 200 to 250 feet. The third of the big mills is the one being built by the Granby Mining and Smelting Co. to take the place of its large custom mill destroyed by fire the latter part of January.

The annual report of the M., K. & T. Railroad shows that $25,000 was paid in 1910 for mine tailing from Galena, Kans., zinc and lead properties. The tailing was used in making better roadbeds for the railroad.

The Golden Rod mill in Galena, Kans., is to be moved to a lease of the Granby Mining and Smelting Co.'s land in the west part of Joplin, where it will be placed in operation by the Postal Mining Co., a new concern of Galena.

Henry Weymann, of Joplin, Mo., has purchased the 320-acre tract of the Bonanza Mining Co., at Galena, Kans., and several new companies are starting work on this property. The ore here, for the most part, occurs near the surface and is mined as a rule by small concerns or individuals, whose capital is limited. It is one of the typical "poor men's" tracts of the Galena camp.

The name of the Little Jew Mine in the West Joplin camp has been changed to the Little Jewel by Clarke Marshal, who recently purchased this old-time zinc producer. Mr. Marshal has remodeled the mill, increased its capacity, drifted east instead of west as formerly, and encountered better and more extensive ore bodies. The mine is now ranking well up toward the top of the producers of the Joplin camp, the weekly production ranging from 80,000 to 120,000 pounds of blende concentrate.

THE CALAMA COPPER DISTRICT, CHILE

*Written for Mines and Minerals, by F. A. Sundt**

Large Deposits of High Grade Copper Ore. Conditions Under Which It Is Mined

The Chuquicamata copper deposits in Antofagasta, Chile, are reached by taking the Bolivian Railroad to Calama, thence to Punta de Rieles, from which point it is 3½ kilometers to the mines. The mineral zone at Chuquicamata has a length of about 4 kilometers, with southern end but little worked, although it is a very important part. In Chuquicamata there are veins containing copper and also irregular mass deposits termed "Llamperas," meaning brittle mineral deposits. Both kinds of deposits are being prospected and worked.

As a rule the fissure veins strike north and south and are parallel, but come together at intervals along their course. The average width of the veins is 1.51 meters, but where two or more unite the combined width may be 8 or more meters; and, what is more unusual, at their junction the ore continues as rich as elsewhere, and sometimes increases in its percentage of copper.

After joining, the veins separate again and as before take the same general direction until the next junction point is reached; and only in exceptional cases are they known to cross each other. From this and other features it is presumed that the fissures and vein filling were contemporary. The hill through which the veins pass is composed of an acid white rock in which the quartz and monoclinic feldspar can be detected with the naked eye. Basic minerals, particularly the dark iron-bearing ones, are seen only occasionally, which would intimate that the rock was a sort of micaless pegmatite. Judging from its appearance, the gangue accompanying the copper is of the same general composition as the wall rocks, although it is softer owing to the weathering and former circulating ore solutions. The copper ore is found first on one wall side, then the other, and sometimes it occupies the entire width of the vein, and then only a part; but it is continuous and not in bunches here and there along the vein. Occasional but unimportant faults are met, being short, horizontal, and normal, and as the resistance of the rock increases with depth, the faults are not found in deep veins.

In the Panizo Mine of the Compania Poderosa de Chuquicamata, there are two faults. One is produced by a diagonal vein which is barren to the west and mineralized to the east; and the other originates through a change in the nature of the rock. All veins from east to west in contact with the main veins are mineralized for a distance of 20 meters, but those branches from the west to the east of the main veins are barren. Some of the Panizo veins are contorted into the form of an S, that has rich ore in one curve and poor ore in the other. The richest veins, called San Gregorio and San Manuel, continue from the Panizo Mine into Rosario del Llano Mine of the Compania de Minas y Fundicion de Calama.

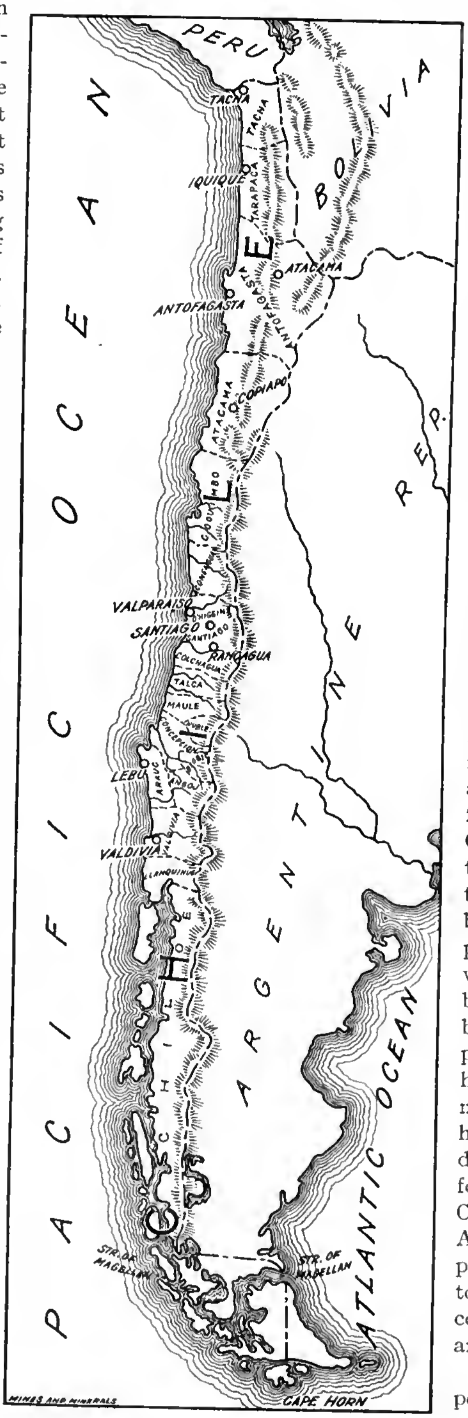

FIG. 1. MAP OF CHILE

Most of the Chuquicamata copper minerals at present worked are oxidized secondary enrichment ores near the surface. Atacamite $CuCl_2+3H_2O_2Cu$ and brocantite Cu_4SO_4+3Aq are found in abundance. Owing to their similarity in color and fibrous structure these two minerals are easily confused. A rosy-colored copper mineral having a similar structure and orthorhombic crystallization is found in some places, and it may be that all three minerals are derived from each other. Copper sulphates, both simple and complex in composition, are found near the surface, and as they are soluble in water, they are a loss when concentrating other copper minerals with water. Copper carbonates are not abundant in this district, although silicates of copper are found quite frequently. At depth the copper sulphides are encountered, but the zone of oxides and that of sulphides is not well marked, in fact one vein may carry sulphides and a parallel vein oxides at the same depth, although both have similar vein materials.

The sulphides most commonly found are chalcocite Cu_2S and covellite CuS. The gangue in the latter instance carries considerable oxide of iron. The chalcocite is purer than the covellite. Bornite and the purple sulphides are not found, at least so far as work has proceeded, although in both the Panizo and Rosario del Llano mines iron pyrite poor in copper appears at a depth of 160 meters. Chalcopyrite free from pyrite has not been found in Chuquicamata, which is peculiar, owing to there being large deposits of pyrite containing less than 6 per cent. copper in both of the mines. Pyrite of this kind is particularly valuable in this district, where matte smelting is carried on and blister copper made, owing to its furnishing both the iron and sulphur needed in the process. None of the Chuquicamata mines have been worked to any great depth, most attention being given to their horizontal extension; consequently at a depth of 180 meters no water has been found, except in small quantities in the Constancia and Flor del Bosque mines. At these mines the water contains sulphates of copper and is removed in carts to a mill where it is employed for wet concentration, it not being suitable for any other purpose.

It is to be remembered that the copper district under discussion is in a desert and all water has to be brought to the mines, where it sells for $10 per ton.* The little veins of water, whose origin is obscure, not being surface water, disappear at greater depth. However, the small quantity found is of sufficient value in this district to be saved.

Those mines which belong to the Poderosa company have been developed systematically by a series of shafts and levels in order to block out the ore. The San Filipe shaft, at the Poderosa Mine, has a cross-section of 2×3 meters, and a depth

* Injeneiro de Minas, Professor Estraordinario de Metalurjia en la Universidad de Chile, Santiago, Chile.

* The translator is not sure whether the prices given are in gold or silver.

of 170 meters. Like the other vertical shafts of this company, it is located so as to cut the vein at certain depths and then deviate from the vein, which must then be reached by driving cross-cut levels from the shaft. At the San Filipe shaft the vein is cut at a depth of 40 meters. That the men may not be subjected to accidents in going in or coming out of the mine, special shafts are put down that they are compelled to use, and this plan reduces hoisting accidents to a minimum. So far the Cia. Poderosa has confined its mining to developing and exploring its property, by which method it has kept up shipments and has 30,000 tons of ore blocked out that carry more than 10 per cent. copper. When rooms are worked, underhand stoping is followed, and this is entirely feasible and safe because no timbering is required except for ore pockets and chutes, and often for these uses timber is unnecessary, as the ore can be worked down the stope floor to the cars as needed. Dynamite and gunpowder are used for breaking rock. So far rock drills have not been used; however, the management appreciates the advantages to be derived from their use, and it is due to adverse conditions that a rock drill plant is not installed. Transportation is carried on by cars wherever feasible, as there is nothing much more expensive in the district than manual labor.

The Panizo Mine has a steam hoisting engine of the two-cylinder single-expansion type. It has a double cylindrical drum and is capable of hoisting with 700-kilogram cages from a depth of 300 meters.

Steam is furnished by a Babcock & Wilcox boiler such as is shown in Fig. 2, working under an average steam pressure of 4 kilograms per square centimeter, although the maximum pressure may reach 8.5 kilograms per square centimeter. Steam is generated by bituminous coal that is bought in sacks containing from 65 to 70 kilograms and costing $3.50 per sack. Four sacks, approximately 560 pounds, are used daily. The boiler consumes 600 liters of water in 10 hours, and probably what is obtained by condensing the steam. Peat was tried for fuel but did not furnish satisfactory results.

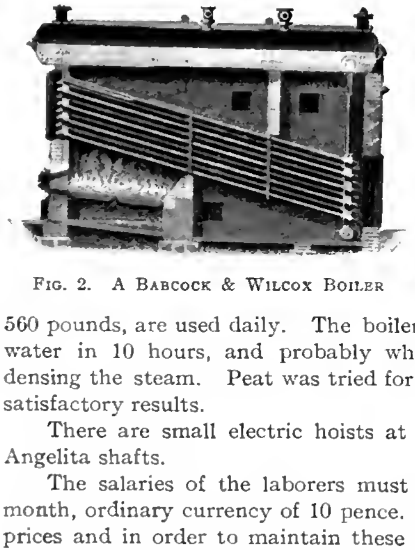

Fig. 2. A Babcock & Wilcox Boiler

There are small electric hoists at the San Filipe and the Angelita shafts.

The salaries of the laborers must not go above $300 per month, ordinary currency of 10 pence. This is the basis of the prices and in order to maintain these figures a careful inspection of the pay roll is made and a rigid watch is kept over the laborers. Piece work is allowed only when it is of absolute necessity, and then the piece workers are carefully watched, and a duty of 15 per cent. of the production is collected from them.

The manager of each mine receives $500 per month; the laborer, $275; the mine boss, $280; the drillers $6 per day; and some $80 per full length meter; the carriers, $5.50; the outside workers, $6. The cost of production fluctuates about $50 per ton.

In July, 1909, the production was as follows:

Ponderosa	266.6 tons, with	38.32 tons of copper
Panizo	275.0 tons, with	30.00 tons of copper
Totals	541.6	68.32

The average copper was 12.6 per cent.

The ores are shipped to England when the copper exceeds 18 per cent., and when the copper is 14 per cent., they are sold to the American Smelting and Refining Co., at Tacoma, Wash., U. S. A. Whenever it is possible, the ores of lower copper percentages are concentrated.

The gangue is softer than the mineral, and that is the reason why the ground ores are superior. When they have a value of 6 per cent. or more, they are sent to the concentrating plant of Huamachuco, and from there they are exported.

Compania de Minas y Fundicion de Calama owns the Rosario del Llano Mine in Chuquicamata. This mine has been one of the greatest producers; its system of working is irregular, however, and it seems that the work has been carried out without sufficient forethought. Its maximum depth is 160 meters, and the horizontal area worked measures 200×200 meters. In some parts of it, iron pyrites with 3 per cent. copper have appeared, but in general the quality has decreased at that depth.

According to the manager's report, the production of this mine during the year 1908 amounted to 13,814 tons of ore, carrying 12.6 per cent. copper, or 1,741 tons. The value of the production of the last 6 months was $581,082.82.

According to the above-mentioned report the cost of the production, including the money spent in new works, amounted to $52.18, which is cheap.

The factors that increased the expenses were:

1. Greater development, exploration, and preparation.
2. Increase of the exploitation of the sulphides on account of the needs of the smelter, and therefore a more elaborate mining system was required, which practically forced the management to use the slicing and filling method of mining.
3. Mining by contract or lease, which is not entirely developed in an efficient form on account of the mine not having been prepared for it.

They have succeeded in reducing the amount of this system of mining until at present it corresponds to 54 per cent. of the total exploitation.

In order to keep down the cost, the following is practiced:

1. To develop as much as possible the practical mining, either by the company or by giving contracts per ton.
2. To prepare the deposits which are not yet in a condition to be worked, and remove them economically.
3. To limit the contract work to the points of difficult access where a mineral of high value lies, paying tariffs in accordance with the market value of the metal, and protecting themselves by charging the contractors a high fee for the right of way to the mines.

The reserves amount to 3,385 tons of minerals of 12.7 per cent. copper.

The price per longitudinal meter in the last 6 months of the year 1908 was $93.

Llamperas Deposits.—Besides the deposits of ore in vein form in Chuquicamata there are other copper deposits of irregular forms termed "Llamperas." "Llamperas" is derived from "Llampos," which means brittle mineral, because the mineral is reduced to a fine powder with a greater facility than the gangue. The Llamperas are found in one of the sides of the mineralized hill of Chuquicamata, at a generally higher elevation than that of the veins. Up to the present time no connection between the Llamperas and vein deposits has been found. An excavation of the Iberia Mine of the Compania Explotadora measuring 80 meters in depth over the brittle formation has not traversed it, nor has it cut through the hard rock passed through by the veins.

It is generally believed that the mineralization of the Llamperas proceeds from the veins with which they are in communication at some depth.

The ground where the Llamperas are found is broken and disintegrated, and inside of the cracks the copper ore is found in the form of colored minerals of brochantite, acatamite, soluble sulphates, etc. The ground is broken with heavy charges of gunpowder, and by means of wedges the mineral is separated from the gangue and crushed afterward to a fine powder. The rock averages 3 per cent. in copper. The crushed mineral is sifted, giving 15 per cent. copper. The sieves have

four openings per linear centimeter. The pieces of mineral containing only 2 per cent. copper are consigned to the waste pile.

The rock of the Llamperas is composed of quartz and monoclinic feldspar seemingly pegmatite in a semidisintegrated state.

The copper appears in the fissures of the rock and is not deposited with regularity. The rock forms strata of uneven and irregular inclinations and directions.

The Llamperas mines could furnish abundant mineral for concentration on vanning tables. The lixiviation of these minerals, as well as that of the poor minerals of Chuquicamata, is a problem to be solved, although concentration has given good results.

LIME REACTION IN CYANIDING

*Written for Mines and Minerals, by Theo. P. Holt**

In comparing the practice in different cyanide mills one cannot help being impressed with the large variation in the amount of lime used in different districts. In the gold mines of the Black Hills for example, from 3 to 5 pounds per ton of ore is considered good practice, in some of the Mexican plants on the other hand as high as 30 pounds per ton, and 20 pounds is not an uncommon figure. In fact, Mexican practice has been criticised by metallurgists of other districts for what they term "an excessive use of lime." They insist that it not only impairs extraction, but needlessly increases the expense of frequent treatment of filter leaves to remove the resulting deposit of calcium carbonate. But, as is usual with established mill practice, it is safe to assume that where there is a "way there's a reason."

The physical property of lime, which coagulates the slime of the ore and causes its rapid settlement, may or may not be an aid in treatment. This depends on the process used. In the Black Hills, where the separate treatment of sand and slime is in vogue, it has been found that the addition of lime makes the classification of sand from slime much more troublesome. The sand particles are coated with slime which makes percolation in the sand tanks difficult. In the "all-sliming plants," where no separation of sand and slime is made, and the rapid settlement of all the solids in the solution is the object sought, the coagulating effect of the lime is desirable. The decanted solution if not perfectly clear may be passed through a sand filter before going to the zinc boxes. The solid particles in such a solution will be attracted to the surface of the sand grains in the filter even though the interstices between the grains are many times the diameter of the particles.

The above conditions in some measure determine the small or excessive use of lime in cyanide mills. Combination sand and slime plants in general use low lime, while the all-sliming plants use high lime. It happens that mills treating silver ores are of the latter class and it is this, probably, rather than the considerations given above that are the chief reasons for wide variation that exists. There is a decided difference in the relative solubility of gold and silver in cyanide solutions of varying alkalinity. Silver is more difficult of extraction than gold, and in addition to finer grinding and stronger solutions, often requires the introduction of special chemicals such as lead salts to hasten the reactions. Lime is an active agent in a chemical way, increasing the solubility of most of the silver minerals. On gold it has the opposite effect. I have observed this fact in connection with experimental work on a large number of gold-silver ores. An increase of alkalinity will increase the silver extraction and decrease the gold extraction in almost every case.

These facts are clearly presented by a few results obtained on three gold-silver ores. The extraction of gold for different tests is represented in the graph, Fig. 1, by full lines, and the silver by dash lines. Samples No. 1 and No. 2 are slightly acid, while No. 3 is strongly so, consuming all the cyanide when less than 3 pounds per ton of lime was present in the test. The number of tests in each case are indicated by the points on the graph. A larger number of determinations would tend to smooth out the irregularities in the curves, but the principal characteristic is evident. For the solution of the gold values in an ore it is best to have only sufficient lime for protection. In other words, just enough to prevent the loss of cyanide by its union with the acid to form salts in the ore. More than this not only adds to treatment costs but decreases the amount of gold recovered.

The effect of an alkali on the solution of native silver is the same as on gold. The reason for this is not apparent. Mr. B. L. Gardiner suggests* that in a special case "it was due to the formation of $Fe(OH)_2$ which is a powerful reducing agent, robbing the solution almost immediately of its oxgyen and thus preventing the solution of the gold." He suggests that "the only remedy for this condition seems to be to remove the $FeSO_4$ by means of water washes preliminary to cyanide treatment, and the use of solutions of as little protective alkalinity as possible, even at the expense of increased cyanide consumption." It is easy to conceive how such conditions might exist in a leaching vat, but in an agitation tank with

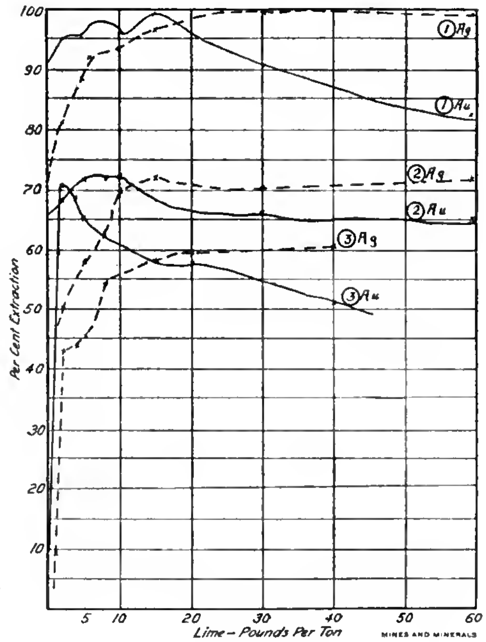

FIG. 1

the constant contact of the solutions with the air such conditions could hardly exist. The $Fe(OH)_2$ formed is quickly oxidized to $Fe(OH)_3$, and the solutions are immediately supplied with the oxygen of the air to supply that removed. A more tenable explanation seems to be that the lime forms a protective covering on the metallic surfaces.

The increased extraction observed for the silver minerals is in accordance with the well-known Mass law. Lime is an effective precipitant of soluble salts which otherwise accumulate in mill solutions and prevent the dissociation of silver compounds. A good grade of lime is soluble in the average cyanide solution to the extent of about 4 pounds per ton. Lime added in excess of this amount is carried in suspension as milk of lime but dissolves whenever the solution falls below the saturation point.

The most economical amount of lime to add in any given case is a matter of experiment. When the values in the ore are divided between gold and silver it often complicates the problem, as one metal can only be secured at the expense of an increased loss in the other.

METALLURGICAL SLEUTHING

Written for Mines and Minerals, by E. B. Wilson

PITTSBURG, PA.

"DEAR EDITOR:—Enclosed find the description of a new metallurgical process which it is said will revolutionize metallurgy. Several of us have about decided to go into the manufacture of 'Borindum,' but I thought I would obtain your opinion before final decision. Kindly send me your advice, together with your bill, and oblige."

Showing the Value of the Application of Deductive Reasoning to Solve a Metallurgical Mystery

The above letter, which, except for the last sentence, reminded the editor of many others that he had received, was read with interest, and he turned then to the enclosed prospectus which was as follows:

BORINDUM

An inexpensive secret compound called borindum has been invented for the treatment of gold, silver, copper, and lead ores and for giving toughness to steel and iron in connection with the Buckenlach inventions of automatically operating machinery. By the various Buckenlach processes a recovery of 97 per cent. to 98 per cent. is effected without the making of slimes. After pulverization the ore pulp passes automatically into a tank containing a solution of borindum, from whence it is poured through a series of gold-saving taps, having been previously scoured by the solution, thus leaving the metals in a state to be readily taken up by the mercury which is rendered extremely powerful by the presence of borindum. Not only is the affinity of the mercury for gold and silver greatly increased but the tendency to flour, foul, or oxidize is prevented, so that waste or loss of the mercury is impossible and its action is made continuously "quick" by a current of electricity.

When used in connection with cyanide, chlorine, and other well-known chemical processes the dissolving of gold and silver and their precipitation become rapid and continuous, with increased percentage of recovery.

The Buckenlach method of recovery for copper ores containing gold and silver provides for the rapid dissolving of the values in a borindum solution and their simultaneous precipitation by both scrap iron and electric current, the copper being deposited in one place, the gold in another, and the silver in a third place automatically.

For use in connection with iron and steel, by a chemical treatment of the iron in the cupola furnace, borindum will produce homogeneous castings free from all blow holes and with its tensile strength increased 25 per cent. This combination will be invaluable for car wheels and axles where great tensile strength is needed. It greatly purifies the iron of titanic oxide and sulphur and phosphorus. It makes clean iron of great toughness and strength and of very close grain. The same advantages may be had in steel and steel castings.

REPLY

DEAR SIR:—Your communication regarding the inexpensive secret compound called borindum, with the request that I look into the merits of the process and inform you whether it can be used at your lime mine is received.

I congratulate you on the wisdom you show in first consulting a metallurgical sleuth before investing in the new process. The compound being secret we must approach it cautiously and ascertain if possible by deductive reasoning whatever it is. All the more cautiousness is needed because it is stated that it is for the treatment of gold, silver, copper, and lead ores, and for giving toughness to steel and iron in connection with the Buckenlach inventions of automatically operating machinery. By not running risks, we learn that borindum has not the entire responsibility in this matter, and that there are various Buckenlach processes which recover 98 per cent. without making slimes, the other 2 per cent. being graft most likely on the part of borindum. We found from reading about borindum that "after pulverization the ore pulp passes automatically into a tank containing a solution of borindum, from whence it is poured through a series of gold-saving taps, having been previously scoured by the solution, thus leaving the metals in a state to be readily taken up by the mercury which is rendered extremely powerful by the presence of borindum." This being somewhat involved, we again were obliged to proceed cautiously, and by this method we ascertained that borindum was a beast.

Secret-process sleuths know that an inventor, after inventing, invents a name which will apply to his invention, and since the inventor's invention is uppermost in his mind, the chances are the inventor furnishes a clew to his invention when inventing a name for his invention; for example, should you go into a drug store and ask for "blockade runners" you would not be handed a gunboat. Dissecting now the name borindum, and correlating, we find that the money put in secret processes is called "*mud*," and the investor claims the inventor has been "*robin*" him. If now the first and last syllables are spelled backwards, and the last syllable prefixed to the first syllable, and the middle syllable suffixed, the word "borindum" will spell mud-rob-in.

No self-respecting secret-process Sherlock considers his work finished with one simple piece of mind reading, and therefore we look up the word *bor*, and find it is derived from the Gaelic *boar*, and means a he hog, so called because he bor-in-mud. Arrange the syllables *ad libitum* and a second time we have deduced the word *mudrobin*; moreover, we have discovered it is a beast, for the inventor says that after pulverization the ore pulp passes automatically into a tank containing a mudrobin, who proceeds to recover 98 per cent. without making slimes. Nothing but a hog would eat 98 per cent. of the values; but hist! why is a tap "automatically scoured?"

Any secret-process inventor who fully explains his invention leaves the investor in doubt as to his reliability; besides most inventors follow the poet's advice, to wit:

"When reaching for a cactus bud
A prick or two pertains."

The inventor leaves the investor and investigator in doubt as to whether the metal in the previously scoured gold-saving taps is readily taken up by the mercury or the metals in the pulp; however, he assures the reader that mudrobin renders mercury extremely powerful, and that "not only is the affinity of the mercury for gold and silver greatly increased, but the tendency to flour, foul, or oxidize is prevented, so that waste or loss of mercury is impossible, and its action is made continuously 'quick' by a current of electricity."

The matter apparently is becoming involved, for (1) the inexpensive mudrobin is said to do the recovering; (2) the mercury is said to do the recovering after the pulp has run through the previously scoured taps in the presence of mudrobin; (3) it is the continuously kept "quick" mercury by a current of electricity that does the recovering.

We find then that the secret process is merely a secret in name, and that mercury is the main and only recoverer of the 98 per cent., which makes the inventor resemble that beautiful stanza:

"When coyote gambols on the plain
The partridge seeks the lea;
The fool beast in chasing after him
Gets a cactus prick in his knee."

Having disposed of the first paragraph, we turn to the second, which reads as follows: "When used in connection with cyanide, chlorine, and other well-known chemical processes the dissolving of gold and silver and their precipitation becomes rapid and continuous, with increased percentage of recovery." In regard to this statement, individually I would not accept it without making the inventor disclose and prove what the other well-known chemical processes were.

We now come to the following: "The method of recovery for copper ores containing gold and silver provides for the rapid dissolving of the values in a borindum solution and their simultaneous precipitation by both scrap iron and electric current,

the copper being deposited in one place, the gold in another, and the silver in a third place automatically." Apparently the mud-rob-in has his own sweet way in this case until he meets and has a scrap with the iron, which takes the copper away from him automatically, after which the electric current swipes the gold and silver. Evidently the action affected by mudrobin is equally acid and basic, similar to that produced by feeding hogs on clams for a considerable period, when they will automatically swell up and collapse as the tide rises or falls.

When a mudrobin can swallow or dissolve the values, and simultaneously precipitate them, the reaction is bound to be continuously automatic, or the circulation would be stopped and mudrobin choked to death instead of Buckenlach. Of course you are aware that all precipitation is not automatic, and that it requires the mixing of different solutions, or a solid substance, or possibly an electric current, or something else either manual or mechanical. You are also aware that eruginous microbes are in solutions of copper containing gold and silver and that they are poisonous, and this naturally raises the question concerning the expense connected with the inexpensive secret; in other words, what is the longevity of mudrobin.

The inventor does not furnish sufficient data on the number of gallons of saliva required to dissolve and simultaneously precipitate, without which the life of a mudrobin is indeterminate. You should obtain his figures.

Much criticism was given the mill men on the Comstock because they used tobacco juice in their pans. The mill men never answered their critics, but laughed up their sleeves at the wiseacres who were unable to understand that tobacco juice looked better in the pans than on the mill floor, and was more efficacious, since saliva will dissolve anything.

If what the investor relates in the last paragraph were true, then the United States Steel Co. must go out of business, and this is too good to be true. This person Buckenlach is the first inventor to invent an invention that so closely approaches the *vade mecum* of the metallurgist, and that can be adapted to fire or water. To place this automatic continuously-kept-quick hog before intelligent men shows his homogenous cast-iron brass is full of blow holes with 25 per cent. increase tensile strength in the blast. My advice to you, sir, is to let borindum severely alone; for a solution that will only greatly purify iron of titanic oxide and sulphur and phosphorus and will dissolve all other metals, is without doubt devilish. If you intended to invest $25,000 in borindum before consulting me you can send your check for $250; if, however, you did not intend to invest in borindum, but simply consulted me out of curiosity, you can send your check for $2,500; my time is valuable and not to be trifled away.

Yours very truly,

来 来

SOLUBILITY OF GOLD IN POTASSIUM FERROCYANIDE

Finely divided gold dissolves slowly in potassium ferrocyanide solution at the ordinary temperature, and forms a distinctly alkaline solution; solution is very slow even at boiling point. Apparently potassium aurocyanide is first formed, and the liberated ferrous ions are oxidized by the atmosphere to ferric hydroxide, which is precipitated, in amount corresponding to the amount of gold dissolved. Prolonged action of a strong solution of potassium ferrocyanide seems to give ultimately potassium auricyanide.—*Monats. Chemie.*

SMALL AIR COMPRESSORS AT MINES

Written for Mines and Minerals

Nearly every mine manager has desired at times an air compressor that might be used to tide him over temporary difficulties; and nearly every mine manager has wished for an air compressor to do work that is done under difficulties by manual labor.

That such machines are not in their equipment is due to the size, weight, and cost of the machines; the expense that must be incurred in their installation, their upkeep, attendance, etc. Realizing the desire that there is for small air compressors among mining men for lifting ore gates, running small pumps intermittently or an occasional rock drill, for running a fan or possibly for ventilation in bad places, for running an engine intermittently at the shop, etc., manufacturers of air compressors are working out the problem. Small machines such as shown in Figs. 1 and 2 are not as apt to receive the same careful attention as larger and more costly machines, while the work demanded of them is no less wearing. The manufacturers realizing this have worked along the lines of the three cardinal virtues of machinery, strength and hence durability; simplicity in construction and parts, features that appeal to the users; and efficiency, which in compressors involves the construction of the air cylinders, valves, and the cooling arrangements to a greater extent probably than the power end of the machine. Fig. 1 is the sectional view of a smaller steam-driven air compressor which mounted on its own bedplate can be moved about and set up without great expense; further, in case it is to go into the mountains, it can be readily taken apart for transportation and almost as readily be assembled. It will be understood that the air cylinder is on the end and that the cylinder ends are water-cooled in addition to the cylinder. Both the inlet valves at the bottom of the cylinder, and outlet valves at the top are poppet valves arranged in a radial direction to the axis of the cylinder and placed close to the ends of the cylinder. This position minimizes the losses due to clearance and the air trapped by comparatively long ports after compression in the cylinder. To remove the valves it is not necessary to remove the cylinder heads as they can be reached by unscrewing the plugs shown in Fig. 2 on the outside of the air cylinder. This feature is one that appeals to users of air compressors as the entire valve can be removed and the parts thoroughly examined without trouble. The valves are so constructed that in case of breakage it is impossible for broken parts to enter the cylinder.

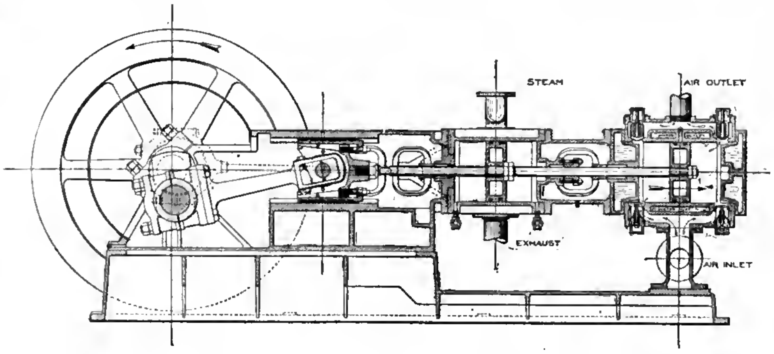

FIG. 1

Fig. 2 shows the steam-driven compressor in elevation, and the steam regulating device which places the throttle valve under the influence of the air-receiver pressure.

Fig. 3 is the section of a belt-driven compressor which may be operated by electric motor, gasoline engine, oil engine, or steam engine.

The power-driven machines are fitted when desired, with an unloading device placed on the air inlet of the compressor. This device is set to shut off the incoming air to the compressor when the receiver pressure exceeds a predetermined point. This enables the compressor to run at regular speed, an essential in power-driven machines, compressing no air until the receiver pressure again falls below the point set. This secures important reductions in the amount of power used when the compressor is furnishing air intermittently. The device is smooth and even

in its action, throwing the load off and on the compressor without sudden jar or strain.

The writer desires to acknowledge the courtesy of the Sullivan Machinery Co., of Chicago, Ill., for the illustrations and information so kindly furnished for this article.

DETERMINATION OF ALKALINITY

Written for Mines and Minerals

Among the various operations performed in the laboratory at a cyanide plant is one which deals with the alkalinity of the cyanide solution. A certain quantity of alkali must be added

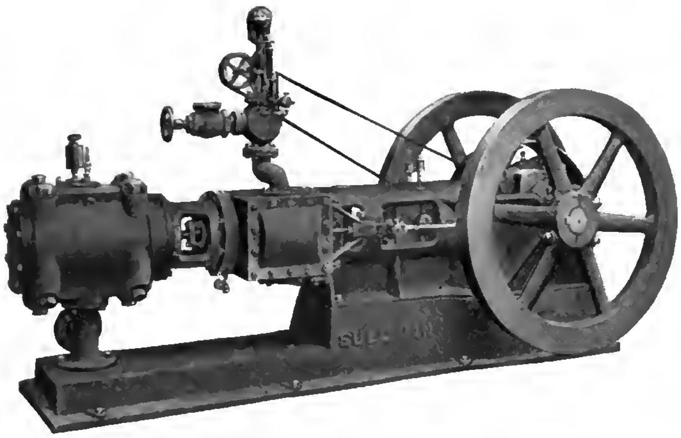

Fig. 2

to cyanide solutions to protect them from acid which may be in the ore. A normal acid solution is one so prepared that 1 liter of the solution contains 1 gram of replaceable hydrogen. Accordingly the normal sulphuric acid solution would contain

$$H_2 + S + O_4$$
$$2 + 32 + 64 = 98 \text{ grams}$$

were it not that there are two replaceable atoms of hydrogen in the sulphuric acid, hence $98 \div 2 = 49$ grams per liter, or .049 gram per cubic centimeter.

A normal alkali solution must contain the chemical equivalent, weighed in grams, of the hydrogen replacing metal or group of elements. For instance, the normal sodium hydrate solution must contain

$$Na + H + O$$
$$23 + 1 + 16 = 40 \text{ grams per liter}$$

or .04 gram per cubic centimeter, because the valency of sodium and hydrogen are the same. Equal quantities of any normal acid and normal alkali solution neutralize each other, and the quantity of any solution of a single acid or alkali that is neutralized by 1 cubic centimeter of a normal solution contains .001 gram of hydrogen equivalent of its active constituent.

To test the alkalinity of a cyanide solution, take 29 cubic centimeters of the solution and place in a beaker, next add silver nitrate solution until there is a slight turbidity. Phenolphthalein is then added and the solution titrated with standard sulphuric acid solution to the end point. Each cubic centimeter of the acid consumed is equivalent to 40 ounces Troy, or 53.9 ounces avoirdupois, of sodium hydrate to the ton. This is the equivalent alkalinity of the solution, and to protect the cyanide from "acid cyanicides," a trifle more alkali should be added. If too much is added, the white precipitates will be increased in the zinc boxes, a feature which should be avoided so far as possible. Caustic soda being expensive compared with lime *CaO*, the latter is used in practice, as it forms lime hydrate with water and neutralizes acid. It is customary to calculate the lime needed for cyanide solutions from the quantity of sodium hydrate used in determining the acidity in the ore. To test for acidity, an assay ton or 29.166 grams of finely pulverized ore is shaken in warm water for ½ hour, after that it is filtered and the solids on the filter washed with water. If the ore is acid the filtrate will turn blue litmus paper red; if it is alkali it will turn red litmus paper blue. Ores to be treated with cyanide solutions are usually acid, and it is therefore necessary to add lime. The molecular weight of sodium hydrate is 40, that of lime 56, but the valency of sodium is 1, while that of calcium is 2, hence $\frac{56}{40 \times 2} = .7$; that is, it requires seven-tenths as much lime as sodium hydrate to neutralize an acid. Assume the following weights of acid solution are taken for testing, and the following quantity of sodium hydrate is used in titration, the quantity of lime needed would be calculated as follows:

	Grams
Weight of beaker and acid	59.396
Weight of dry beaker	30.230
Weight of acid solution	29.166

	Cubic Centimeters
Final reading of burette	15.9
First reading of burette	13.4
Normal solution used	2.5

From the assumption, 29.166 grams of acid solution contains 2.5 cubic centimeters of standard acid, because normal acid and the alkali soda are equivalent, therefore each cubic centimeter of sodium hydrate corresponds to 49 ounces Troy, or 53.8 ounces avoirdupois, of sodium hydrate per ton of ore. The pounds of lime required to neutralize the acid properties in 1 ton of ore will be

$$\frac{53.8 \times 2.5 \times .7}{16} = 5.88 \text{ lb.}$$

SCANDIUM

Scandium has been found to the extent of more than 1 per cent. in the mineral wiikite from Finland, and in small amounts

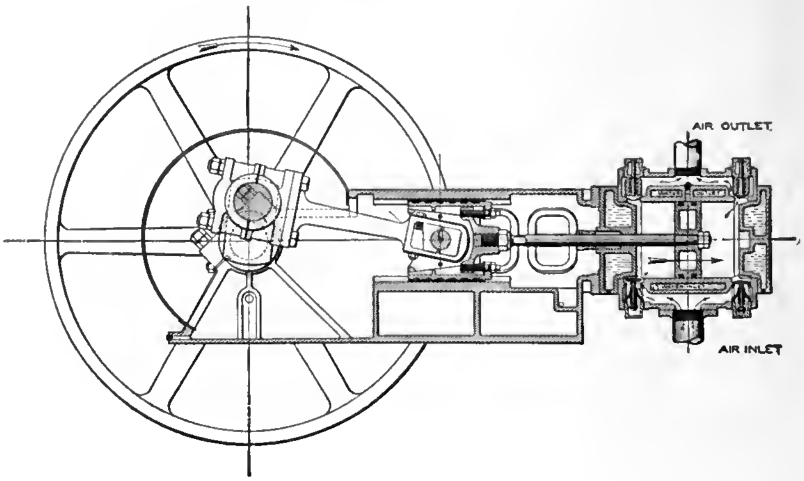

Fig. 3

in many other minerals. By a systematic series of fractionations it is possible to separate scandium from most associated elements; ytterbium is the most difficult to separate because its nitrate is decomposed almost as readily as scandium nitrate. In view of the atomic weight relationships, and of the frequency with which these elements occur together in nature, it is suggested that yttrium and scandium are degradation products of ytterbium. Scandium can be separated from ytterbium by precipitation as metanitrobenzoate. Sir W. Crookes. (Phil. Trans. Roy. Soc., A209, 15.)

TITRATING FOR PROTECTIVE ALKALINITY

*By H. L. Sulman and Frederick Reade**

The authors, under the heading "Errors in Testing Cyanide Solutions," disagreed with Bede Collingridge as to the effect of potassium iodide in titrating cyanide solutions for protective alkalinity, and experimented themselves. They found that the presence of potassium iodide obscured the end point. In presence of silver cyanide and potassium iodide, phenolphthalein fails to give a sharp end point; the indistinctness is a double one, due, principally, to the constant return of the phenolphthalein color indicating alkalinity after its discharge by standard acid to an apparent neutral point, and, to a minor extent (owing to the employment of unnecessary amounts of potassium iodide and silver solution), due to the masking of faint alkaline colorations by the iodide of silver suspension.

When using a solution one-tenth normal, the end point of the reaction is sufficiently sharp to give accurate results, but to determine small amounts of protective alkali in small quantities of highly dilute cyanide solutions (such as may be derived from the treatment of slimes by decantation) standard acid should be employed of a dilution commensurate with requirements, say .04 normal. Under such conditions the error becomes noticeable, and is further accentuated by the use of silver nitrate in excess in the first (or cyanide) titration. If, however, no potassium iodide be used, the results with the weak acid are accurate and the reactions normal.

DEL CARMEN MINE, WORKINGS ON HILLSIDE AT LEFT

The phenomena are explained as follows: "In the titration for cyanide, with silver all potassium cyanide (which would otherwise give its full alkali value on titration with acid) must first be converted into the double cyanide *KCN, AgCN*, a compound which is not decomposed by dilute acid in which the combined moiety of *KCN* does not therefore show alkalinity on titration with standard acid and an indicator.

"The end point of the cyanide reaction is, however, necessarily marked by the precipitation of silver cyanide as a cloudy suspension. This precipitated silver cyanide now reacts with potassium iodide, forming yellow silver iodide, and free potassium cyanide, of course with its equivalent alkalinity."

The authors conclude by restating Mr. Collingridge's proposition thus: "If small amounts of protective alkali are required to be measured by dilute standard acid solutions, the use of potassium iodide as an indicator for the cyanide reaction point will give rise to serious error in regard to protective alkalinity present.

"Further, the error will be greater in proportion to the overdoing of the cyanide end reaction with silver-nitrate solution, in presence of an equivalent addition of potassium iodide; this is due to the reaction between argentic cyanide and potassium iodide in producing free potassium cyanide."

BOQUILLAS ZINC DEPOSITS

Written for Mines and Minerals, by Carlos Moser

Only 4 miles south of the Rio Grande, in the state of Coahuila, Mexico, is a deposit of zinc carbonate, which has lately attracted the attention of all men interested in this metal. The western foot-hills of the Sierra del Carmen are very much changed, broken and distorted by a porphyry dike several miles long and from 100 to 200 feet wide, along which caves and fissures were eaten out of the lime-rock mountain by solutions and afterwards filled with lead and zinc ores of remarkable purity. About 20 years ago these deposits were first discovered and mining started by the old Consolidated Kansas City Smelting and Refining Co., which, of course, was only interested in the lead ores, which they at first shipped to their El Paso plant, but eventually smelted at the river's edge in the village of Boquillas, about 8 miles from the mines.

ZINC CARBONATE AT DEL CARMEN MINE

The lead ore was first discovered on top of the Puerto Rico hill, where it appeared in the form of galena in a chimney some 30 feet in diameter. Later the same class of ore was found in the Zaragoza hill, where the deposit at the surface was 40 ft. × 120 ft. in thickness. After some 8 years of mining these surface lead bodies were exhausted and the mines abandoned. Some 5 years ago the writer examined these abandoned properties and to his astonishment found the old stopes filled with carbonate of zinc ores and great masses of it reaching to the very surface on three sides of the chimney in Puerto Rico mine. Since then the properties have been developed to such an extent that it is claimed more than 50,000 tons, averaging 46 per cent. throughout, with less than 3 per cent. iron, and no other injurious minerals, are actually blocked out. As mentioned before, these deposits appear in chimneys and caves, the chimney in Puerto Rico being 220 feet deep, the area being about 30 feet in width by from 40 to 80 feet in length. At its bottom this chimney connects with a cave 700 feet long, running northwest, which was practically filled with lead ore and where the east wall is covered with the zinc ore spoken of. To the southeast a regularly formed fissure contains a mixture of iron, zinc, and lead of little value, until it reaches a deep arroyo, also some 700 feet distant from the main chimney. On the other side of the creek rises the Zaragoza hill with large deposits of

iron ore unexplored for nearly a mile, till the Zaragoza lead mine, now mostly caved, is reached.

The very steep slope of the main mountain to the east of the Zaragoza is covered with boulders of high-grade zinc ore, but on account of the high walls, rising in short terraces to 5,000 feet above the foot-hills, the source of this phenomenon has not yet been discovered.

Further, north of Puerto Rico, are strong outcroppings of zinc and small stringers of lead ores, but also not explored. Apparently there are a number of veins parallel to the porphyry dike, but their contents are unknown as they are principally barren, or nearly so, on the surface. The greatest drawback to the full development of this region is the long distance from a railroad. The nearest railroad point in Mexico is Cuatro Cienegas, over 200 miles away, and, of course, it is out of the question to haul the product from these mines such a distance. Last year a Leschen patent aerial tramway was constructed to transport the ores into the United States direct. This tramway is 6 miles long, 2½ miles in Mexico and 3½ miles in Texas.* From the Texas terminal of this cable it is exactly 80 miles to Marathon. A splendid highway connects these points, but common wagon freight and the high duty on zinc ores make it rather an expensive affair to make shipments now. There is

Puerto Rico Hill, Boquillas Zinc Mines

a movement on foot to build a railroad either from Marathon, Haymond, or Paisano on the Sunset line to Boquillas.

The lower section of Brewster County, in which Boquillas, Tex., is located, promises large freight resources, as ores of many kinds, cinnebar, lead, zinc, iron, and silver, also strong beds of first-class cannel coal; immense quantities of sotol; guayule, the rubber plant; and mariala, for the manufacture of linoleum, besides the productive wax plant, locally known as candelilla.

WISCONSIN ZINC ORES

The mining rights of the Jarrett Lead and Zinc Co., at Pt. Rose, Wis., have been transferred to the M. & D. Mining Co., of Madison, Wis. Drills will be put to work to prove the ground, and an attempt made to get the big plant built a year ago at a cost of $30,000, into commission once more. A fine showing of ore was made in the Jarrett during the progress of shaft sinking, and much was expected of this property. It lies along the same range as the Board of Trade and other producers in this district. Results were obtained from milling the stock pile, and further underground work was disheartening.

Another profitable producer is the Henrietta, and a good showing is being made by the Peaceful Valley Mining Co. With the Baxter mine in shape again by April 1, a good output of all grades of ores may be expected the coming summer.

The Frontier Mining Co. has purchased the power and concentrating establishment built for the Hoosier Mining Co., and a transfer will be made to one of the new Benton prospects under development. Much was expected from the Hoosier but the ground failed to make good. The Frontier has a very likely producer in the new Sedgwick and the plant may be rebuilt.

W. L. Thorne, the expert driller, is operating with two Keystone steam drills upon the mining allotment of the Fields at New Diggings. This mine is operated by R. N. Hunt & Co., of Chicago, under the direct personal management of R. S. Landers, of Galena. A new shaft is being sunk upon the Crawhall land adjoining. More extensive mining operations have been planned for the coming season.

The mill, machinery, and mine, at Dodgeville, formerly owned by the McKinley Zinc Mining Co., has been purchased at foreclosure sale by McKinley Bros., of Dodgeville, and they will continue to operate this property.

The New Jersey Zinc Co. continues its buying program, the last deal involving the Carrow farm, at Linden, the consideration being $25,000, which carries with it the mining rights to the allotment. The Rajah Mining Co., of Milwaukee, is located upon this land and this latest news would seem to indicate that the proposition has failed under the Rajah management. The surface equipment was brought over from the Trio mine and was known for a time as the Racine-Linden. The plant failed to give satisfaction and the development of the ground while showing zinc ore in disseminated formation made it plain that better facilities for handling the ore must be had before results could be obtained. More capital was required which the Rajah management tried hard to raise but failed. The Linden-Mifflin Mining Co. was none other than the New Jersey Zinc Co. and operated what was known as the Mason mine with a big power and milling plant. This was closed up some time ago on depleted ranges and it was believed that the surface equipment would be removed. Except for a portion of the machinery the plant remained intact and it is more than probable that this plant will now be made to do service for the Carrow mine.

The Drumm mine is shipping about a car of ore daily. With heavy shipments of ore for more than 6 months it begins to look as if this property would yield some measure of profit to the owners of the mining rights, the Benton Mining and Developing Co. The surface equipment is installed by the Wisconsin Zinc Co. and must of course be paid for out of the first net earnings of the corporation.

The American Zinc Ore Separating Co. finds the electrostatic method, the Huff process, of separating ores so profitable that additions are planned in the near future. It is proposed eventually to bring the capacity of the plant up to 1,000 tons weekly. Machinery is being installed with all possible haste at the Cleveland Victory Lead & Zinc Co. dry process plant on the Klondyke allotment. This process is entirely new and the outcome is being watched with much interest by mining men.

The Dodger Mining Co., at Mifflin, is installing a new hoisting and air plant. Drilling operations are in progress at the Cruson mine with variable results. Late reports from the Dall Lead and Zinc Co. are to the effect that the main ore body has been picked up once more east of the new shaft and that the outlook is now better than at any time since this portion of the mine has been developed. The Dall is one of the big producers of the field and at one time was one of the strongest dividend payers. The ore runs have been badly broken up, accounted for by the fact that the first mining was done in a draw where the ground is productive of numerous crossings and spur ranges. Sooner or later the Dall is destined to develop a large permanent deposit of zinc ore. The power and milling plant is one of the best in the field and is valued at $35,000. A new shaft has recently been completed.

* Described in Mines and Minerals for Feb., 1910, page 437.

COAL NOTES

Intensive Working.—The *Mining Journal*, of London, England, when commenting upon the Hulton colliery disaster of December 21, 1910, has this to say concerning intensive working: "Certain facts have been mentioned, such as the excellent ventilation of the Hulton pits and the up-to-date appliances for rapid working, as if they represented safety factors in the working of a mine. The better the equipment of a colliery for rapid production, the greater the amount of dust produced in the workings; and the freer the ventilation, the greater the opportunities for an explosion of dust, owing to the added dryness of the workings. These are matters which will, no doubt, be admitted theoretically, but are often overlooked in practice, and we mention them to remind readers that there is nothing surprising in the fact of such explosion overtaking new and up-to-date collieries; and that, in fact, the more intensive becomes the system of colliery working, the greater the liability to serious disasters."

A combination of intensive working, free ventilation, and freshly mined coal dust, which is more explosive than that which is weathered, is so common, that quotations such as given at the outset are explicable.

Vacuum Coal-Dust Removers.—The vacuum carpet sweeper is to be introduced into the coal mines of Colorado to remove the dust. It will now be necessary to have a new official, preferably of the fairer sex, to supervise the work. It is unfortunate that this idea was not evolved before the commission to revise the mining laws of the state had made its most excellent preliminary report, as some recommendations covering the duties of the new official should be made to the legislature. If a suggestion is permissible the inspector should not be allowed to wear hobble skirts. However, the plan has been tried on a small scale with ordinary room sweepers and satisfactorily removes the dust, including pieces of coal up to ¼ inch in size, from the rough floor of a boiler room. The idea is revolutionary, of course, but there seems no reason why it should not work if proper modifications are made to adapt the machine to underground conditions.

Bellevue, B. C., Disaster.—Mr. James Ashworth, when giving evidence before the coroner's jury in the case of the Bellevue, Alberta, B. C., mine disaster, said: "The Mt. Killner mine, in New South Wales, was standing idle. Three men were in the mine, one at pump and two in the shaft, when a great rumbling was heard, after which the mine blew up, and was found to be completely filled with afterdamp. The jury that sat upon the case rendered a verdict of spontaneous combustion, but when the mine was explored it was found that the roof had fallen and there were no traces of fire in the mine." Mr. Ashworth stated that he was of the opinion that the cause of the Bellevue accident was due to a fall of rock. The inference is that the heat brought about by the concussion due to the fall of rock might be sufficient to cause a dust explosion. Referring to an explosion in a mine in South Wales he stated that on the upper side of the gangway where the rooms were wide the men were all able to walk out after an explosion, while those who were working on the lower side in narrow rooms were all killed.

Coal at Elkton, Mich.—Well drillers on a farm 3 miles northeast of Elkton, Mich., drilled through 6 feet of bituminous coal. Samples were reported to be entirely free from sulphur, which is the case in the Sebewaing mines, 20 miles west of there. Just how far the deposit extends is not yet known. Oil prospectors have secured options on thousands of acres of land north and east of Elkton, and while they are secretive regarding the matter, it is expected that active drilling and developing will begin in the early spring.

More Coal Found in Canada.—Coal, said by experts to be of better quality than any yet found in the West, has been struck by well drillers at Salvador, a station 9 miles west of Luseland, Sask., in the territory being colonized by a land company of St. Paul. It was found at a depth of 260 feet, and the bed was 5 feet wide.

Birch Grove Colliery.—Development work at the Birch Grove Mine, Sydney, B. C., is proceeding very quietly. Both slopes are now down a distance of 400 feet. They have passed the dip in the seam and are now ascending to the southern outcrop. When the slopes were started, they were driven at an average of 43 degrees for about 200 feet, when the trough of the basin was reached. At this point they became level and continued so for another 100 feet, when they again took a rise of about 5 per cent.toward the southern outcrop. A carload of coal has been sent from the mine to the washing plant and chemical laboratory at the steel works, where it is being tested to determine its value for coking purposes; its value in that respect is believed at present to be quite high.

Big Muddy Coal, Wyoming.—It is reported that a new bed of coal has been discovered at the Big Muddy Mine, Basin, Wyo.; also that good coal has been found between Bodie and Wellington, Nev.

Coal Mine Owner Badly Burned.—Thomas Wanless, owner of the Wanless coal mines, and two miners were burned by an explosion in the mine at Providence, Ky. Two miners were shooting preparatory to leaving the mines, and the owner was down inspecting the work. Four or five shots went off at the same time, and it is supposed that a blown-out shot must have occurred, igniting the powder supply. The mine immediately became a mass of flames, which died out after 20 minutes. The men, when found, were unable to speak. Wanless is in a critical condition. The other two men will recover. The mine is a mass of debris. It is a slope colliery, and 20 men were employed.

He Had Cold Feet.—On Sunday night as the curfew bell was ringing out the old and ringing in the young, the staff of the Fernie Hospital was thrown into consternation by the loss of a patient, one Xenophon Pouplos, a Greek who had acquired some frosted pains at Elko and had been brought there for treatment.

Like his lamented and illustrious namesake of Elea, this sport believed that phenomena was merely an illusion and that cold was a chimera. So he proceeded to demonstrate his belief by wandering out of the hospital, clad in a nightie, one sock, and one slipper. It was about 10 degrees below zero at the time.

But if consternation reigned in the hospital, she reigned there as over a tributary state, her real throne and imperial dominion being over at the coke ovens, where Jimmy McLean's gang of nihilists were down on their prayer handles, worshipping a luminous being in flowing robes that was toasting its shins over a glowing vent above one of the ovens.

One of the Russians called for the priest, but an M. F. & M. man thought he said "police" and phoned for the "force." Xeno was persuaded to go into camp temporarily in the car shops and was taken later in a pung to the hospital. Strange to relate, he was little the worse of his adventure.

A Nova Scotia Mine Tragedy.—An explosion January 3 set fire to Sydney No. 3 mine of the Nova Scotia Steel and Coal Co., at Florence, N. S., and eight men were entombed. The explosion occurred about 4 o'clock in the morning, when Under Deputies Ferguson and Purchass went into the mine accompanied by six workmen, making preparations for starting the mine. For 8 hours Manager John Johnstone, assisted by Inspector Nicholson and others fought the fire, and at last found the charred bodies of six shift men who were clumped together and so burned that it was impossible to recognize one from the other. Then failing to reach the bodies of Deputies Ferguson and Purchass, owing to the deadly gases, they were compelled to retreat to a place of safety.

PROPOSED COLORADO COAL MINE LAW

ON ANOTHER page we have criticized severely the vicious and ridiculous proposed Colorado coal mine law.

The first rational mine law enacted in the United States was framed by Mr. T. J. Foster, then editor of this journal, which was at that time known as The Mining Herald. Incomplete as that first law was, it was a step in the right direction and its enactment in the state of Pennsylvania was largely due to the then editor of this journal. From that time on, every coal mine law enacted in the United States has to a greater or less extent been influenced in its character by the criticisms and suggestions made by the practical men connected with the editorial management of Mines and Minerals. In no instance has it opposed any law which would tend to increase the safety and conserve the health of coal miners, but, on the contrary, has strongly advocated the passage of such laws. Naturally, from time to time in Pennsylvania and in other coal-mining states, proposed acts or amendments have been introduced in the legislatures that in some instances were merely attempts to make trouble, or were the mistaken ideas of men who were honest in their desire to remedy certain conditions, but whose proposed remedies would have made those conditions worse rather than better. Such acts Mines and Minerals has always opposed, and in most instances has succeeded in defeating them.

The proposed law now before the legislature of Colorado is one that we do not believe can be tinkered into rational shape, and it should be thrown out bodily; otherwise the state of Colorado will be worse off than if it had no law. We do not believe that any half dozen intelligent, conscientious miners in that state would, on its merits, favor the passage of such a bill as the one in question, and we know that no mine manager or mine owner will commend it.

If the proposed law is really the work of the commission appointed by Governor Shafroth, we are greatly disappointed in our previous estimates of the practical mining knowledge possessed by its members.

COLLIERY WARNINGS

APROPOS of the increasing interest displayed in explosions of coal dust and the causes leading up to them and the suggestion sometimes heard that the government be requested to send out warnings of changes in temperature and relative humidity, that the mines might be more thoroughly watered before an approaching dry spell, an editorial in a recent issue of *The Mining Journal*, of London, England, is of interest. Commenting upon the Hulton colliery disaster it says: "The Royal Commission on Coal Mines points out that there is no longer any controversy that coal dust is the agency to which alone great explosions are due, and that the only question at issue now is what means are to be taken to prevent them." Putting this more broadly

the Commission might have said: "Regardless of the initial cause, whether a blown-out shot, or mine fire or explosion of firedamp, there has been no accident within the past 30 years, and presumably not in history, involving an explosion and the loss of as many as ten lives which should not be attributed to the agency of coal dust and to that agency alone."

In England, of the initial causes leading up to an explosion of coal dust perhaps the most usual is the firing of a pocket or feeder of marsh gas, with blown-out shots second, and mine fires or "crossed" electric wires third, while in the United States the order of the first two causes would probably be reversed. It has long been known that changes in atmospheric pressure, as measured by the rise and fall of the barometer, have some effect upon the entrance of gas into the workings of a mine, but it has seemed to us that the importance of these barometric changes have been much exaggerated. The barometer has been the "bogey man" of the mining engineer for many years, and it has always been believed, in the United States at least, that the so-called "colliery warnings" sent out in England were official and had the sanction of the government. But it seems that we were mistaken and we are glad to rectify the error.

Continuing, the same editorial says: "There is one other small matter which invites a word of observation at the moment. *The Times* (London), of Friday's date says: 'A disaster has followed immediately upon a colliery warning which appeared on Monday in newspapers circulating in the various mining districts; it is now 30 years since the warnings were started, and the interval has witnessed an enormous diminution both in the frequency of explosions and in the loss of life caused by them.' For ourselves, we have never been able to understand the meaning of the so-called 'colliery warning,' and we would venture to direct our contemporary's attention to the following passage in the report of the Royal Commission on Coal Mines: 'Our attention has been drawn to the issue in the newspapers from time to time of the so-called colliery warnings. These warnings are based upon observations of barometric changes, and are supposed to indicate the need for special precautions being taken against firedamp in collieries. In some cases these colliery warnings have been quoted in connection with the occurrence of fatal explosions. We were informed that these warnings are not issued with the authority of the Meteorological Office, and that they have no official sanction. *They are misleading, and, so far as we can see, their publication serves no useful purpose.*' (The italics are our own.) Perhaps, if our contemporary is in possession of information denied to the Mining Commission, we shall at length be able to discover the reason for a faith in these mysterious warnings which to us, at any rate, have always seemed in the nature of a shibboleth."

The Royal Commission on Coal Mines states the case with true British conservatism when it says of these warnings: "Their publication serves no useful purpose." In Great Britain, where the miners are almost entirely natives, they may do no particular harm, but in the United States where perhaps as many as 90 per cent. of the mine workers are of non-English speaking birth, such warnings might be a source of actual danger. Few men, and particularly those of the class composing our foreign mining population, are cool in the face of impending danger and are then very apt, through sheer nervousness, to be guilty of acts imperiling their safety, which would be improbable, if not impossible, under ordinary mental conditions. An illustration of the effect of the ill-advised statements of public officials has recently occurred in one of our western states. There, the officer in question while in no way connected with the mining department and obviously ignorant of the first principles of the profession, appeared in print as saying that three mines which he specifically named, were due "to blow up." When this item of alleged news was distributed around the mines, it caused an exodus of men from the workings, and they remained out until the State Mine Inspector reported that the mines in question were absolutely safe. If a minor state official with no particular standing, and in no way connected with a mining department, can cause so much harm by erroneous statements, how much more would be induced by "warnings" issued officially by the national government and coming with authority? If these warnings were sent privately to the officials of the mine who are responsible for the safety of the workings they would, at least, do no harm, but falling into indiscriminate and too often ignorant hands, they would more frequently be a source of serious menace.

A NEW BOOK CATALOG

FOR the convenience of our readers who may want the most up to date and reliable books on Mining, Mineralogy, Metallurgy, Prospecting, and Assaying; and on Mechanics, Electricity, Chemistry, etc. as related to mining and metallurgy, we have prepared for the Technical Supply Co., ,of Scranton, Pa., a comprehensive and convenient catalog of *"books worth while,"* which will be sent free on request to any reader on application to either Mines and Minerals or the Technical Supply Co.

The prices quoted in the catalog are strictly publisher's prices and any books ordered from the Technical Supply Co., will be sent postpaid. Orders received by Mines and Minerals will be promptly filled by the Technical Supply Co.

BOOK REVIEW

Electric Circuit Problems is the title of a book by Ellis H. Crapper, B. Eng., M. I. E. E., and head of the Electrical Engineering Department at the University of Sheffield, England. The book deals with the applications of electricity to mining

operations, which are now so extensive and varied as to form an important part of their equipment.

When an electrical system has been properly installed at a mining operation and qualified electricians are placed in charge the dangers attending the use of electricity in mines may be reduced to a minimum, provided that adequate and systematic inspection is forced.

The contents are: Units of Measurements; Insulation; Circuit Testing; Cables; Alternating and Polyphase Currents; and Polyphase Current Circuits, which with the index cover 159 pages. There are 57 illustrations, and the text is replete with formulas and examples. The book is printed by the Colliery Guardian Co., London, England. Price 3s. 6d.

The Mineralogy of Arizona, by F. R. Guild, Professor of Chemistry and Mineralogy, University of Arizona. According to the author, in certain respects many of the minerals in Arizona are sufficiently unusual in their mode of occurrence and in their composition to warrant special attention. The order of treatment, according to minerals in this book, is the same as under Dana's classification. The elements found as minerals are considered first, then the sulphides and others as outlined. There are seven chapters devoted entirely to minerals. The publishers are the Chemical Publishing Co., Easton, Pa. The price of the book is $1.

Heaton's Annual for 1911. This is the Seventh Annual Commercial Handbook of Canada and Boards of Trade Register. It is published by Heaton's Agency, Toronto, Canada, and contains much valuable information concerning Canada, its banks, resources, mining and general information. The price is $1.10, postage paid.

Mechanical World's Pocket Diary for the Year 1911. This is the twenty-fourth year of this publication. It contains a great deal of useful information for mechanics and mechanical engineers. It is printed by the *Mechanical World*, London, England. The price is 6d. net.

The Mechanical World's Electrical Pocketbook for 1911 is printed by the *Mechanical World*, 20 Bedford St., London, W. C. Price 6d. net.

A Manual for Assayers and Chemists, by W. H. Seamon, B. S. A., chemist and metallurgist. This book is the result of the experience of 14 years as a teacher of chemistry and assaying, and 15 years of practical work in the mining districts of the southwest. On reading over the work one is particularly impressed with the system followed, in that when a subject is taken up the various methods by which it may be assayed are given. For instance, mercury. First the ores are mentioned, then the method of the detection of mercury; the method of determining mercury, the method of decomposition, the titration of mercury, the gravimetric method, and, finally, the valuation. There are four parts to the book. The first part treats of metals; the second of non-metallic elements, chlorine, phosphorus, selenium and tellurium, silica, and sulphur; the third part is miscellaneous, and the fourth part contains tables which are much used by assayers and metallurgists. The book is 12mo, contains 255 pages, and the price is $2.50. It is published by John Wiley & Sons, New York, N. Y.

Elementary Crystallography, by W. S. Bayley, Ph. D., Associate Professor of Mineralogy and Economic Geology, University of Illinois, Urbana. The book does not pretend to be a treatise on crystallography. It is a guide for those attempting to gain an insight into the fundamental principles underlying the science. It is the direct result of the need felt by the author in his own classes for a simple discussion of crystals and a series of simple statements of crystallographic conceptions. It is divided into three parts, Geometrical Crystallography, Physical Crystallography, and Chemical Crystallography. Pentagonal hemihedrism of the positive and negative dyakisdodecahedral class are both illustrated and given the positive and negative symbols of the diploids. Right orthorhombic bishpenoids and left orthorhombic bisphenoids are illustrated under the hemihedral division. From any pyramid it will be remembered two of these forms are produced. They are enantiomorphous, and are therefore known as right and left forms. The book contains 241 pages, and is published by the McGraw-Hill Book Co, New York.

Pocketbook of Mechanical Engineering, by Charles M. Sames, B. Sc. This is the fourth edition of this pocketbook, which has been revised and enlarged. It has a flexible cover 4 in.$\times$6⅝ in. and contains 220 pages. The price is $2, and is for sale by C. M. Sames, 542 Bramhall Ave., Jersey City, N. J. The contents are mathematics, chemical data, materials, strength of materials and machine parts, energy and transmission of power, heat, and steam engines, hydraulics and hydraulic machinery, and electrotechnics. The *Engineering News, Scientific American, Engineering Record and Machinery*, make favorable comments on this work of Mr. Sames.

Corrosion and Preservation of Iron and Steel, by Allerton S. Cushman and Henry A. Gardner. The authors are well known as investigators of physical and chemical phenomena, Mr. Cushman having been Assistant Director of Chemists in charge of chemical and physical investigations in the United States Department of Agriculture, and Mr. Gardner, Director of the Scientific Section of the Paint Manufacturers' Association of the United States. The authors have made the effort to include or mention the results of all recent investigations and original researches touching on the corrosion of iron and steel which have appeared up to the time of this book going to press. The book is written mainly to elucidate the electrolytic theory of corrosion and includes an appendix presenting a discussion before the American Institute of Mining Engineers on the "Corrosion of Water Jackets of Copper Blast Furnaces." No two men are better qualified to write a book of this description. It is dedicated to the memory of Charles B. Dudley, who did so much in the line of investigations for the prevention of corrosion and wear of steel. The price of the book is $4; it contains 363 pages and index, and it is published by the McGraw-Hill Book Co., New York.

The School of Mines and Metallurgy, University of Missouri, Rolla, Mo. The bulletin of this school, issued in December, 1910, will be found exceedingly interesting to mineralogists. It contains an article on "Some Relations Between the Composition of a Mineral and Its Physical Properties."

The Cement Age and Concrete Engineering, the latter formerly of Cleveland, Ohio, have been consolidated, and will hereafter be published under the title "*Cement Age*." The magazine will be larger than the present size of *Cement Age* and will have a type page 6 in.$\times$9 in. The headquarters of the publication will be 30 Church St., New York, N. Y. Allen Brett, Editor of *Concrete Engineering* for the past two years, will take the position as associate editor of the new publication, and Arthur E. Warner, formerly business manager of *Concrete Engineering*, will become western manager. There will be no change in the present staff of *Cement Age*, Mr. Lesley continuing as editor, Frederic F. Lincoln as president of the Cement Age Co., in charge of the New York office at 30 Church St., and of the eastern advertising field, and Edward A. Trego, as associate editor.

Metal Statistics for 1911. This makes the fourth edition of Metal Statistics, published by the American Metal Market and Daily Iron and Steel Report, 81 Fulton St., New York, N. Y. This book is made up of statistics. Under the headings "Iron and Steel" there are statistics on ore, pig iron, fuel, finished products, scrap iron, and miscellaneous information relative to iron, coke, etc. Under the heading "Metals," statistics relative to copper, tin, lead, spelter, antimony, aluminum and silver, are given. This includes production at home and abroad and the total production for a number of years previous to 1911; also the consumption of metals in the United States and the exports from this country as well as imports. Under the heading "Miscellaneous" there is a large fund of

information which will be of interest to almost any one who desires statistical information in regard to metals. Messrs. Luty and French, editors of Metal Statistics, believe that the 1911 edition is in many respects the superior to any of the previous issues. The price of this book is 50 cents.

TWENTY-FIVE YEARS OF ENGINE BUILDING is the title of a most interesting and handsome publication issued by the C. & G. Cooper Co., of Mount Vernon, Ohio. It is a well-written and interesting historical sketch of the origin of the Cooper plant in 1833, followed by a description of its growth to its present size and reputation. It is illustrated by remarkably fine engravings, and the typography is of the highest standard. In fact, it was designed and laid out by an artist in typography, and no expense was spared in the mechanical work done in its production.

CLAYS AND CLAY INDUSTRY OF WASHINGTON, a report published by Solon Shedd, Ph. D., Professor of Geology at the Washington State College, Pullman, Wash. The report is neatly bound in cloth, illustrated on good paper, contains 325 pages of descriptive matter, 42 plates, and in all, is a very creditable report. Part 1 covers clay and its properties, dealing with the mode of occurrence, classification, general description, chemical and physical properties, and suggestions in regard to prospecting for clay. Part 2 covers the technology of the clay industry, and deals with the mining and preparation of clay, the preparation of clay wares, drying and burning of clay wares. Part 3 treats of clays and the clay industry of Washington, covering in order, Olympic Peninsula, Coast Mountains, Puget Sound Basin, Cascade Mountains, Okanogan Highlands, Columbia Plain, and the Blue Mountains. In treating the clays of Washington, the author classifies the various clays into (1) residual and (2) transported clays, and then gives data on the tensile strength, shrinkage, and plasticity of clays. This part is followed by a description of the various clay plants of the state. Ten counties of Eastern Washington and an equal number in Western Washington are represented in the list, as being valuable clay producers.

UNITED STATES GEOLOGICAL SURVEY PUBLICATIONS, Washington, D. C., Bulletin 436, The Fauna of the Phosphate Beds of the Park City Formation in Idaho, Wyoming, and Utah, by George H. Girty; Bulletin 442, Mineral Resources of the Southern Part of Kenai Peninsula, by U. S. Grant and D. F. Higgins; Bulletin 470A, Phosphates in Montana, by Hoyt S. Gale; The Production of Quicksilver in 1909, by H. D. McCaskey; The Production of Gold, Silver, Copper, Lead, and Zinc in the Eastern States in 1909, by H. D. McCaskey; The Production of Mica in 1909, by Douglas B. Sterrett; Lithium in 1909, by Frank L. Hess; The Production of Petroleum in 1909, by David T. Day; The Production of Antimony, Arsenic, Bismuth, and Selenium in 1909, by Frank L. Hess; The Production of Tungsten, Nickel, Cobalt, Vanadium, Titanium, Molybdenum, Uranium, Tantalum, and Tin in 1909, by Frank L. Hess.

BUREAU OF MINES, Washington, D. C., Bulletin No. 5, Washing and Coking Tests of Coal at the Fuel Testing Plant, Denver, Colo., by A. W. Belden, G. R. Delamater, J. W. Groves, and K. M. Way; Bulletin 2, North Dakota Lignite as a Fuel for Power-Plant Boilers, by D. T. Randal and Henry Kriesinger; Bulletin 3, The Coke Industry of the United States as Related to the Foundry, by Richard Moldenke.

DEPARTMENT OF COMMERCE AND LABOR, Washington, D. C., Bulletin of the Bureau of Labor, No. 90. This bulletin is of special interest at the present time. It contains fatal accidents in coal mining, recent action concerning accident compensation, foreign workmen's compensation acts and cost of industrial insurance. It may be had by addressing the Department of Commerce and Labor, Washington, D. C.

MICHIGAN GEOLOGICAL SURVEY, Publication No. 2, Geological Series No. 1, The Monroe Formation of Southern Michigan and Adjoining Regions, by A. W. Grabau and W. H. Sherzer. This is published as a part of the annual report of the Board of Geological and Biological Survey for 1909. Geologists in charge, Dr. L. L. Hubbard, Houghton, Mich., and Prof. W. H. Hobbs, Ann Arbor, Mich.

DEPARTMENT OF GEOLOGY AND NATURAL RESOURCES OF INDIANA, Thirty-Fourth Annual Report for 1909, W. S. Blatchley, State Geologist, Indianapolis, Ind.

NINETEENTH ANNUAL REPORT OF THE MINING DEPARTMENT OF TENNESSEE, Mineral Resources of Tennessee, by R. A. Shiflett, Chief Mine Inspector, Nashville, Tenn. This book can be had by addressing the Mining Department of Tennessee.

NEW ZEALAND GEOLOGICAL SURVEY, Bulletin No. 10 (New Series), The Geology of the Thames Subdivision, Hauraki Auckland, by Colin Fraser. Address J. M. Bell, Director of Department of Mines, Wellington, N. Z.

THE FARMERS' HANDBOOK OF EXPLOSIVES, by the E. I. du Pont de Nemours Powder Co., Wilmington, Del.

HOW TO OPERATE A PNEUMELECTRIC COAL PUNCHER, Pneumelectric Machine Co., Syracuse, N. Y. This information is printed in English, Slovak, Italian, Polish, and Magyar.

UNIVERSITY OF ILLINOIS BULLETIN No. 43, Freight Train Resistance, and Its Relation to Car Weight, by Edward C. Schmidt, Urbana, Ill.

CANADA DEPARTMENT OF MINES, Mines Branch, Ottawa, Canada, The Production of Cement, Lime, Clay Products, Stone, and Other Structural Materials in Canada for 1909, by John McLeish, B. A.

REPORT OF THE COMMITTEE OF THE TRANSVAAL STOPE DRILL COMPETITION, price 7s. 6d. Printed by the Transvaal Government, Transvaal, S. Africa.

THE WISCONSIN ENGINEER, which is a monthly publication of the students of the College of Engineering, University of Wisconsin, has an exceedingly fine issue for January. The contents embrace "The Strength of Oxyacetylene Welds," a thesis by Herbert L. Whitmore, B. S. '02; an article entitled "A Travel on Hudson Bay," by C. K. Leith, Professor of Geology, who is well known through his geological writings; also an article on "The Utility of the Metallographical Microscope in Engineering," by James Ashton, and still another under the caption "Telephone Service in Chicago" by Alfred U. Hoefer. There is an editorial on "The Honesty of Mining Engineers" which is well worth reading. At some future time we hope to comment along this same line.

ANTHRACITE AND BITUMINOUS OUTPUT

The first records of bituminous coal production in Pennsylvania are for the year 1840, when 464,826 short tons were mined. The total output of bituminous coal from 1840 to the close of 1909 has amounted to 2,101,215,571 short tons, from which it appears that the total production of anthracite and of bituminous coal in Pennsylvania has been nearly equally divided between the two. At the close of 1908 the total production of anthracite from the earliest time to the close of that year had exceeded the total bituminous production by about 51,000,000 tons. As, however, the production of bituminous coal in 1909 exceeded that of anthracite by more than 56,000,000 short tons, the total production of bituminous coal now exceeds that of anthracite. The Geological Survey's report on coal production in 1909 can be obtained without charge by applying to the Director of the Survey at Washington about February 20.

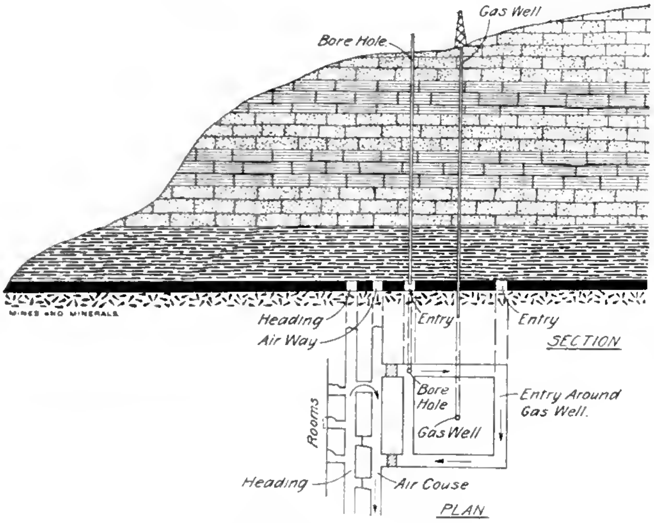
Engineer Antonio Llambias de Olivar, the representative of the boring company subsidized by the government of Uruguay, informs the Minister of Industries, Labor and Public Instruction, that in the middle of August, in the fourth boring which the company is making in the Department of Cerro Largo, a bed of coal was found at a depth of 124 meters, more than a meter thick and of quality superior to that met in the boring of November, 1908, at a depth of 140 meters.

CORRESPONDENCE

Mining Around Gas Wells

Editor Mines and Minerals:

Sir:—I am enclosing you sketch of a plan of working around a gas well which I think would be a help to some of the coal companies. The entry is to be driven around the well, and stoppings put in as shown, with a bore hole from the surface to the entry for gas to go through to the outside, or the return air could be circulated around it and remove all gas. The



Plan of Workings Around Gas Wells

arrows indicate the way the air could be circulated around the wells. I do not think the plan will stop all trouble from the wells, but I do think it will be some benefit from gas coming through the coal in any way. E. P. McOlvin

Meadowbrook, W. Va.

Editor's Note.—The subject of abandoned well holes is one of importance to the coal-mining industries in Ohio, Indiana, Illinois, Pennsylvania, and West Virginia. Mr. George Harrison has forced legislative enactments in Ohio, and other states will undoubtedly, yet the fact remains that the abandoned holes on hand must be dealt with, irrespective of the future. Mines and Minerals invites correspondence in order to bring out ideas which will cope with the undeniable danger and nuisance from these holes.

Steam in the Air-Current

Editor Mines and Minerals:

Sir:—We understand that a number of coal-mining companies in Western Pennsylvania have adopted a plan of turning exhaust steam into the fan house following a sudden drop of temperature. This is said to keep the air-currents moist and prevents the mines from becoming filled with dry dust. It is presumed that the plan adopted minimizes the danger of dust explosions.

A few years ago Mr. Galey patented a process for extracting moisture from air. This he accomplished by first passing the air through a cooling apparatus and afterwards to the hot-blast stoves where it is preheated. I have always understood that low-temperature air might contain as much moisture per cubic foot as a higher temperature air, but as soon as the cool air from outside came in contact with the warmer air inside it expanded and therefore did not contain so much moisture per cubic foot, and consequently absorbed moisture from the mines, in addition to what it would absorb before it became saturated. If the exhaust steam heats the air going into the mines and its moisture is absorbed by that air, would not the air deposit its moisture after it reached the cooler inside air of the mines, and then would not conditions be the same as if the air had not been steam heated?

Recently a patent was taken out in which a number of steam coils were used to prevent the incoming air from losing its moisture. Possibly some of your readers might throw considerable light on this subject, which is of so much importance to bituminous coal miners. X. Y. Z.

James Blick

Written for Mines and Minerals

Mr. James Blick, a Pennsylvania bituminous mine inspector for 20 years, died at Crafton, Pa., on January 4, 1911. Being so well and favorably known to the readers of Mines and Minerals, a few incidents in the life and work of this man may be of interest. Mr. Blick, 65 years ago, was born at Berkeley, Gloucestershire, England. He came to Neshannock, Mercer County, Pa., about the year 1880, and entered the coal mines there as a miner, the occupation which he had followed in England. He became a naturalized citizen at the expiration of 5 years, and was commissioned a bituminous mine inspector immediately thereafter. I became acquainted with Mr. Blick in 1880 at a mass meeting of miners held at Neshannock, and after hearing him discuss the issues then being considered, concluded that he was a miner of more than ordinary ability. Our acquaintance ripened into a lasting friendship. Recognizing Mr. Blick's ability I urged him to prepare for the mine inspectorship, and he was appointed from Mercer County to the Seventh, or Pittsburg District, which he held until obliged to give up the work owing to failing health. Mr. Blick was one of the most capable mine inspectors the state of Pennsylvania ever had in its service. No single individual did more for the bituminous miner in securing and attempting to secure efficient mining legislation.

Mr. Blick had grown into manhood before he had acquired the rudiments of education. He attended a technical night school 2 years before he came to this country. When he, however, began to realize the great handicap under which he was living and began to view life and its great responsibilities, he set his mental machinery to work to recover lost ground, and with that will power so manifest in that resolution and persistency so characteristic of the man, he mastered the fundamental principles of the sciences as they relate to mining.

Mr. Blick was thoroughly familiar with the mining literature of the present and past, and this, combined with his large and varied experience and practical knowledge made him a mining authority whose advice was much sought and accepted. He had written much on mining and humanitarian topics. His essays were written in a lucid style, never obscuring his subject by the embellishment of pretentious phrases. His aim was to furnish ideas, state facts, and establish truth in a clear and simple manner. His writings conveyed to the reader a clear idea of the man. He was a keen observer and aimed at great accuracy in all of his statements. Blick, a splendid type of the Anglo-Saxon race, stood for courage, self-control, honest and temperate habits. While he was unemotional, he was not lacking in tenderness of heart that made him feel for the unfortunates of life, and he made much personal sacrifice in their behalf. In the death of this sturdy miner, the state has lost a valuable citizen, the people of these mining communities have sustained an almost irreparable loss, and the mine inspectors with whom he was so long associated a wise counselor and a friend. Thomas K. Adams

The volume of air delivered by a mine fan varies directly as the number of revolutions. That is, a fan running 80 revolutions per minute delivers 100,000 cubic feet. How much air will this fan deliver at 160? Solving the proportion: $80 : 160 :: 100{,}000 : x$, we have $x = 200{,}000$ cubic feet.—*Jeffrey Catalog.*

THE PROPOSED COLORADO MINE LAW

By the Editorial Staff of Mines and Minerals

In our February issue we noticed in a general way, and mildly criticized, the preliminary report of the Commissioners appointed by the Governor of Colorado to suggest laws for the governance of coal mines in that state.

A Bill Introduced in the Legislature of Colorado, Which Is Unique in Its Impracticability

A bill has been introduced in the House of Representatives of Colorado, which we assume is the new law proposed by the Commission. If we are mistaken in this assumption, we most humbly apologize to the members of the Commission, and we sincerely hope, for the sake of the Commission, it is not guilty of the paternity of such a monstrosity.

Naturally, the proposed law is not all bad, but so much of it is vicious and ridiculous, and the bad so thoroughly mixed up with the good, that we hope for the sake of both the coal miners of Colorado and the mine owners of that state, that the legislature will throw out the entire proposed law and insist that a rational and practical mine law be prepared by a properly appointed Commission of men familiar enough with actual mining operations as to make it of real value.

We have not space to print the proposed law in full and will, therefore, pass over those portions which are not either vicious or impracticable without comment, and give our attention to those which are.

Section 2 of the proposed law provides for a Chief Inspector, seven Deputy Inspectors, and one Electrical Inspector. There may be some opposition to the increase of Deputy Inspectors from four to seven, but we are compelled to say that we do not agree with that opposition. If mine inspectors are to *inspect* mines, there must be a sufficient number of such officials to do it. Usually there are too few inspectors to enable more than perfunctory inspections to be made. But why an Electrical Inspector? If the men appointed to deputy inspectorships are not technically and practically capable of passing judgment on the safe use of electrical machinery and the safeguarding of electrical conductors, they are not fit for the positions.

The following extract from Section 2, providing for the appointment of a Chief Inspector, Deputy Inspector, or Electrical Inspector, will strike every reasonable man as either vicious or ridiculous.

"Whenever there exists a vacancy in the office of Chief or Deputy Inspectors or Electrical Inspector, the remaining Inspectors, excluding the Electrical Inspector, shall submit, from each of the four inspectoral districts hereinafter provided for, to the Governor, the names of two reputable coal miners of known ability and experience. From the names so submitted, the Governor shall appoint one miner from each of the four districts, and the Governor shall appoint a mining engineer of like ability and experience, and these five men, so appointed, shall constitute a Board of Examiners, whose duty it shall be to inquire into the character and qualifications of the candidates for the offices left vacant. The representatives from the inspectoral districts on successive Boards of Examiners, shall be appointed in numerical order so that all the seven districts shall share equally in the appointments of said Boards.* * *

"The Board of Examiners shall then proceed to the examination of those who may present themselves as candidates for said office or offices, and shall certify to the Governor the names of all such applicants as any four of the examiners shall find competent to fill the office under the provisions of this Act,* * *

"The Governor shall from the names certified appoint the person or persons possessing the best qualifications of the vacant office or offices of Inspector of Coal Mines."

It is hardly necessary to point out the viciousness of this section of the proposed law. It gives the mine owner no justice whatever, neither is it in the real interest of the miner It does not tend to the selection of Mine Inspectors. It tends to the appointment of political heelers, or irresponsible demagogues to positions in which they can do incalculable damage to capital invested in coal mines, and render the safety of the working miners less secure than at present.

It is ridiculous in that the Examining Boards practically appoint the Inspectors, and the Inspectors appoint the Examining Boards.

That State Mine Inspectors should be able and honorable men, fair in their dealings to both workingmen and employers, and working faithfully to carry out the provisions of all laws tending to safeguard both life and property is what the Commission evidently intended to provide for. But they will not insure the appointment of such men by the method proposed.

The ideal examining board for such purposes should consist of one qualified mining engineer of high character, one mine owner, mine manager or mine superintendent and two intelligent experienced coal miners. They should be appointed by the Governor, and in cases where both the workingmen and employers are organized, the suggestions of the mine owners as to the appointment of their representative on the board, and similar suggestions as to the appointment of the two miners, from the miners' organization, should be heeded. With such a board, the recommendation of any three of the members should suffice.

The portion of the proposed law which states that "It shall be unlawful for the Chief Inspector of Coal Mines, or any Deputy Inspector to be interested as owner, operator, engineer, stockholder, manager, director, or otherwise in any coal mine," is unjust to the inspectors. It is just and right that he shall not be interested in any way in any mine in Colorado, but why should he be prevented from investing his savings in the stock of a coal-mining company in another state, provided he does not neglect his duty as an inspector to look after his invested interests?

The proposed law also provides that the Governor *may on consultation with, and by the advice of the Chief Inspector* remove a Deputy from office. As the Chief Inspector and Deputies, under this act, will be practically appointed by the Board of Examiners, and the Inspectors will practically appoint the Boards of Examiners, there will naturally be a "community of interests" and it is hard to see what power the Governor will have in the premises. About the only thing that will tend to the removal of a Deputy will be the fact that he has made himself distasteful to his associates.

The Chief Inspector's tenure of office is 4 years, but there is no provision for his dismissal if cause for such action should arise. The Governor may be impeached, but not the Chief Mine Inspector.

Section 2 also provides that after a Deputy has inspected each mine "there shall be posted in a conspicuous place near the entrance of the mine his report of the conditions of the mine, and he shall send a copy to the Chief Inspector."

Why in the name of common sense should a copy of the report be posted at the mine entrance? That will not remedy unsafe conditions if such exist. Why not require the Deputy to notify the mine management of the nature of his findings, and if unsafe conditions exist require the management to remedy them at once? A report of his findings should naturally be sent the Chief Inspector, and also a report of his action with the mine management and results obtained thereby.

Section 4 of the proposed law, defining the Police Power of Inspectors is both incomplete and vicious. It empowers the Chief Inspector, any Deputy, any Company Inspector, and any Constable or Sheriff to arrest any person or persons who, *he has reason to believe*, is guilty of any violation of the Act. It is not necessary for any complaint to be made or warrant issued. A citizen of Colorado it matters not if he be miner, laborer, mine official, or mine owner is to be subject to arrest without warrant.

While we believe competent and qualified State Mine

Inspectors should be empowered to make arrests for violations of rational mine laws which come under their own observation, or regarding which proper sworn complaints are made; we do not believe that such power should be conferred on company officials and irresponsible constables.

Section 7, which provides for "Notice of Accidents in Mine," requires that whenever loss of life or "serious injury" shall occur, the owner of the mine must notify both the Deputy and the Chief Inspector within 24 hours. In the first place "serious injury" is not defined. What some men call serious injury others call trivial. In the second place, why should the mine owner notify *both* the Deputy and the Chief Inspector. Official notice to the Chief Inspector should go through and from his subordinate, the Deputy.

Section 8, entitled "Checking In and Out System," has considerable in it to commend it. By its use the number of men in the mine at any time would be definitely known, and by a little amplification it could be so improved that not only the number of men in the mine, but their identity would be known. The defect in this section is that it provides punishment for the mine owner who violates its provisions, but provides no penalty for the miner who may violate it by surreptitiously entering the mine through some short cut or opening other than that used regularly by the workmen.

Section 9, which provides for Company Inspectors, is one of the ridiculous features of the proposed law. It takes from the mine foreman and his assistants the responsibility which should rest on their shoulders. While company inspectors, such as some of the larger coal companies voluntarily employ, are commendable, they do not usurp the functions of the foremen. They visit and inspect the mines and report to the management, and the latter through the superintendents and foremen sees that abuses or unsafe conditions are corrected. One of the greatest elements of danger in American coal mines is, and always has been, lack of discipline, and the framers of this proposed law actually provide for still less discipline by providing officials to interfere with the one official who should have supreme authority.

Section 12, entitled "Explosives," is one that merits severe criticism. It prohibits the use of black powder under any circumstances and allows the use of "permissible" explosives only.

In the first place, black powder is better and safer for use in non-gaseous and non-dusty mines than any other explosive. It does not shatter the coal as much, and when used in shot holes near the roof is not so liable to break the top rock as is the quicker and more powerful "permissible" explosive. Experience has shown that the so-called "permissible explosives," while unquestionably the safest in gaseous and dusty mines, have a tendency to crack the roof, make it less safe, and to allow, under certain conditions, the ingress of large quantities of water. Again, the section provides that only enough powder for one day's work shall be taken into a mine at one time. Can any one tell how much this is? The skilled Welsh miner, for instance, will mine more coal in a day with half the consumption of powder than the unskilled Slav or Italian will in two days. The same skilled Welshman may, and frequently does, use twice as much powder some days as he does on others.

This section also requires the employment of shot firers in *all* mines regardless of whether they are gaseous or dusty or not, *except in mines where the longwall system of mining is used.* The fool killer has work to do when he meets the man who framed this section. We heartily commend the proper safeguarding of shot firing in gaseous or dusty mines, but we fail to see why special shot firers are necessary in non-gaseous and non-dusty mines. We also fail to see why shot firers are not necessary in longwall work if there is gas or dust present.

Section 13, entitled "Underground Workings," is very long and seems to indicate that the Commission was actuated by a desire to incorporate in the bill every conceivable idea, no matter whether it is applicable or injurious to Colorado's mines. While the items include practically all the good features of all laws of other states, they also contain all the weak, bad, and vicious features. This section should be rewritten entirely, a great deal omitted, and then arranged in some order that it may be intelligible. We note that "the maximum distance between props in room or pillar work shall be 7 feet." Here is an instance of the incorporation of a provision applicable only in special cases. There are hundreds of rooms in the mines of Colorado that do not require a single stick of timber, and there are others where the props should be almost "skin to skin." The use or non-use of timber and the distance apart of props is a distinct proposition for each and every mine in the state, and for each section of each mine as well. The provision that "every owner shall provide and maintain a water system for the purpose of conducting water to the face of each working place and throughout the entire open part of the mine in sufficient quantity to wet down the dust, and the said owner shall cause the dust to be wetted down on the *roof*, walls, timbers, and in the roadways," is superfluous and vicious, although it is provided that steam may be used and an appeal may be taken to the inspector for relief from the extreme provisions of this act. There are many mines in the state that require no watering, and water may be applied in other ways without being piped in. Likewise, the promiscuous watering of the roof is to be severely condemned. The increased fatalities due to falls from roof weakened through watering will far more than offset the possibly decreased death rate through lessened dust explosions. As in all cases the question as to whether the roof shall be watered or not must be decided for the particular mine.

"All drift and slope openings shall be lined with incombustible material for a distance of 150 feet from the mouth of the opening," should be changed to read "no outside frame building shall be constructed within 50 feet of, or be in any way connected with the timbering of any drift or slope." Mine fires do not start in the timber at the drift or slope mouth.

Section 14, relating to ventilation, is sound and should be adopted as it stands, although there are sundry items that might well be added.

Section 15 provides for the exclusive use of electric or safety lamps in Colorado mines. This is a mischievous proviso which will tend to increase accidents and lessen the earning power of contract miners. Electric mine lamps are on the market and are adapted to certain uses in the mines, but there has not yet been one produced that is entirely suitable for the working miner.

Under certain circumstances, safety lamps should be required, but when required, the type of lamp should be specified. This is not done in the proposed law. The primitive Davy lamp for instance is a "safety lamp" but it is far from being a safe working lamp and should not be allowed in any mine except when used by a competent fire boss for testing purposes only. There are a number of other types no more safe than the Davy, without its merit as a testing lamp.

Experience has shown that the best types of safety lamps yield so little light and are so constructed that a careful inspection of the roof cannot be made; consequently an increased number of accidents due to falls of roof is due to their use. Besides, no miner can accomplish as much work in the almost total darkness incident to the use of safety lamps as when he has the better light of an ordinary miner's lamp. As a matter of fact, safety lamps, like permissible powders, should only be required where absolutely necessary. Cases of absolute necessity are comparatively few where proper ventilation is provided. Even in very gaseous mines, safety lamps are not required in all portions, as the headings at least, when they are intakes, except possibly at the working face, can be kept free from gas.

Section 16, relating to abandoned workings, gob fires, safety devices, shafts, rescue apparatus and the like, contains too much under one heading. As in all sections, all the good and bad practice is included in it. It is impossible to remove *all*

fine coal or slack. The provision for double drawbars on cars where the grade is over 6 per cent. is entirely unnecessary. What is to be gained by the requirement of printing the "code" on a "board or metal plate"; why not on paper or cardboard and renewed frequently? We do not see the idea in providing that all shafts be lined with concrete or other incombustible material. If this means that no timber at all is to be used in shaft construction, what is to be done for guides and their supports? At "each mine the owner shall have trained for rescue work not less than three crews of four men each." This is a most peculiar provision. Suppose that the men refuse to be trained, where will the owner get the rescue crews? And who is going to do the training as the law has made no provision for this?

Section 17, providing for second openings, would be all right if properly constructed. If there are any mines in Colorado not provided with a second opening, the law should require such an opening, but a reasonable time in which to provide it should be allowed. This reasonable time is not provided for in the Act.

Again in Section 17 it is required in one place that every escapement shaft over 75 feet in depth shall be equipped with a "safe, adequate, and independent hoisting plant." Later on in the same Section, the proposed Act provides that "every escapement shaft over 75 feet deep and *not* equipped with a hoisting plant shall be provided with a safe and substantial stairway, etc."

This is just one instance of the carelessness with which the proposed law is drawn. There are many of them throughout the copy at hand. In this instance the proposed law requires a hoisting plant at every escapement shaft over 75 feet deep, and in the next paragraph it is implied that a hoisting plant is not necessary at escapement shafts over 75 feet deep.

Section 18 treats of mine maps and is very long. So much is required to be placed on a mine map, that it is doubtful whether anything could be clearly and distinctly shown on such a map. Again the Act requires that all maps shall be made on a scale "Not to exceed 100 feet to the inch"; this should read all maps shall be made on a scale of not more than 100 feet to the inch. This would make clear what the Commission evidently meant.

This Section also requires that copies of all maps and plans shall be kept in the office at the mine, that one copy shall be deposited in the office of the Chief Mine Inspector, in the Capitol at Denver, and that one copy shall be deposited with the Recorder of the county in which the coal mine is located. Why in the name of common sense should the Recorder of the county have a copy of the mine map and not the Deputy Inspector? There is no sense in the County Recorder having on file open to the public, including farmers, shyster lawyers, and busybodies generally, what is purely the business of the mine owner and his employes. Why a copy of the map should be filed with the Chief Inspector is another point we cannot understand; if the Deputy Inspector has his map that should be all that is necessary, and is all that is required in other states.

The proviso requiring maps mentions about everything possible to be shown on the map, including underground oil houses. This implies that the Commission framing the law did not have enough practical experience to know that the storage of oil of any character in a mine is radically wrong from the point of safety to the workingman.

It also provides that "whenever an owner is about to open a new mine, or materially extend the workings or rearrange the plan of operation or ventilation of a mine already opened, he must make a detailed surface map and a detailed plan of the proposed operation and submit it to the Chief Inspector of Coal Mines for his approval, before proceeding with such work." This is the veriest rot. No mining engineer or mine official ever laid out plans for the opening of a new coal mine or the extension of the workings of an old one, that he would be willing to stake his reputation on as being what would actually be done. Local conditions met with in a mine often materially change plans. The Commission evidently imagined that it is as easy for the mine manager or mining engineer to determine the exact plan of future workings of a coal mine as it is for them to lay out a flower garden in regular beds. Some of the provisions regarding maps, especially that one requiring maps of mines about to be closed or abandoned, are excellent.

Section 19, entitled "Fencing Piles of Slack Coal and Abandoned Pits or Shafts," was evidently framed as a sop to farmers and herdsmen. It is all right enough to require that shafts should be fenced or otherwise protected so as to prevent human beings from falling into them, but why a proviso to protect horses, cattle, and other live stock, roaming at large, should be incorporated in a mine law is beyond our comprehension.

Section 20, providing for a method of appointing an Electrical Inspector, would be commendable if an Electrical Inspector was at all necessary. It provides a method whereby an honest, capable man, free from political or other affiliation might be selected. But, as we stated before, such an official is unnecessary. In this Section there are incorporated 67 rules governing the use of electricity under ground. Whoever framed these rules knew infinitely more about the practical use of electricity in mines than the members of the Commission did about practical mining, and as a whole the rules are excellent.

Section 22, among other things, prohibits smoking in all mines. This is perfectly absurd and will work a most undeserved hardship on the majority of the miners. Why a miner working in a non-gaseous mine should be prohibited from the comfort of a pipe of tobacco after his noon-day lunch is more than we can conceive. Possibly the Commission called in Mrs. Carrie Nation to help on this Section. Smoking should not be permitted where safety lamps are necessary but there is no reason why it should not be allowed when there is absolutely no danger attending it.

Section 23 provides that "For any injury to person or property occasioned by any violations of this Act, or wilful failure to comply with its provisions by any owner of any coal mine, a right of action against the party at fault shall accrue to the party injured," but there is no provision for any right of action against the workingman who wilfully violates the provisions of the Act, and not only endangers his own life but the lives of his fellow workmen, and the safety of his employers' property.

Section 24, providing for "Scales, Inspection of Scales, Weighing of Coal, and Check Weighmen," is in line with similar legislation in other states at the instance of the miners' unions. This is a question to which two sides of an argument can be applied. We believe the matter should really be left as a matter of contract between the operator and the men. We do know of instances in some mining regions where advantage was taken of the miners by unscrupulous men engaged in the coal business. Of course, such contemptible actions were comparatively few and we never knew of a large corporation wilfully doing such things; but the writer does know as a fact and saw specially constructed screen bars, made for certain individual operators, which could be regulated surreptitiously by the use of an "S" wrench and the quantity of slack produced increased at the will of the operator, while, when the Inspector came around the openings between the bars could be speedily made of legal size. It was such occurrences as this that brought about the necessity of scales and check weighmen, and it is unfortunate that the action of a few should bring on the many the necessity of such provisions in the law.

Section 25, reading "Oils Permissible in Coal Mines," does not agree with the Section on Mine Maps, in that it limits the amount of lubricating oil which may be taken into the mine at one time as one barrel, while the Section referring to Mine Maps provides for the showing on the maps the location of inside oil houses. Does the Commission mean that only one barrel of

lubricating oil may be kept in the mine at one time and that it makes no difference if 50 barrels of lamp oil are there at the same instant, or what does it mean?

Section 26 provides for a "Coal Mine Inspection Fund" out of which all salaries, etc., to the Mine Inspectors are to be paid by imposing a tax of 1 cent per ton on the coal mined in the state. Colorado produced 12,000,000 tons of coal in 1910; 1 cent a ton tax levied on that number of tons would amount to $120,000.

Bandaged Patient in Underground Hospital

According to the salaries required to pay the proposed Inspectors, with reasonable traveling expenses and with a fund of $15,000 to cover incidentals, the Department would probably need $50,000 yearly. What is to become of the other $70,000, provided the coal production of Colorado does not exceed 12,000,000 tons? Again, why should coal-mine owners pay such a tax as this? They must necessarily pay taxes on their property the same as other property owners do, but why they should be made to pay a special tax and not the railroads, the ore mines, or any other industry, we do not understand. This is wholely repugnant to American principles, and inasmuch as in the framing of the bill the operators are given no representation in the selection of Mine Inspectors, or any other consideration, it certainly is a strong case of taxation without representation.

In framing the proposed law, the Commission failed entirely in providing for the most important requirement, if the safety of the miners and the mine is desired. That is, competent, technically informed mine foremen. There is no provision whatever for certified mine foremen; and even though the proposed law provides for "company inspectors," it does not require that they should be proven competent for such a job by any examination whatever.

In commenting on this proposed bill, we have merely taken up the worst parts of it. As a whole, it is vicious and impracticable, and if enacted in a law will tend to work an incalculable injury to the coal miners of Colorado, both in the matter of earnings and safety, and it is likewise unjust to the mine owners. It will tend to put a serious handicap on the future development of the coal mining industry of the state.

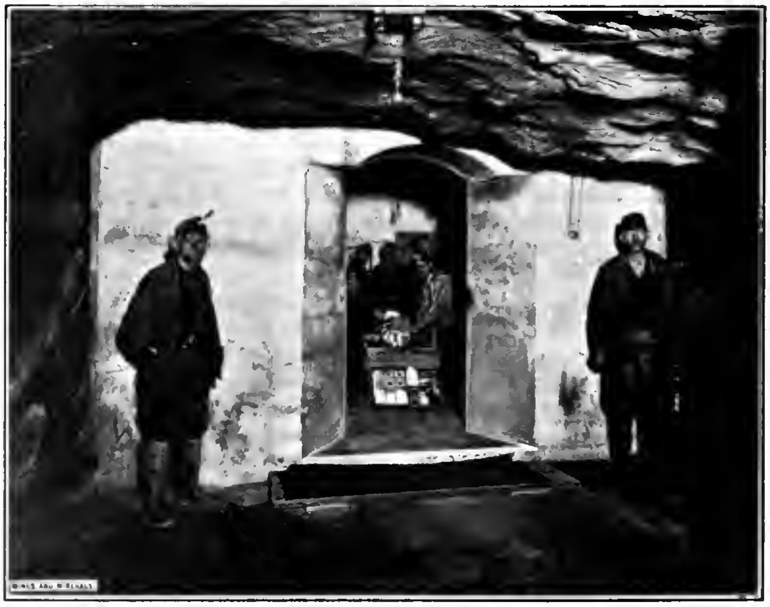
FIRST-AID WORK AT COAL MINES

*Written for Mines and Minerals, by John H. Ketner**

The very general movement on the part of mine owners, mine officials, and workingmen, in many of the coal fields of America, in the direction of "First Aid to the Injured" has been described in more or less detail in past numbers of Mines and Minerals; and the activity in this line on the part of the officials and employes of the Mineral Railroad and Mining Co., the Susquehanna Coal Co., the Lykens Valley Coal Co., the Summit Branch Coal Co., and the Lytle Coal Co. in the Schuylkill and Shamokin regions, has been previously referred to in a general way.

It is the purpose of this article, therefore, to describe in more detail the excellent means for first aid provided by the Mineral Railroad and Mining Co. and the Susquehanna Coal Co., in the Shamokin, Pa., region, and the excellent work of the officials and employes of the mines.

As in the case of the officials and employes of the Philadelphia & Reading Coal and Iron Co. and the officials and employes of the larger companies in the Lackawanna and Wyoming regions, the first-aid corps of the first-named companies held a competitive exhibition and contest on September 3, 1910, at Edgewood Park, Shamokin, Pa. The results of this field day were a revelation to the spectators and showed conclusively the value of the training and lectures given by Dr. J. M. Maurer, First-Aid Surgeon of the Mineral Railroad and Mining Co., and others engaged in the movement. At each mine in the vicinity of Shamokin and Mt. Carmel there is a first-aid corps composed of five intelligent miners and under-bosses, one of whom is appointed captain of the corps. These corps are given monthly drills in practical first-aid work, while the advisory surgeon directs the members in the proper methods of dressing and bandaging injuries. Lectures are also delivered by the surgeon and captain of each corps, the latter being chosen for his superior intelligence and talent for looking after the injured. The captains give their corps more frequent drills and impart to the members the rudiments of first-aid work as it has been



Exterior of Underground Hospital, Mineral R. R. & Mining Co.

*City editor *Shamokin Dispatch.*

given them by the surgeons. The results are that the corps at each mine is as efficient as any well-trained national guard ambulance corps, though detailed methods differ somewhat, owing to different environments and exigencies.

The mine hospitals are interesting and unique in their construction. They are located inside the mines, and when practicable they are small rooms cut into the rock. In all cases the walls and roof of the rooms are either the natural rock, whitewashed, or they are made of white concrete. They are constructed in the most durable manner, and are supplied with steam heat, and hot and cold water. Arrangements are also provided for sterilizing the water used. In the walls, closets or cabinets provided with iron doors are set. These cabinets

Interior of Underground Hospital

contain bandages, splints, sterilized gauze for wounds, picric-acid gauze for burns, roller and triangular bandages, stimulants, and appliances for treatment of shock. Each room also contains a dressing couch, a dressing chair, a stretcher, and a metallic first-aid case completely equipped with similar supplies and appliances as are in the cabinets. These cases are for use at the immediate scene of the accident in preventing hemorrhage and other deleterious effects. Each mine has an emergency hospital of this kind on every level, some having as many as four inside in addition to one on the surface. The corps connected with the surface emergency hospitals consist of outside men of various occupations, such as machinists, breaker men, blacksmiths, carpenters or any other class available for immediate service with sufficient intelligence to act properly at the proper time. The Mineral Railroad and Mining Co., and the Susquehanna Coal Co. maintain in the vicinity of Shamokin and Mt. Carmel about thirty such emergency hospitals, and they have proved invaluable in lessening suffering and aiding in the recovery of injured men.

In the furtherance of this humane work the workingmen take great interest and cooperate earnestly in the efforts of their employers to lessen the dangers and suffering due to inattention to injured men. The former inefficient and often unclean methods of handling wounds are no longer followed, and as a result, through modern methods, infection is prevented and lives saved, and permanent disability is often prevented. In addition, the example set by these emergency corps has been a great factor in educating the entire community in the necessity of up-to-date aseptic treatment of the numerous accidents and surgical contingencies of every-day life.

FIRST-AID GRADUATES, BRIER HILL, PA.

The first-aid-to-the-injured class of the Brier Hill Coke Co. graduated at Brier Hill, Pa., recently.

The American National Red Cross

Chartered by Congress

First Aid Diploma

This Certifies that David R. Millward has satisfactorily completed the course of instruction in FIRST AID, given under the auspices of THE AMERICAN NATIONAL RED CROSS, at Brier Hill, Pa.

Issued at Washington, December 27 1910

Chairman Central Committee

Chas. L. Magee
Secretary

Fig. 1. Certificate Issued to First-Aid Graduates

The class was organized by the Red Cross Society in April, 1910, and took the examination for certificates December 2, 1910. All of the 15 members passed a creditable examination, which was conducted by two physicians appointed by the Red Cross, Doctor Lang, of Pittsburg, Pa., and Doctor Lilly, of Brownsville, Pa. This class is the first to receive certificates in the soft coal or Connellsville region. The coke company gave the class all the support needed by furnishing them the necessary books and materials for practical work. Dr. Charles C. Gans, the company's physician, was the medical director, and gave the class lectures and practical work every week during the entire time. The meetings lasted from 1 hour to 1½ hours. All the men became enthusiastic over the work when once they understood the good results it could bring to themselves and fellow workmen. The doctor has found a decided difference in the men who are injured in the mine. They are bandaged or splinted as the case may call for, and instead of a large chew of tobacco being found on a cut it is nicely bandaged with the clean cloth from first-aid cabinets of Red Cross style which are furnished by the company.

Doctor Gans, who is organizing another class at the mine, expects it to be larger than the first one on account of the first class being more of an

Fig. 2. First Aid Graduates, Brier Hill, Pa.

experiment than anything else. Doctor Gans suggests that in organizing a first-aid class the bosses and superintendents should enter the first class, then later the working men. His first class was organized on this plan and included the mine foremen, assistant mine foremen, fire bosses, yard bosses, labor bosses, superintendents, and assistant superintendents, mining engineers, and then boss drivers, pit bosses, and so on, embracing the heads of different departments and fitting them for first-aid work. The plan worked admirably well, as one first-aid man can take a half dozen men and can tell them how to handle an injured man.

The members of the class shown in Fig. 2, were as follows: Thomas McCaffrey, superintendent and general manager; Robert McKay, assistant superintendent; W. M. Phelan, secretary of company; Harry Blackford, mining engineer; David Millward, mine foreman; Harry Millward, mine foreman; Thomas Rose, assistant mine foreman; Abe Gunter, fire boss; Richard McKay, fire boss; Andrew Dulik, fire boss; Ernest Elby, fire boss; Harry Hopkinson, chief machinist; John Scteffbouer, assistant machinist; John Noon, yard boss; Arthur Wilson, principal of Brier Hill Schools; Dr. Charles C. Gans, medical director.

Fig. 1 shows the certificate granted to the graduates by the Red Cross Society. The graduates of this class must feel satisfaction in knowing that they are the first in the soft-coal regions to be certificated by the Red Cross Society, but a greater satisfaction to know that they are able to relieve suffering humanity.

COMBUSTION OF COAL IN BOILERS

The quantity of smoke issuing from chimney shafts, and the number of articles upon "Smokeless Combustion," make it apparent that there is considerable difficulty in so arranging the apparatus and conditions as to obtain such perfect combustion of the fuel that no smoke shall escape from the boiler chimney, while at the same time only a slight excess of air and no unconsumed gases shall be found on analyzing the products of combustion.

Why is it difficult to obtain smokeless combustion? A little consideration of the composition and physical properties of coal, and the amount of air required for its combustion will give the reason. Take, for example, a Lancashire coal of the chemical composition, shown in Table 1.

Calculating the quantity of air required for the perfect combustion of this coal, we find that one pound of coal requires:

Coal		Air Required		Per Cent.
	Pound	Pounds	Pounds	
Fixed carbon	.6198	7.1896	7.1896	61.1
Carbon	.1802	2.0908	4.7560	38.9
Hydrogen	.0766	2.6657		
Nitrogen	.0162			
Oxygen	.0499			
Sulphur	.0064			
Ash	.0352			
Moisture	.0157			
	1.0000		11.9456	100.0

* Bulletin No. 18, Mining and Metallurgical Society of America.

Or one pound of coal requires 12 pounds of air to burn the hydrogen to water and the carbon to carbonic acid.

From these calculations it would appear that if 12 pounds of air were admitted for every pound of coal, combustion would be perfect; but as the volatile portion of the coal is liberated before the fixed carbon is consumed, and the volatile gases require a larger proportion of air than the fixed carbon, the time in which each of these constituents are consumed must be taken into account. In the case of a boiler consuming 12 pounds of coal per minute, and assuming that all the volatile gases are given off and consumed in one-quarter of a minute, the amount of air required would be as follows:

First quarter of minute for volatile matter,
$= 12 \times 4.756 = 57.072$ pounds of air,
$= 749$ cubic feet, or at the rate of 2,996 cubic feet per minute.

Three-quarters of a minute for the fixed carbon,
$= 12 \times 7.1896 = 86.275$ pounds of air, $= 1{,}133.64$ cubic feet, or at the rate of 1,511 cubic feet per minute.

The total quantity theoretically required $= 1{,}904$ cubic feet per minute.

From these figures, it will be seen that if the air supply is so regulated as to consume the volatile gases perfectly—2,996 cubic feet per minute—the quantity of air per pound of coal is greatly in excess of that theoretically required by the coal.

This excess of air carries off heat, and leaves it to be determined whether it is more economical to reduce the supply of air, thus allowing some combustible gases to escape, or have smokeless combustion with excess of air. If the volatile matter and fixed carbon burned away at a uniform rate, of course the air supply could be easily regulated, but this is not the case when coal is burned directly with air. It may be said that admitting the supply of air for the volatile matter above the fire-grate and that for the fixed carbon below and through the fire would solve the difficulty, but again the unequal rate of burning renders this impossible.

TABLE 1

Proximate Analysis

Fixed carbon	61.98

		100.00

In the case of firing by hand, where, say, 100 pounds of coal is put on the fire at a time, it is doubtful whether it would be possible to admit the large quantity of air necessary for the volatile gases in time to consume them before they escaped from the chimney.

It is the usual practice to allow 24 pounds of air per pound of coal, instead of the 12 pounds theoretically necessary, and this is in agreement with the foregoing calculations; but even this amount of air, as a constant supply, will not give smokeless combustion unless the coal is put on the fire in small portions at a time, or is fed continuously by mechanical stokers. The extra 12 pounds of air carries away heat equal to about 9 per cent. of the heating power of the coal; in this example

Weight of air		Temperature		Specific heat		Heat Units
12 lb.	×	500° F.	×	.238	=	1,428

The quantity of air necessary for the perfect combustion of any coal, therefore, depends upon the proportion of volatile matter in the coal, the rate at which this volatile matter is given off in the hot furnace, and the rate at which the fuel is put upon the fire; the perfect admixture of the air with gases, and the heating of this air also tend to minimize the quantity of air necessary to prevent the escape of smoke from the chimney.—*The Engineer, London.*

In early November, 16-year-old Miss Jones lifted 52,800 tons of rock with 400 pounds of explosive. Miss Jones then fried an egg with the same kind of powder scattered on the ground to demonstrate its safety.—*Cleveland Press.*

ELECTRIC SHOCK IN MINES

*Written for Mines and Minerals, by Sidney F. Walker**

An English View of the Conditions Affecting the Use of Electricity Underground

Not long ago the Miners Union in the County of Durham, England, passed a resolution that no electrical apparatus should be used in the mine, and the manager of one of the largest coal mines in the county will not use electrical apparatus anywhere except in the immediate vicinity of the pit bottom. In 1909 the Association of Mining Electrical Engineers was formed in Great Britain, with branches in various places, which at the time of writing this article totaled more than 500 in membership.

The object of the association is to bring about an exchange of opinions between men engaged in the practical work of electricity in mines, as it is the very small matters that give the trouble and not the theory. It is the little bit of dirt where it ought not to be, the loose wire on the terminal, the loose cable end in the screw, the loosely made joint, the badly covered joint, the carelessly insulated cable, and so on, which lead to trouble. It is these and many more similar things that have been the cause of the greater number of deaths.

It has been stated that 80 per cent. of the members of the Association of Mining and Electrical Engineers are engaged in looking after apparatus in mines, the remainder being colliery managers, consulting engineers engaged in mining work, and a certain number of representatives of manufacturers. The use of electricity in mines is a three-sided problem at least.

There is the electrical side, there is the mechanical side, and there is the mining side; and the mining side is at least as important as either of the others. Electrical men cannot possibly know much about mining. They will acquire a knowledge of mining sufficient for their needs as they go along if they are wise and keep their eyes and ears open. The president of the association gravitated into mining work from electrical. He commenced life as an articled pupil to a firm that was fitting up electrical apparatus in mines, and was left in charge of an electrical plant at a colliery in the Midlands. While there he made use of the opportunity to study mining and to qualify as a mining engineer, and from that he gravitated to a subordinate position on the mining staff, and thence to that of the manager of the large concern he now superintends. Every electrical engineer engaged in mining would do well to follow his example, so far as studying mining conditions goes. It is a very old rule, originally applied to barristers, that a man should know everything of his own profession and as much as he can of every other. In the case of electrical engineers engaged in mining work, they should know everything about electricity, as far as time will allow, and as much as they possibly can learn about mining. In the carrying out of electrical installations in mines it often happens that the requirements of the electrical engineer run counter to the conditions that the colliery manager considers safe. The electrical engineer cannot easily understand the limitations that are imposed upon him, and it is only by a friendly exchange of views, a friendly exchange of thought, such as took place during the meetings of the branches of the association during last session, that the two views of the two branches of engineering can be reconciled.

There is another very serious point in connection with the use of electricity in mines; viz., the want of familiarity of the great bulk of electrical engineers with mining conditions. The conditions under which miners have to work are totally different to those under which men work on the surface, and miners may often be found carrying out operations under conditions that to the ordinary surface workman appear just as marvelous as those of the sailor on a topsail yard. In the navy in the old sailing-ship days they had a saying, "One hand for the Queen, and one for yourself," but in a great many instances both hands were given for the Queen. In mining work it is somewhat similar, often one hand for the colliery owner, and one for yourself, and again it very often happens that both hands have to be used in the service of the mine owner.

It is necessary to have electrical engineers to keep electrical apparatus in order, but they are not able to do as much work and to work as comfortably, or with as little danger, on apparatus in mines as they would work on the surface, until they have been working in the mines for a considerable time. When the writer was investigating the working of coal-cutting machines in British collieries some years back he found that the working miner who had been given a certain amount of instruction in the handling of a coal-cutting machine—sufficient to enable him to turn the power on and off, to guide the machine, etc.—produced far better work, cut far more coal, and that his machine gave far less trouble than the mechanic who was brought to the machine from the surface. The mechanic who was accustomed to working on the surface felt just as little at home at the face of the coal as a landsman would feel "outside the lift" on a topsail yard. This, it will easily be understood, leads to many difficulties in the way of keeping apparatus going. It leads to the requirement of a considerably larger number of men to look after electrical apparatus than would otherwise be necessary. In a great many instances a man executing a repair to a cable, to a switch or distribution box, to a motor or its controller, is working under very awkward conditions, and is only too anxious to get it done and get away. If this side of the question be considered, the writer thinks that the toll of life, and the number of accidents that have taken place in British mines, will be seen not to have been so large as from their actual number they would appear.

The writer has summed the matter up on several occasions in two words; viz., insulation and care. If the insulation of the whole of the apparatus is maintained at a certain standard, the chances of shock are reduced to a minimum, and the writer believes would be very few indeed. If to the maintenance of good insulation everywhere, care were added on the part of every one concerned, he believes that accidents would be practically eliminated. One of the most striking features which came out in the discussions which took place at the branches of the Association of Mining Electrical Engineers was the fact that a very large number of the accidents in mines were due to want of care. In some cases the carelessness actually approached foolhardiness. Men who knew, or should have known, the risks which they took in doing certain things, deliberately did them, and were killed. One very striking instance will probably illustrate the matter. At a certain colliery there was an extra high-tension switchboard working at somewhere about 3,000 volts or over. Some alterations were required to the connections at the back of the board, and that portion of the apparatus was disconnected from the service and carefully rendered harmless. The other portion of the space at the back of the board, where the live conductors were fixed, was carefully divided off from the portion where the alterations were being carried out, so that unless a man wilfully and knowingly removed the division it was practically impossible for him to do himself any harm. The man who was carrying out the alterations was a highly skilled electrical engineer, in receipt of a fairly substantial salary. Apparently he was in a hurry to get away to a football match, or something of that kind, and after carrying out the alterations to the portion of the board required, he deliberately removed the partition mentioned above, either to get something behind the other portion of the switchboard or to get at some connection there, and accidentally touching a live conductor, was killed. In another case, which is also illustrative of the want of care, a comparative youngster, who was not so fully imbibed with respect for the killing properties of electrical conductors as he ought to be have been, made connection for testing purposes between two conductors at the back of the board by means of a piece of stiff bent copper wire held in his

* Bloomfield Crescent, Bath, England.

hand. By accident he also made connection with another live conductor, between which and one of the conductors he was connecting considerable pressure existed. Fortunately for himself, the connection was only for an instant. The result was a powerful flash, which blinded him for some weeks, and which it is to be hoped was a lesson to him. In this case also the youngster had a certain amount of knowledge, which ought to have kept him from playing monkey tricks such as that described. A more serious monkey trick that a youngster played at a central generating station, and which also resulted in temporary blindness to the operator, was the throwing of a piece of fuse wire up in the air, in the neighborhood of a switchboard; the fuse wire fell upon a pair of conductors between which a considerable pressure existed, and being immediately melted, a blinding flash followed, with the result mentioned.

Shocks occur when a man either touches one conductor between which and the ground upon which he stands a considerable difference of pressure exists, or accidentally touches two conductors between which a considerable difference of pressure exists, by his two hands, or two other parts of his body. Cases have occurred in which men have accidentally made contact with their heads against a conductor, between which and the ground on which they stood a considerable difference of pressure has existed. In other cases men while holding one conductor with the hand have accidentally made contact with another conductor at a considerable difference of pressure, with either hand, head, or some other part of the body. More than one accident has occurred from a man's back coming in contact with a conductor. In the upper part of the back, it will be remembered, the delicate organs of the chest are exposed, and a conductor touching the skin there a current passes through the lungs, which may easily cause such serious damage as to destroy life.

How the Conditions Occur Under Which Shocks May Be Taken.—The conditions under which shocks have been received by men working in mines, arise in two ways, both being really due to want of insulation. In one class of cases the insulation of some portion of the apparatus has either perished or been damaged in some way, and a man has caught hold of what he has supposed to be an insulating envelope, or a metal or some other body that was insulated from the service, and has actually brought his hand into more or less intimate connection with the service itself. One fruitful cause of accidents of this kind is the imperfect covering of joints. In mines generally, and in certain British coal mines in particular, falls of roof are somewhat frequent. Cables furnishing current for lamps and motors have been suspended from insulators secured to props by the side of the road. Falls of rock have sometimes merely damaged the insulation of the cable, and sometimes have parted the cables. In either case, if the damaged insulation is not made quite good, if the covering of the joint, or of the damaged portion of the cable, is not made of as high an electrical resistance as that of the cable before the accident took place, a man touching the presumably covered joint may receive a shock that will be fatal. Unfortunately, numerous cases have occurred of this kind. In the West of Scotland, for instance, it is the practice for what are called "brushers" to go into the mine after the coal has been filled into the trams to clear out the coal dust. In one instance at any rate, and probably in more, a "brusher" has found a cable in his way and has caught hold of it, believing it to be perfectly harmless, as it was apparently insulated, and has attempted to move it out of the way, with the result that he has received a shock and been killed. A striking instance, that was mentioned in the discussion upon shock at the writer's branch, of the danger of imperfectly covering joints was the following: A haulage motor had stopped working and an electrician had been sent for to put it right. He found a wire broken in the motor, repaired it, and, as he thought, covered it, leaving the machine running all right. He proceeded to go out of the mine, but when he had walked a little way, as men often do, feeling anxious about the work, he returned to see that it was still working all right. Unfortunately, the motor being stopped between journeys, he touched the joint that he had made and received a shock by which he was killed. In this instance it was apparently want of knowledge that was at the bottom of the trouble. The man thought he had covered the joint sufficiently. According to the information that was given during the discussion, the joint was covered with wet tape and of course the insulation resistance was very low.

In other cases, what ought to have been perfectly harmless metallic bodies have been rendered alive, and have been the cause of fatal shocks to men touching them, through defective insulation of some parts of the electrical service. Cases such as the following have been again unfortunately only too frequent. Men walking to the face, or returning from it, have caught hold of the galvanized iron electric signal wires that form part of the equipment of nearly every engine plane in British collieries, and have received shocks from which they have died. In other cases, a man has caught hold of the iron edge of a mine wagon and been killed. Again, a somewhat fruitful source of fatal shock has been the haulage rope of coal-cutting machines. In British collieries the longwall coal-cutting machine is very largely employed. It will be remembered that in the working of this machine it is usual to have a working face ranging from 100 yards upwards. The machine, whether it is one of the disk, the bar, or the chain type, is drawn along the face, cutting its groove as it goes along. For the purpose of hauling the machine along the face a small galvanized-steel haulage rope is carried out in front of the machine, and is wound up upon a small haulage drum attached to the machine, as it moves along. The length of the rope being limited, it has to be moved forward from time to time, during each cutting shift, as the machine comes up to the prop to which the rope is attached. It is the work of an unskilled man who goes with the machine, usually to move the rails where rails are employed, and to carry forward the haulage rope, making a fresh attachment in front of the machine, and seeing that the haulage gear is working properly. In several instances the carcase of the machine has become connected to the electrical service through the defect of the insulation of a cable, or some other part of the apparatus, and the whole machine, and all the cables that are connected with it, including the haulage rope, have been made alive. The result has been that a man taking hold of the haulage rope, standing upon the ground, has received a shock that has killed him.

EXPORT OF COAL

Coal is becoming one of the most important and useful articles of exportation in the foreign trade of the United States. The important items of exportation are: cotton, approximately $530,000,000; meat and dairy products, $130,000,000; copper and mineral oil about $94,000,000 each; lumber about $40,000,000; corn about $28,000,000; wheat, approximately $23,000,000; leather, $38,000,000; and tobacco, $36,000,000. While, of course, cotton, meats, copper, and mineral oil are of much larger value in their respective totals, coal now exceeds in value of its exportations corn, wheat, tobacco, lumber, leather, and numerous other articles which have been looked upon as important factors in our export trade, and the growth in the exportation of coal has been more rapid than that in many other leading articles of exportation. About one-third of the $45,000,000 worth of coal exported, or $15,000,000 worth, is anthracite; about $27,000,000 worth bituminous coal, and about $3,000,000 worth coke. The growth in the exportation of bituminous has been of late more rapid than that of anthracite, the increase in bituminous in 1910 over 1908 being more than $3,000,000, and in anthracite an increase of about $1,000,000 in the stated value as shown by the export figures published by the Bureau of Statistics of the Department of Commerce and Labor.

METHODS OF REMOVING COAL PILLARS

*By F. W. Cunningham**

Different Methods in Use in Pittsburg Coal Seam—Their Advantages and Disadvantages

The subject of this paper embodies one of the most important features in coal mining. It carries with it a combination of perplexing and difficult problems, among which are the following: How is it possible to afford the greatest degree of safety to the workmen, and recover the largest percentage of coal with the least possible danger to the property from squeezes, creeps, etc., and at the same time to arrange the system of mining so as to produce the largest percentage of lump coal and the smallest percentage of fine coal? If the operator is to continue in the business of shipping coal, make a reasonable profit on his investment with the present prices and profitably recover all the pillar coal, he has indeed a serious problem to solve.

It can readily be seen that this is a broad subject, because each coal seam has its own local difficulties to contend with, therefore, not having the time to prepare an article that may cover all conditions, the Pittsburg coal seam is used as an example; however, where conditions are similar in other localities the remarks will apply.

The first thing to be considered is the size of the pillar and the room. These matters will depend on the thickness of the cover, which determines the roof pressure, strength of roof, and whether the floor is hard or soft. A soft floor or hard roof requires wide pillars, while with a hard floor and a soft roof the width of pillars may be less. The inclination of the seam should be considered, as a wider pillar should be left where dip is steep than where the inclination is less. The thick seam requires a greater width of pillar than one that has less thickness.

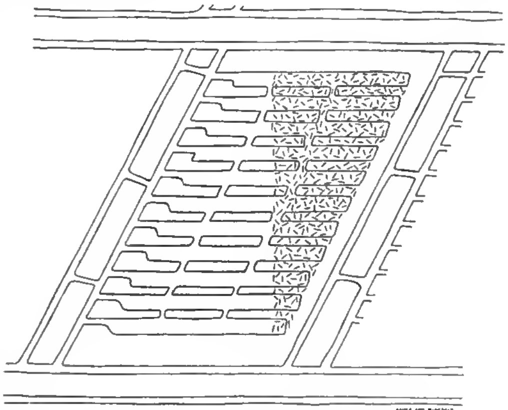

FIG. 1. SHOWING FACES OF PILLARS PERPENDICULAR TO THE SIDE

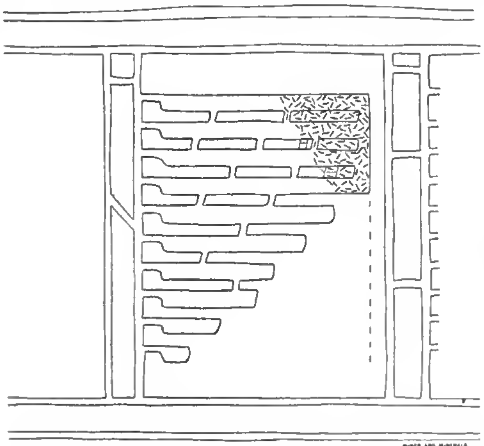

FIG. 2. PILLAR DRAWING, FACES AT ANGLE TO SIDE

The physical structure of the coal has a bearing on the thickness of pillars to be left; for instance, a soft or slippy coal requires wider pillars than a hard compact coal. The width of the rooms will depend largely on the width of the pillars, and the strength of the roof rock.

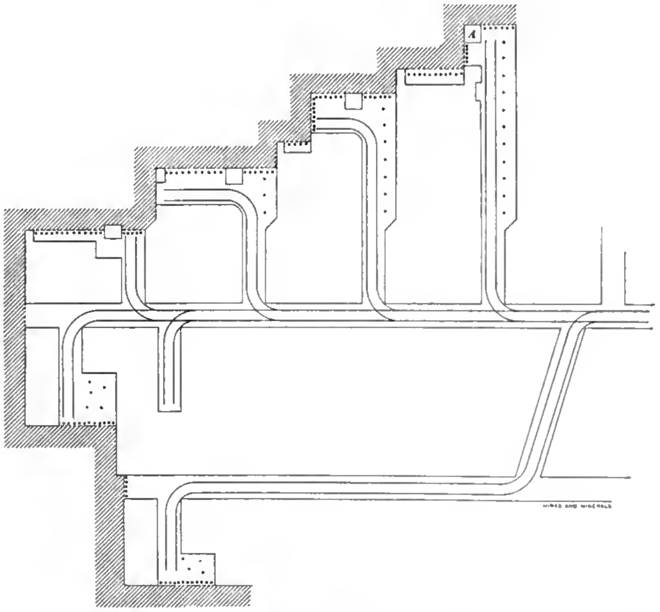

FIG. 3. RIB WORK WHERE CURVE IS USED, SHOWING LOCATION OF TRACKS AND POSTS

It is impossible to give exact rules for determining the proper size of pillars, as each case in practice requires special consideration.

The roof pressure per square foot exerted on pillars is proportional to the thickness of the cover and the total width of the room and pillar, and inversely proportional to the width of the pillar.

Let depth of cover $= d$; width of room opening $= O$; width of pillar $= w$.

The roof pressure per square foot exerted on the pillars is proportional to the expression, $d\left(\frac{w+O}{w}\right)$.

There are a number of ways of drawing pillars, or at least a number are being tried, but when all are classified they may be divided into drawing pillars at the end and drawing pillars in sectional divisions. In drawing pillars on the end the first attack is made by cross-cutting the pillar after the room or entry is driven its distance. This furnishes a retreating face that permits the pillar to be worked back, sometimes square and sometimes by offsets, depending on the width of the pillar, the strength and thickness of the coal, and the nature of the overlying strata. In the second method of drawing, the pillars are cross-cut into sections along their length so they may be drawn by end or side slices, depending on the nature of the coal, inclination of the seam, the thickness of the overlying cover, and the kind of roof.

The greatest percentage of pillar coal is obtained under the system that does not allow the pillars to be squeezed.

The two general systems of drawing are: (1) All the pillars in a panel are taken out together with the end lifts in such a way as to keep the faces of all the pillars stepped in line, or echelon, and perpendicular to the sides of the pillars, Fig. 1; (2) the pillars are drawn by cross-cutting through the fast ends of the innermost pillars in a panel; then two or more pillars, according to the circumstances, are drawn and the centers of the faces of the pillars are made to lie in a straight line that makes an angle of 35 to 50 degrees with the sides of the pillars, Fig. 2. It is very important that the pillars should be kept in the line of roof fracture so that each shall support its proportional share

* Read before Coal Mining Institute of America, December, 1910.

of the overlying strata, then the roof pressure will not bear too heavily upon any one of them and crush the coal. The timbers supporting the roof should be drawn to within a short distance behind the end of the pillars so as to induce a roof fall up to them.

Before pillar drawing is commenced the following system should be planned and carried out unwaveringly: Draw the

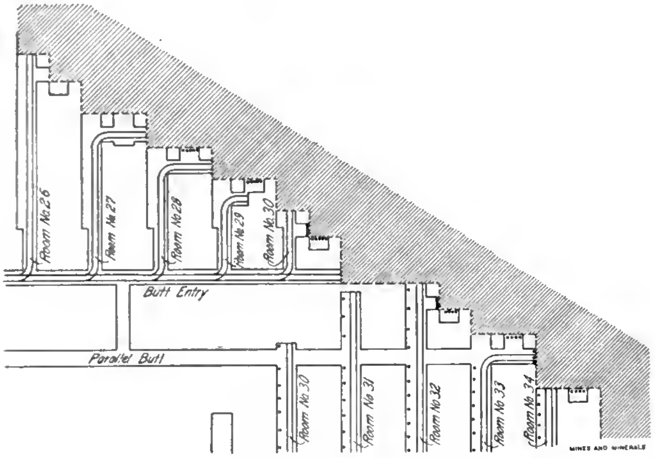

Fig. 4. Rib Work Showing Method of Working Ends of Pillars

room pillars back regularly so soon as the rooms reach their limit. This will avoid the possibility of starting a creep or squeeze by holding open too large an excavated area. Before room pillars are drawn, however, the effect their withdrawal will have on adjoining workings and at the surface should receive attention.

Before the entry pillars are drawn, it should be ascertained whether all the coal possible has been mined through these entries, and whether or not the entries will be required for later development of the mine.

Among other causes, squeezes in the mines are sometimes due to the improper drawing of pillars and to leaving pillars too small and in the wrong places.

The topography of the surface relative to hills and dales should be considered when starting to draw pillars, and relative to this subject a question may be asked, which is an important one; viz., How many coal properties have contour maps of the surface? While it is true that some coal companies require these data, a number of operators consider them an expensive luxury as they did the mine survey in years passed, and if their mines are examined it will be seen that very few have escaped squeezes. Suppose, for example, the rocks at the surface rise abruptly each side of a narrow valley to say 200 or 300 feet. Would it be proper to commence the pillar drawing under this valley? And if so, what effect would it have on the adjoining pillars, considering that no provision has been made in the plan of the mine for the surface conditions, and the mine is worked as are those usually in the Pittsburg district?

In such cases the cover, especially that directly above the coal, is a very important factor in determining the width of rooms and pillars. With strong roofs, wide rooms may be worked, but with increased width comes increased weight upon the room pillars. With weak roof and thick cover the conditions necessitate narrower rooms and larger pillars. Therefore, in view of the fact that there is no exact rule to predetermine the size of pillars, width of rooms for the different conditions met with in the mines, the nature of the overlying strata, only as experience has taught locally, it is suggested that the size of pillars and width of rooms be such as to effectively support the heavier and weaker strata that overly the mine, irrespective of the stronger and lesser thickness of the overlying cover in other parts of the mine.

In the removal of pillars, and regardless of the method adopted in their extraction, systematic timbering should be carried on by competent persons employed for that purpose in order that the timbering be done in accordance with the system adopted.

In the Connellsville coke region systematic timbering and pillar drawing is more carefully followed than in mines outside of this region. It has been found that by strictly enforcing the rules relative to timbering and pillar work it is possible to maintain perfect fracture lines in the roof, some of which are over a mile in length. The overlying weight is therefore evenly divided on the end of the pillars throughout the whole line. By making use of the fracture lines and proper timbering, it is possible to recover practically all of the coal.

In the Connellsville coke region the large pillar and narrow room system is adopted; very little coal is cut by machines, and the smaller and finer the coal, the better it is adapted to coking purposes.

Pillar drawing in the Pittsburg coal seam, especially in those mines outside of the coke region, that ship coal to market, has been so irregular that a vast amount of coal left in the pillars will never be recovered. This is due to the fact that most of the coal mined from the pillars is small and the market is not active for this sized product. The operator to meet the demands of the coal market frequently issues orders to stop the pillar work, and especially when the trade is slow this is a common order. The results are that an excessive number of rooms are driven their distances and pillars stand a number of years before an attempt is made to pull them. When the pillar work is again started, the rooms are required to be retimbered and old falls cleaned up, making an expensive operation that could have been avoided had the pillars been mined at the proper time. Frequently, after a suspension of pillar drawing, when a panel of pillars is again attacked a squeeze makes its appearance and extends over a large area before it is stopped.

The remedy for this would naturally be (and is suggested by the practice in the coke region) to leave large pillars and narrower rooms, a system of mining which would probably overcome the difficulty so far as squeezes are concerned. But the product of the mine is not used for coking purposes, nor is it put on the market as slack or fine coal.

The operator in the Pittsburg coal field, with the price of coal where it is today, must get the largest percentage of lump

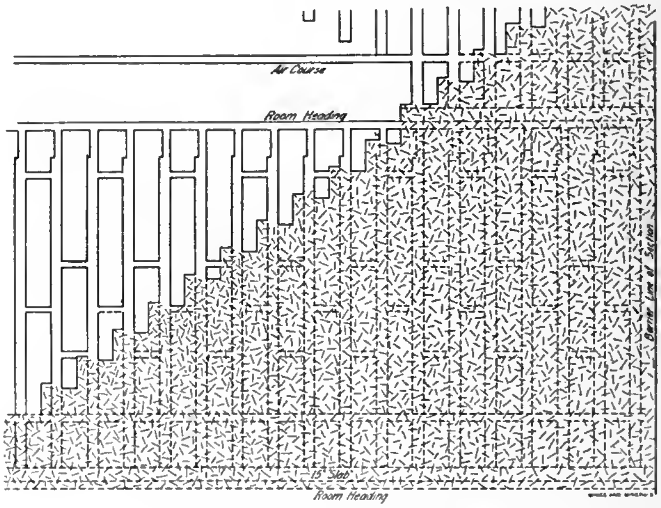

Fig. 5. Pillar Drawing by Steps

with the least amount of fine coal, and this by machine mining, in order that he may compete with coal operators in other fields. To accomplish this the rooms are driven as wide as is possible in order to obtain the greatest percentages of lump coal, and the room pillars are left as narrow as possible, for from them comes the greatest percentage of crushed coal. Under such conditions it is readily seen that the coke region system of wide

pillars and narrow rooms does not appeal to the operator whose product goes on the market for other than coking purposes.

A system that would appeal to the operator in this strait, is the one in which the greatest amount of lump coal can be recovered by the use of mining machines, and the least amount of pick work is needed.

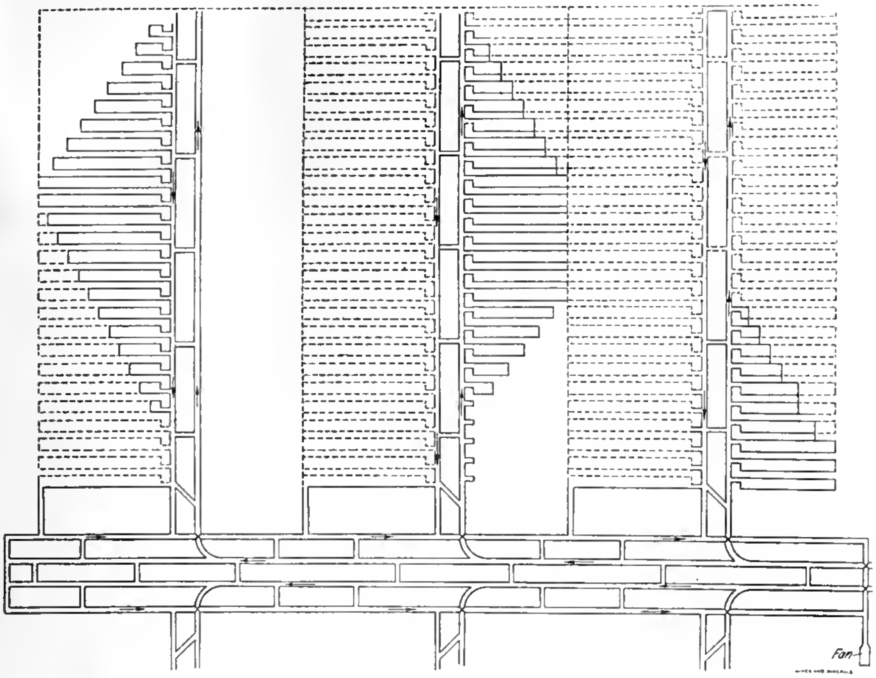

FIG. 6. PLAN OF PILLAR DRAWING USED IN PITTSBURG DISTRICT

The sizes of pillars are regulated by the depth of the overlying cover, physical structure of the coal, kind of roof and floor, and the inclination of the coal seam.

The width of the room is regulated according to the width of the pillar, excepting in the Connellsville coke region where the narrow room and wide pillar is adopted.

Pillar drawing, either on the end or in sectional divisions, requires that the ends of the pillars be kept in perfect alinement, whether or not the line of roof fracture is perpendicular or at an angle of 50 degrees or less with the room pillar.

Systematic timbering is necessary in the extraction of pillars and should be carried a short distance behind the pillar. A competent person or persons should look after the pillar work, to see that the timbering and the proper mining of the coal are strictly in compliance with the rules laid down for such work.

Pillar work should be so arranged that when a room is driven its distance the pillar could be started back immediately, with the end of this pillar stepped in line with the other pillars that are being drawn back in the section. This mining system avoids too large an open area being supported by room pillars longer than is necessary to remove the pillars. If the mining is not carried on with regularity, and there is a large open area supported by room pillars, especially if they are small and irregularly worked, squeezes are likely to cause trouble and the workmen encounter a greater degree of danger.

To show some of the methods adopted in pillar drawing the following plans are presented for consideration: Fig. 3 represents rib work showing where curves are used, and the location of the tracks and posts. This method is principally followed in the coke region; it is being replaced by later methods which have proved to be more successful.

Fig. 4 is a plan showing rib work, the location of tracks and posts, the method of working the ends of the pillars. The difference between this and the method shown in Fig. 3 is that the chain pillars are worked from the rooms off the next butt entry. It has an advantage over the method shown in Fig. 3, in maintaining a more uniform fracture line on the chain pillars.

Fig. 5 is a plan showing rib work without curve, a slab taken off the right-hand side of the room, also chain pillars taken out from rooms on the next lower butt. This system is adapted to the coke region or where narrow rooms are worked and they do not have to contend with the storing of refuse along the side of the rooms; however, it could be worked from wide rooms with the refuse in the middle of the room and a track along each rib. This system has been tried at some mines in the Pittsburg district, with a track along each rib; it did not prove a success.

Fig. 6 is a plan of rib work used in some of the mines in the Pittsburg district with a wide room and a narrow pillar and the track along one side of the room; the refuse on the other side fills the rooms in some mines to within 2 or 3 feet from the roof. The rooms are worked from 21 to 24 feet wide and the pillar 15 feet thick.

Fig. 7 is another plan of rib work used in some of the mines in the Pittsburg district, a wide room with a narrow pillar. The pillar work starting on the first end of No. 1 butt, then being worked to the top, then from the top of No. 2 butt to the bottom of this butt. One advantage in working the pillars as shown by this plan is that the pillar work is always in the return end of the air-current, then if open lights are used in the rooms, the air-current passing the goaf would not be carried by the rooms where open lights may be permitted. The methods in Figs. 6 and 7, if carried on regularly will give as good a result as any that have been tried in this district, that is, considering lump coal and it cut by mining machines.

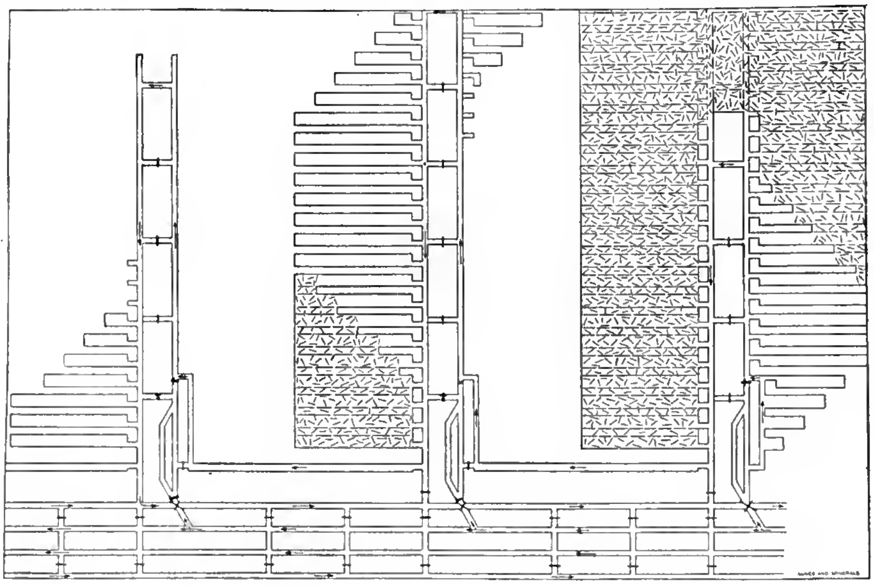

FIG. 7. PILLAR DRAWING WITH WIDE ROOM AND NARROW PILLAR

Fig. 8 is a plan showing the amount of coal left in the room pillars where the system is the road in the middle of the room

and the room pillars not being drawn. These room pillars are left as narrow as possible after the room has advanced 100 feet, or to the first cut-through, then as a general rule, about the time the room is up its distance, the room caves and the coal in the pillars is lost; however, the coal in the first end of the room pillars is very often all recovered by working the pillar along the side of the fall up to a point where it is considered dangerous to advance farther. There is one company in my district that mines over 2,500,000 tons of coal annually by this system, and their claim is that they recover 90 per cent. of marketable coal. There are features connected with this system that I do not approve of, and do not think it a proper system to be used in this district.

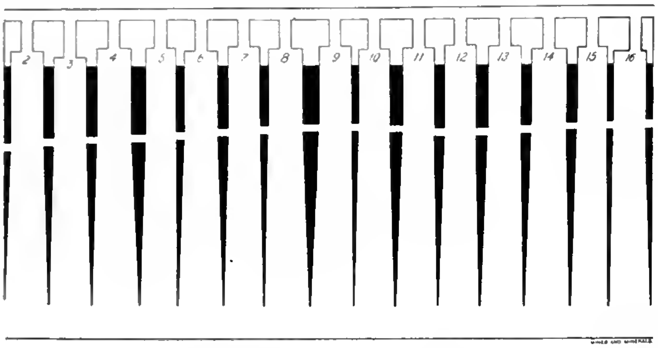

Fig. 8. Method With Narrow Pillars

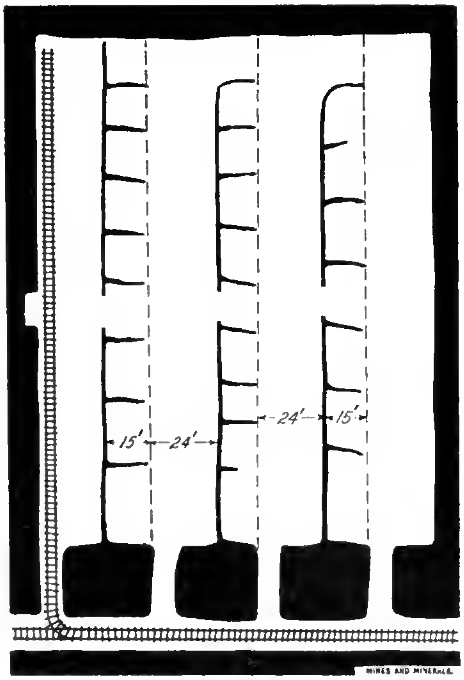

Fig. 9. Showing Coal Left in Room Pillars

Fig. 9 is a plan showing the amount of coal left in the room pillars on rib work where the system of mining is the road on the side and draw the pillar; the room is 24 feet wide and the pillar about 15 feet wide, where it is impossible to keep the goaf from sliding down where the miner is doing his work, as is usually the case in many mines in the Pittsburg district. The coal left in the pillar, as shown on the plan, varies from 12 to 18 inches thick, and this coal is left next the goaf on each cut the miner makes across the rib. There is about as much if not more coal left in the pillar where this system is carried out as in the system represented on Fig. 8, and very often blocks of coal in addition to what is represented on the plan are lost. I do not want to be understood that it is necessary to leave this sheet of coal next the goaf throughout the whole Pittsburg district, but there are sections in this district where it is impossible to keep the rib falls from taking the face and knocking out any posts set to prevent it. Where this condition exists it is necessary to make a new cut across the rib each time a fall is made.

Figs. 10, 11, and 12 are sketches showing location of tracks, posts, and the size of falls to be made. This is one of the latest systems and is claimed to be the best yet adopted in the coke region.

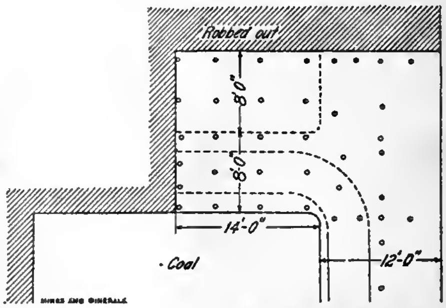

Fig. 10. Coal Extracted, Place Ready to Make Last Fall in 42-Foot Center Rooms

Fig. 13 is a plan showing where 70 per cent. of the pillars were recovered by mining machines; the machine would make a cut 21 feet wide through the rib, then leave a stump of 8 or 9 feet to be taken out by pick mining, as shown by the different cross hatching. In this particular mine they have been very successful in the removal of the pillars by this system and up to this writing, covering a period of over one year, there was no coal lost nor is there any appearance of a squeeze or creep. The surface is from 150 to 250 feet above the coal.

Fig. 14 is a sketch of longwall retreating in a modified form. This plan is suggested in order to eliminate the cost of narrow work in turning rooms and making cut-throughs to recover a larger percentage of the coal, and to reduce the chances for a squeeze or creep to a minimum. It is realized by the writer that this system cannot be adopted at most mines, but there are some mines in the western part of this state where he feels confident that the system, if carried out properly, could be worked to a good advantage.

The system requires the butt entries to be driven up their distance, then cut across the block of coal toward the next butt entry one-half of the distance, usually 150 feet; then a cut is made from the next butt entry toward this one until the two cuts meet, the one being kept about 25 feet in advance of the

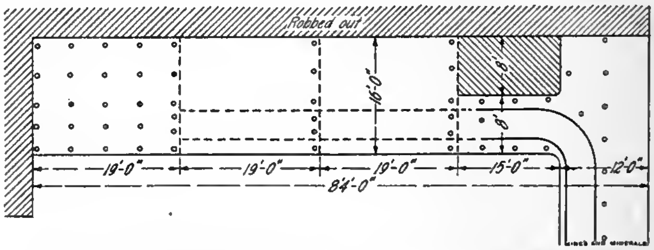

Fig. 11. Posting and Size of Falls in 84-Foot Center Rooms

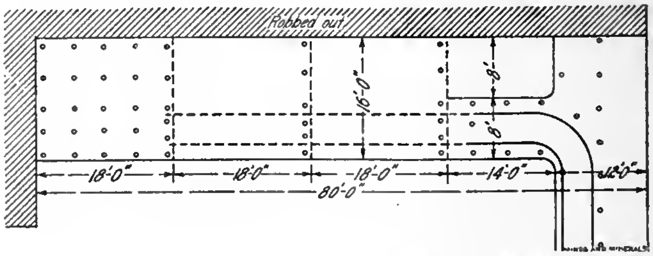

Fig. 12. Posting and Size of Falls in 80-Foot Center Rooms

other; the track is kept close to the face, the timbering will require three or four rows of posts in order that the falls will not take the face; the coal could be cut by mining machines and quite a large number of loaders could be worked on each lift; the ventilation could be very easily controlled and the workmen receive the benefit of the air-current while doing their work. If it is found that the system works to a better advantage

on the butts, the system could be changed by driving two rooms through the block, then using the same method in the middle of the block that is shown at the end in the sketch.

PARAFFINE OIL IN OHIO MINES

Section 974 of the Mining Laws of Ohio, provides: No person, firm or corporation shall compound, sell or offer for sale,

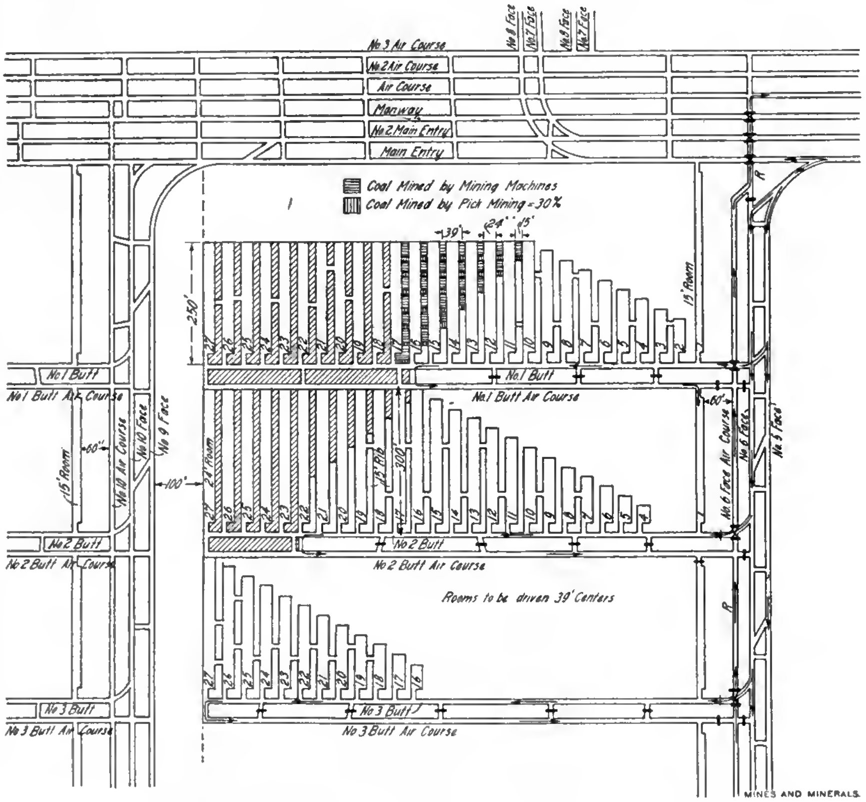

Fig. 13. Method Where Pillars Are Recovered by Mining Machines

for illuminating purposes in any coal mine, any oil other than oil composed of not less than 84 per cent. of pure animal or vegetable oil or both, and not more than 16 per cent. pure mineral oil. The gravity of such animal or vegetable oil shall not be less than 21½°, and not more than 22½° Baume scale, measured by Tagliabue or other standard hydrometer, at a temperature of 60° F.; the gravity of such mineral oil shall not be less than 34°, and not more than 36° Baume scale, measured by Tagliabue or other standard hydrometer, at a temperature of 60° F., and the gravity of the mixture shall not exceed 24° Baume scale, measured by Tagliabue or other standard hydrometer at a temperature of 60° F. Paraffine wax reduced to a liquid state is a mineral oil, and contains no animal or vegetable oil; this fact alone, under the provisions of Section 974, just quoted, would make it unlawful for any person, firm or corporation to sell or offer it for sale for illuminating purposes in any coal mine in the state of Ohio; and the use of the same by any person or persons for illuminating purposes in mines is prohibited by Section 975 of the mining laws. Another reason is that the law provides that the specific gravity of the mixture shall not exceed 24° Baume scale, measured by Tagliabue or other standard hydrometer at a temperature of 60° F. As reported to me, the gravity of paraffine oil is 34° Baume scale; therefore, the use of paraffine wax reduced to a liquid would be prohibited for that reason also.

I am of the opinion that paraffine wax can not be sold or used as an illuminant in mines for open lamps, because it does not come up to the requirements of Section 974 of the Mining Laws of Ohio. Timothy S. Hogan, Attorney General

GRAVITY DETERMINATION OF COAL

*By Abraham G. Blakeley and Edwin M. Chance **

During the routine work of this laboratory, it is necessary to determine specific gravity on a large number of samples of anthracite coal. As the methods available gave but little satisfaction commensurate with the time and labor entailed, we had recourse, after considerable experimentation, to the herein described procedure.

The apparatus, first of all, is simple, and may be found in almost any laboratory. The first requirement is a stout flask of about 250 cubic centimeters capacity, with a long and rather slender neck, terminating in a flaring mouth, such as the "copper determination" flask supplied by the Denver Fire Clay Co. This flask is to be marked at the base of the neck, either by a file scratch or by etching, and its volume up to this mark determined by means of a 100-cubic-centimeter automatic pipette and a 100-cubic-centimeter burette, graduated in .2 cubic centimeter.

The burette should have a three-way stop-cock, and be connected with a reservoir either below or above the level of its top. In the former case suction is used to fill the burette, while in the latter case gravity is the means. It is better to use the elevated reservoir and gravity feed for the pipette. Of course it is understood that a plain burette and pipette can be used, the form described merely having the advantage of rapidity.

The flask is calibrated as follows: The flask is rinsed with water, inverted, and allowed to drain for 1 minute; 100 cubic centimeters of water are then added from the pipette; the flask is then filled to the mark from the burette. In calibrating by this method, inaccuracies in either pipette or burette do not militate against the accuracy of the specific gravity result, as the same method is pursued in the final determination.

The actual determination is carried out as follows: 100 grams of coal previously crushed to about 4 mesh, and carefully sampled, are weighed to .1 gram, and placed in the

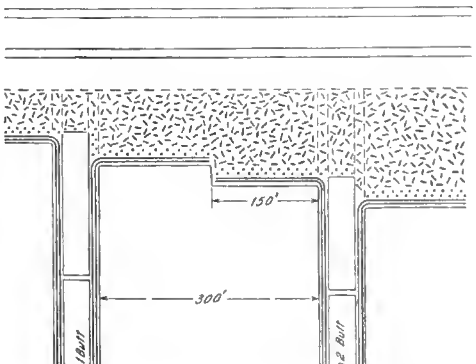

Fig. 14. Modified Longwall Retreating

flask; 100 cubic centimeters of water are run in; a one-hole stopper fitted with bent glass tube and rubber connection is inserted in the mouth of the flask; suction is applied, and the flask is shaken, care being taken that no water is splashed

* Chemists for Philadelphia & Reading Coal and Iron Co.

into the glass tube. When air bubbles cease to be disengaged, the suction is interrupted and the stopper withdrawn. Water is now run in from the burette till the flask is filled to the mark, care being taken to work down any coal which may have stuck to the neck.

The results may be calculated as follows:

$$\text{Specific gravity} = \frac{100}{V_0 - V_1}$$

wherein V_0 = volume of the flask; V_1 = number of cubic centimeters of water added to coal.

No calculation at all need be made if a table of reciprocals be available, as specific gravity = 100 × reciprocal of $V_0 - V_1$. As an example, 100 grams of coal were taken; volume of flask, $V_0 = 262$ cubic centimeters; volume of water added to coal, $V_1 = 197$ cubic centimeters;

$$\text{Specific gravity} = \frac{100}{262 - 197} = 100 \times \frac{1}{65} = 1.54$$

After making a determination the flask is emptied and rinsed, then allowed to drain for 1 minute, when another determination may be made.

This method is very rapid and so simple that an inexperienced operator can without difficulty make over 80 determinations per day, accurate to within .02 unit of specific gravity. It is, of course, self-evident that this method has a wide range of applicability; the gravities of such materials as rocks, drillings, etc. may be determined with ease.

While the authors claim nothing new or radical in this process, still they submit it as a procedure by which results of moderate accuracy can be obtained with great rapidity, while the outlay for special apparatus is practically nil.

Weight of 1 Cubic Foot at Different Specific Gravities

Specific Gravity	Weight Per Cubic Foot	Specific Gravity	Weight Per Cubic Foot

TO PREVENT DUSTING OF CONCRETE FLOORS

By Albert Moyer, Asso. Am. Soc. C. E.

Cement floors, particularly in office buildings or warehouses, which do not have the advantage of obtaining the necessary moisture from the atmosphere such as outside floors and sidewalks on which the dew falls at night, if not properly protected and kept damp, become prematurely dry and are therefore more or less porous and weak, causing easy abrasion under foot traffic, or what is commonly known as dusting.

Care should be exercised in keeping such floors damp by covering with wet sand, wet hay, or straw, for a week or more until the floor has properly hardened. If this has not been done and the floors are found to dust under foot traffic, the following remedy will be found very easy to accomplish, economical, and effective.

Wash the floor thoroughly with clean water, scrubbing with a stiff broom or scrubbing brush, removing all dirt and loose particles. Allow the surface to dry; as soon as dry apply a solution of one part water glass (sodium silicate) of 40° Baume, and 3 to 4 parts of water, the proportion of water depending upon the porosity of the concrete. The denser the concrete the weaker the solution required. Stir well, and apply this mixture with a brush (a large whitewash brush with a long handle will be found the most economical). Do not mix a greater quantity than you can use in an hour.

If this solution is sufficiently thin, it will penetrate the pores of the concrete. Allow the concrete surface thus treated to dry. As soon as dry, wash off with clean water using a mop. Again allow surface to dry and apply the solution as before. Allow to dry and again wash off with clean water, using a mop. As soon as the surface is again dry, apply the solution as before. If the third coat does not flush to the surface apply another coat as above.

The sodium silicate which remains on the surface, not having come in contact with the other alkalies in the concrete, is readily soluble in water and can therefore be easily washed off, thus evening up the color and texture of the floor. That which has penetrated into the pores, having come in contact with the other alkalies in the concrete, has formed into an insoluble and very hard material, hardening the surface, preventing dusting and adding materially to the wearing value of the floor.

DISCOVERY OF COAL IN BRAZIL

Quite recently, within the state of Pernambuco, was discovered what promises to be a most valuable coal field. The area embraces about 22 square leagues, about 300 meters (1 meter = 3.28 feet) above the level of the sea and, according to the opinion of experts, has every appearance of true Carboniferous strata.

The first vein was encountered at a depth of 20 meters underlying a formation of clay mixed with sand and coal fragments impregnated with sulphides. While the analysis shows the first vein exposed to be of only fair quality, its richness increases as the shaft deepens. The following published analysis is from the expert's report:

Moisture	1.900
Volatile matter	18.815
Ash	20.520
Carbon	58.733
Loss	.032
	100.000

Notwithstanding that this coal area is quite small in comparison with many in the United States and other countries, nevertheless this discovery will act as a strong incentive toward further exploration in Brazil. As this particular field is located so that the coal can be advantageously mined and transported, it will prove of great value in furnishing cheaper fuel to the existing factories and manufacturing concerns, as well as to those contemplated within the states of Pernambuco, Alagoas, Sergipe, and Bahia.—*United States Consular Report.*

LIABILITY FOR INDUSTRIAL ACCIDENTS

*By Sion B. Smith, Esq., Pittsburg, Pa.**

Different Methods by Which the Losses From Personal Accidents May Be Equitably Distributed

The whole country stands aghast when a disaster in a coal mine wipes out 200 lives, yet it is a lamentable fact that the Juggernaut of industry takes toll of 150 lives every day and merely brings forth sociological discussions in literary magazines. Has it occurred to any one that we have a very considerable body of natural resources in the shape of 150 human beings a day who are not only subtracted from the productive efficiency of society, but whose going leaves added burden on society. A vast army of over half a million every year, which to the unbiased onlooker seems sorely in need of conservation as a natural resource of great value to society, is not easily placed. No amount of legislation or inspection, or safety devices will prevent there being accidents, and consequently uncompensated loss to society. The loss must be paid for in some way. In the very nature of things it must fall on the employer, the employe, the families of the employe, or the general public.

The law of the land makes division of this loss as between the employer and employe; the law of necessity performs the same function as between the family and the public. All of the load that cannot be put on the employer falls on the employe and his family. If they have no means, the public must carry the load through our poor houses and charitable organizations. Each one in the line from the public back to the employer tries to shift the burden to the next fellow, but so far the employer seems to have been the most successful in avoiding responsibility. The poor workman and his family gets it both going and coming; the employer will pay him no damages that he can avoid and the public will not take care of him until he begins to starve.

But you may ask, has the employe no rights at all? He has the best right in the world against the fellow servant whose negligence causes him injury. If that fellow servant happens to be a "Hunky," with no property, that is his misfortune; but it does not impair the injured man's right in the least. He has a beautiful right that is just as good as new, not worn a bit, though absolutely worthless.

There are many fire-escapes to save the employer from being burned in a damage suit, as most of you know from observation at least.

It is a matter of common knowledge that recoveries are had in court but for a very small per cent. of the accidents that occur. The injury or death of a workman is as certainly a loss to society as the burning of a machine is to its owner. Who stands the loss? If the workman can be made to carry the loss, it is on him. If he has no accumulations with which to carry it, then the proverbial impossibility of getting wool off a toad forces the load on to the next pair of shoulders, the public, otherwise known as society. The poor fellow must live and be supported, or die and be buried. Both cost money, and he has a family that cannot afford either.

You and I do not realize that the injury or death of a workman is any loss to us, until we see him and his family as wards of the county or subjects of charity. Then we see the money go and set up a howl.

That howl is resulting in more or less general enactment of two classes of laws, designed to throw the load back on the employer; first, safety appliances and inspection laws; and second, laws imposing liability either directly or indirectly upon the employer for injuries to and resulting death of employes. Laws of the first class either contain a specified penalty or liability for their violation, or the mere fact of the violation is construed to be negligence which renders the employer liable. With this you are familiar.

* Read before the Coal Mining Institute of America at Uniontown, Pa., June, 1910.

The second class of laws gives a right of action against the employer to the survivor or dependents of a workman whose death results from an injury received in his employment, a right which did not exist at common law; and in some countries, though not as yet in the United States, a right to compensation from the mere happening of the accident, irrespective of the question of negligence.

This is not based on any principle of natural right or justice, for there is no natural justice in compelling one man to pay for the misdeed of another. But it is founded purely on necessity, the supreme necessity of the state to protect itself against having the maimed and crippled and their dependents become public charges, and to place that burden upon the one who can best sustain it. It is the same reason exactly, before the law, for marriage, i. e., to fix responsibility for the support of offspring.

All attempts in this country to make the employer directly liable for injuries to his employe, irrespective of the question of negligence, have failed, generally, through being held unconstitutional by the courts. The Act of Congress of 1900 is a shining example. One of the high officials of this Institute encountered the same stumbling block some years ago before the Pennsylvania legislature.

Under a government like ours it seems impossible to get over—and pretty hard to get around—the Constitution in matters like this. But in monarchial governments they can and have gone to the root of the matter, and in a score or more foreign countries laws are in force providing compensation for industrial accidents.

The earliest form of this compensation was by mutual insurance. Insurance against industrial accidents can be traced back to the old trade guilds. It existed before 1600 in the Hartz Mountains in Germany. The first attempt to administer it through governmental agency was in Germany in 1861. Ten years later an employers' liability law was enacted, and in 1883 compulsory sick and accident insurace was added.

The system has been adopted in some form in 22 foreign countries. In some instances the compensation is paid by the government; in others by the government in part, and in part by the employers; in others by the employers alone; and in still others by the employers and employes in varying proportions. The administration of the indemnity funds is by insurance departments of the government, by mutual companies under governmental supervision, and sometimes by a board in which the employes have representation. The funds are raised by mutual contribution, by special taxes on the employers collected as other taxes, or in some instances from general taxation.

In a majority of the cases the benefits of the compulsory insurance are limited to workmen whose earnings do not exceed a certain amount per year, ranging from 720 marks ($138.96), in Finland, to £300 ($1,459.95), in Great Britain, and £400 ($1,946.60), in Queensland, the average being about $500.

The amount of indemnity paid is usually based on the amount of the workman's earnings for the preceding 1, 2, or 3 years. For partial disability they are usually paid hospital and surgical expenses and a percentage of their weekly wage for a limited length of time. For total disability the indemnity ranges from 50 to 100 per cent. of the actual or estimated wage of the preceding 1, 2, 3, or 6 years. In case the injury results in death the family or dependents receive from 40 to 60 per cent. of the earnings, with provision that the amounts paid shall in no instance be less than a certain minimum nor more than a certain maximum. In Sweden and New South Wales the indemnity is placed at a fixed sum for all, regardless of the previous earning capacity. And in substantially all countries a fixed funeral expense is allowed.

There are, of course, certain healthy limitations imposed upon both parties. An employe who wilfully injures himself cannot recover compensation, and where the injury is the result of his drunkenness the compensation is reduced one-half.

Where the injury results from the wilful act of gross negligence of the employer he loses the benefit of these acts, and where it results from violation of protective measures of the law the liability is increased.

In some countries the employer is exempt from all civil liability outside of the fixed legal compensation, except where the injury occurred through his intentional act; in others the common law liability remains, and the employe has the choice of which right he will pursue, the common-law right subject to the uncertainties of a law suit, or the statutory right, which is sure but limited.

Any agreement by the workman, as for example an agreement to release the employer from responsibility in case of accident, is absolutely void. And any attempt by the employer to load the cost of the insurance on the laborer, either directly or indirectly, is in some instances made a criminal offense.

In one instance the shyster lawyer got a black eye when the law fixed the fees that might be charged and invalidated any agreement to pay more. Another clog on crookedness is a provision that in case the employer goes into insolvency the indemnities that he may be bound to pay, for example, in the form of weekly payments, are capitalized and made a lien on the bankrupt estate.

Usually, and properly, the employer who has to pay an indemnity is subrogated to the rights of the injured employe as against third parties, and thereby he may sometimes be able to put the load on the one really to blame. In some instances where the workman gets a benefit from a society in which the employer pays a part or all of the dues, the indemnity to be paid by the employer is reduced proportionally.

That this system works, is proved by the extent to which it has been adopted. And their statistics show that the number of accidents has actually been decreased by the adoption of the system of universal compensation for injury, and also that the actual amount paid out is not as great in proportion as the cost of accidents in the United States.

In the United States there has been but little accomplished in this direction until within the last 5 years, and mostly within 2 years. The "fellow servant" defense has been modified or abolished in 35 states, counting the District of Columbia, the Philippines, and Porto Rico as states. This modification extends only to railroads and common carriers in 23 of those states. And the doctrine of "assumed risk" has been modified in nine states along the line of saving the right of a workman to recover who reports a defect and goes back to work before it is remedied.

A peculiar development of the last 2 years has been the introduction of a doctrine of comparative negligence in 14 states, whereby the amount recoverable is proportioned to the degree of culpability of the respective parties.

State supervision seems to have reached the limit in Illinois, where a law was passed last year requiring even the common miner to pass an examination before a state board and obtain a certificate before he will be allowed to work in a mine.

In Pennsylvania both legislative enactment and judicial interpretation have stood steadfast against any lightening of the perils of labor or increasing of the burdens of production. But a few of the states have at various times attempted to obtain compensation for all workmen who are injured in the course of their employment. A number of years ago Maryland passed a compulsory industrial accident insurance law, but before it drew its first long breath it was declared unconstitutional by the courts. Early in the present year a somewhat similar bill was introduced, which provides for indemnity for all industrial accidents from a fund provided by mutual compulsory contributions from employers and employes.

New Jersey attempted to reach the question indirectly by authorizing insurance companies to make special rates for associations of employes of one employer.

Two states, one in the East and one in the West, have been notable in the past year for legislation along this line, Massachusetts and Montana. Under the Massachusetts act either the employer or 10 per cent. or more of his employes may submit to the Board of Conciliation and Arbitration a plan of compensation for injury received in the course of employment, without reference to legal liability, based upon a percentage of average earnings, and, when approved, the employer and employe may contract that the benefits provided by this plan shall be in lieu of all legal right of action. This is purely voluntary.

In Montana, the act requires all workmen, laborers, and employes employed in and around any coal mines, etc., to be insured in accordance with the provisions of this act, against accident occurring in the course of their occupation. To pay this a fund is raised, under the control of the auditor of the state, from a tax of 1 cent a ton on all coal mined, and 1 per cent. of the gross wages of the employes, to be deducted by the employer and paid over. The amount of compensation provided is $3,000 to the family or dependents in case of death, and not to exceed $1 per working day for permanent disability. Acceptance of benefits under this act bars action for damages, and the commencement of an action forfeits all claim to benefits.

A particularly encouraging development of the past few months is a voluntary indemnity plan adopted by the United States Steel Corporation and the International Harvester Co., which disregards all question of legal liability, does away with "contributory negligence," "assumed risk," and the "fellow servant" doctrine, and compensates every employe injured while at work.

Under the corporation plan the relief is greater for married men than for single, and increases according to the number of children and length of service. During temporary disablement single men receive 35 per cent. of their wages, and married men 50 per cent., with an additional 5 per cent. for each child under 16, and 2 per cent. for each year of service above 5. For permanent injury a lump payment is made, based upon the extent to which the injury interferes with employment, and also upon the annual earnings. In case of death the widow and children receive 1½ years wages, with an additional 10 per cent. for each child under 16 and 3 per cent. for each year of service above 5.

The Harvester company's plan calls for a payment equal to 3 years average wages, in no event less than $1,500 or more than $4,000. For loss of a hand or foot, 1½ years wages, not less than $500 or more than $3,000. For loss of both hands or feet, or one hand and one foot, 4 years wages, but in no event less than $2,000. For temporary disability, one-fourth wages for 30 days, one-half wages beyond that for 2 years, and a pension if the disability continues total.

If a few individual corporations do this through a dawning consciousness of the duty resting on the "brother's keeper," if one state can pass a law to accomplish the same result—which pray God the courts may sustain—if employers' accident insurance, the cost of which is based upon the pay roll, can make a profit out of this traffic in the blood of the workman, surely it is but a short step to a universal indemnity law. Every up-to-date employer carries employers' accident insurance. What possible difference can there be practically whether he does this voluntarily, at a profit to the insurance companies, or under the compulsion of the law and saves the profit?

To be sure, the insurance company may fight the poor devil who is injured to the last ditch of litigation, and pay as few losses as possible; but statistics in foreign countries show that even that process costs more in this country than their system of universal compensation at a fixed moderate rate.

It would seem to be more than a hair-brained phantasy that we can subserve the ends of justice and equity toward the injured, the protection of society from possible charges upon it, and do this with less derangement of existing con-

ditions and more effectively, by a system of universal indemnity at a definite rate. Whether this be accomplished by government indemnity, by compulsory employers' liability, by mutual insurance, or in any other way, is a purely incidental matter. The main point is the certainty of compensation and the consequent security and protection not only to the injured, but to society. It may be ideal; it certainly is not an unapproachable

Fig. 1. Corner of Mine Room, Jeffrey Exhibit

ideal; and it seems to be an ideal of which social necessity demands the speedy realization.

In order that you may know just how the law distributes this particular portion of the cost of production represented by the lives and limbs of the employes, it may be well to state in general terms and in a very untechnical way the legal liability of employers for injuries to their employes.

The English common law lies at the foundation of our doctrine of employer's liability, but its principles have been so differently interpreted by the courts and modified by the legislatures that there is nothing approaching unity in the law as it stands today.

In the earlier days the whole risk of the employment was deemed to be assumed by the employe. You say at once, that is an unfair imposition. Is it? Last week the lightning struck your chimney and knocked the top off. Before you went to work you hired two men to top it out again. While you were in the mine the mason carelessly let a brick slip and it hit the hod carrier and broke his leg. Are you to be obliged to pay the hod carrier for that carelessness of the mason? But you quit work at night and started up the shaft, and the engineer carelessly lost control of the hoist and allowed the cage to drop, and you got your leg broken, and you were mighty glad it was not your head. Is there any more reason why the company should pay you for your broken leg? To the average intelligence it would seem just that the one whose negligence caused the injury should be held responsible for it. Therefore the earlier interpretations of the law imposed all the risks of the trade upon the employe.

But gradually there developed an idea that the employer owed certain duties of protection to the employe, and the original law has been modified to the extent of requiring the employer to afford such protection to the employe as a working place, tools, appliances, materials, etc., that are reasonably safe for the intended use and reasonably well adapted to perform the work in contemplation.

And he must use the same degree of care in the maintenance and repair of those appliances, and therefore he must make inspection adequate to discover the need of repairs or the lack of safety conditions.

In the same way he must use that care in the selection of his employes that he bestows on the selection and maintenance of the inanimate and irresponsible instrumentalities of the business; and the employment of workmen of improper age, habits, morals, or practices may charge him with liability for accident resulting through them.

It is also his duty to provide and enforce proper and adequate rules for the conduct of the work, and to give inexperienced workmen instruction and warning as to the hazard of their employment.

When a man enters into a contract of employment, the law imports into that agreement the assumption by the employe of the risks ordinarily incident to the employment, and such other risks as are known to and appreciated by him. This is on the theory that if he is competent to do the work, he must understand the conditions under which it is carried on and therefore takes the chances and is bound by the result.

MINING INDUSTRIAL EXPOSITIONS

Written for Mines and Minerals

Permanent and portable industrial expositions are so common they receive little attention except in the towns where they are held. Within the past year there have been several expositions in which the displays of mining machinery and apparatus attracted widespread interest. Meyers & Whaley introduced their coal-loading machine for the first time at the Appalachian Exposition, and the Jeffrey Mfg. Co. their Armorplate locomotive at the Western Pennsylvania Mining Exposition. It would appear as if manufacturers and others were inclined to use these expositions as "coming-out" functions in mining-machine society. The brain work and money expended in arranging the reception rooms in which the functions are held appeals undoubtedly to the decorator, and the display is a matter of pride for the exhibitor, who expends money lavishly that his product may be well furbished.

In the Western Pennsylvania Mining Exposition the Jeffrey Mfg. Co. placed their mining machinery in an artificial coal mine which had a built-up coal face 45 feet long and 6 feet high, and altogether their exhibit occupied a floor space 100×30. The coal face shown in Fig. 1 is masonized to represent as close as it was possible an artificial rib constructed from the Hazel Mine coal of the Pittsburg-Buffalo Coal Co. In this the shortwall electric coal cutter, in charge of a demonstrator, made an undercut. At the left of this machine was a self-propelling steel truck equipped with an automatic cable reel that winds up the electric cable as the truck moves out of the room. This coal cutter was unloaded from the truck by its own power, made the sumping cut at the right-hand rib and a cut across the face until the left-hand rib was reached. A steel feed-cable,

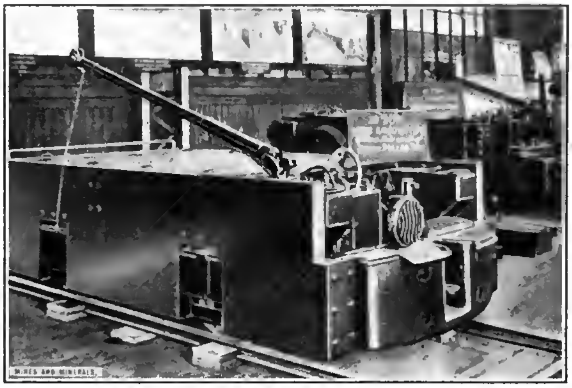

Fig. 2. Armor Plate Locomotive, Jeffrey Exhibit

wound on a power-driven drum at the front end, but not shown, pulled the machine across the face of the coal at a speed regulated by the hardness of the coal in which the cut was made. Another cable which had no connection with the power served as a guide to hold the machine to its work at a proper angle for its greatest cutting efficiency.

When the machine finished the cut it was loaded on to the truck with its own power. The narrow cutter head and short distance from the machine to the coal face appealed mostly to those who are obliged to undercut coal pillars that have a tendency to come down when undercut by hand. In order to show the regular electric chain mining machine, that also was set up as shown in Fig. 3. The flame and gas-proof motor and starting box on this machine was new to some and interested those whose mines generated small quantities of gas. To the left of this coal cutter was an electric auger drill, and to the right an air-driven auger drill attached to a small motor-driven air compressor by a hose. The coal cutter and electric auger were explained and operated by the demonstrator.

Another interesting exhibit in this section was the 13-ton electric mine locomotive, with its frame made of armor-plate

Fig. 3. Chain Mining Machine at Work, Jeffrey Exhibit

steel, and its sides and ends made of rolled steel, the object being to strengthen the machine so as to withstand the heaviest kind of service.

Two other Jeffrey locomotives shown at the exhibit were built with structural-steel frames and equipped with motor capacity sufficient to slip the wheels and to stand continuous mine service. Each of these locomotives had mounted on the front end an independent motor-driven crab, having a drum to hold 300 feet of $\frac{3}{8}$-inch flexible steel rope. Daily demonstrations were made with this crab device which hauled pressed steel cars from one end of the room to the other end, to show how loaded mine cars are pulled from the face of the mine room while the locomotive remains in the entry.

On the wall back and above the exhibit were a number of photographic reproductions showing the Jeffrey machines and locomotives in various situations in large mines all over the country.

UNITED MINE WORKERS' EXPENSE ACCOUNT

The cost of strikes met by the international organization of the United Mine Workers in the past 11 years is stated as follows:

Year 1900	$ 144,462.50
Year 1901	202,202.71
Year 1902	1,834,506.53
Year 1903	301,922.44
Year 1904	1,065,435.47
Year 1905	753,626.02
Year 1906	805,599.92
Year 1907	105,045.57
Year 1908	744,897.19
Year 1909	600,267.39
Year 1910	1,532,020.42
Total	$8,089,986.16

A statement by districts shows that the enormous sum of $1,286,031.32 has been spent in the unsuccessful effort to organize in Alabama, $968,775 in Nova Scotia, $707,676.45 in Colorado, and $669,938.81 in West Virginia.

"To the $8,000,000 spent by the international organization," adds Mr. Lewis, "must be added the hundreds of thousands of dollars contributed by our members to the districts, and spent for the same purpose. If you will examine these two statements, you will discover that where we have spent the most money, in support of strikes, is where we have the least membership."

BAVARIAN GRAPHITE INDUSTRY

By George Nicolas Ifft, Nuremberg

The incorporation at Munich of an association for the development of Bavarian graphite deposits calls attention to an industry which for several centuries has been carried on in a remote corner of Germany, and according to methods as primitive today as they were 300 years ago.

In the Bavarian forest northeast of Passau, are found deposits of graphite, which is especially adapted to the manufacture of crucibles. In this respect, only the Ceylon graphite and certain graphite found in the United States, it is claimed, is equal to the Bavarian product.

That graphite deposits, presumably so valuable, have heretofore played so unimportant a part in the industrial life of the country is largely due to the fact that the mineral is the property of the owners of the land upon which the deposits are found. The graphite deposits are thus owned by innumerable small farmers, who mine it according to individual ideas and in the crudest manner, through shallow surface diggings, and mostly only in the winter months as a side issue to farming, forestry, or laboring. The mining so far has been little more than grubbing about on the surface, the ore being found in pockets, when a cellar or a shallow excavation is made by the farmer who happens to own the land. No one has ever gone to any depth for the ore or tried to mine it systematically. The ore is found in an out-of-the-way and primitive district without railway communication. A branch railway from Passau into this section, however, is now in course of construction, and already a number of the land owners at Pfaffenreuth have pooled issues and are preparing to inaugurate graphite mining in a more systematic manner, if still on small scale. How trifling has been the work in the past is illustrated by the total production of graphite ores from this district during the past years; as follows:

Year	Tons	Value	Year	Tons	Value
1905	4,921	$49,703	1908	4,844	$58,907
1906	4,055	46,092	1909	6,774	63,272
1907	4,033	47,921			

This seems to show a steady increase in production, but the average is not above that of the preceding five years. It represents work on 50 to 70 farms and employment for part of each year of 200 to 300 men. The ores run 10 to 25 per cent. pure graphite, averaging about 15 per cent. It is expected that modern methods of refining and handling will increase this average materially.

The new company which has just been organized will make the first attempt at systematic mining in this district. For the beginning it has secured control of about 750 acres of graphite land in the so-called Rampers, Haunersdorf, and Taubinger districts. It has also options running until 1917 upon about 1,500 acres more in the same and neighboring districts. The company estimates a minimum production for the first year of 13,500 tons of graphite ores. It will begin work with a force of about 450 men.

During the year 1909 Germany imported 29,191 tons of refined graphite, 9,080 tons of which were from Ceylon and 14,512 tons, a much inferior product, from Austria-Hungary. The new company hopes to be able to supply in a large measure the German demand for graphite for crucible purposes and at the same time develop a considerable industry and a new source of wealth in a remote and sparsely settled section of the Bavarian forests.

DATA OF PETRODYNAMICS

By R. Dawson Norris Hall, Consulting Engineer, Du Bois, Pa.

Of all the overlying coverings of mineral bodies, the weakest are those consisting of sand, loam, or clay, which often have practically no cohesion.

Flow of Loose Measures. Contraction of Volume of Clay After Settling in Water and Drying

Sand has its greatest strength when moderately wet; when dry, it runs freely if it be piled at an angle exceeding 30 degrees; when very wet, it is a "quicksand," the word well expressing its liveliness and fluidity.

Loam and clay on the other hand, become cemented on drying and stand at a steeper angle, depending on the relative quantities of their constituents and the strength of the binding cements.

While either open-cut or forepoling methods must be used in mining the minerals under such incoherent materials when they are found alone, it usually happens that a thin layer of rock will be found as the main covering of the mineral; but if this rock is badly creviced or becomes sheared in any way, the loose material, which rested upon it, will flow in and almost completely fill the mine workings, especially if there be water present, either in the loose material or supplied by some run or by an underground water channel.

These bodies of quicksand and bog are of recent formation, the remains of lakes, glaciers, and buried rivers. The water drains into such deposits, and where the geologic formation is a basin does not drain away from the loose material. Often no cements have made their appearance to create rocks out of loose shifting beds, or in the presence of so much water these fail to react or harden in such manner as to bind the measures they impregnate.

Such deposits may be very thick. The glacial drift in the states of Ohio and Michigan reaches in places a thickness of 300 feet. The Wyoming buried valley has deposits of incoherent sand 200 feet deep and the weight of this body of loose sand was the probable cause of the Pittston disaster. The flow of ice in the glacial period dammed back many of the streams, which till that time flowed northward, and later reversed their direction. Before this reversal, naturally, large bodies of water were impounded, in which were deposited thick beds of sand and slime, which are often not well cemented and compacted to this day. If such deposits are self-draining, they are well compacted; if not, they are still in a somewhat fluid condition.

The flow of quicksand, owing to the strength of the immediate covering, may not take place till after the final caving of the workings takes place. An instance has been reported to the writer, where a mine was worked up to and below the surface of a town lot. The pillars were withdrawn. No damage was done to the adjoining lot, which had not been undermined, but strange to say, a third lot, beyond the second, which also was not undermined, was seriously affected. A loose sand, on this lot, washed down into the cave under the property which had been undermined, passing beneath the stable intermediate lot without disturbing its surface.

How readily a quaking bog can move is well illustrated by the moving peat bogs of Ireland, which occasionally break loose from their moorings, engulfing houses and property. Wherever there are quicksands or bogs, there is a risk that the mining on one property will cause a sinkage on another neighboring to it, and the damage may be quite widespread. These quicksands and bogs are often covered by ground, which, being well drained, affords a fair foundation and good farming land. Moreover the sands and bogs may not be very "quick" until a cave permits the water to wash them down into the cracks and cavings beneath. It would appear that shafts sunk through quicksands or quaking bogs should have the protection of larger pillars than are provided for shafts in solid material. For whenever mining is completed around the shaft pillar and caving takes place, the flow of sand or bog toward that caving may threaten the stability of shafts, head-frame, and mine buildings. The same security might be insured by only mining out the mineral in part near a small shaft pillar as would be obtained by leaving a very much larger shaft pillar, so that a removal of silt around the shaft could not occur. The shaft workings will ultimately drain the water from the overlying silts of the region, and after that is thoroughly done the danger to the mine property will be reduced, as the dried silts are less likely to be engulfed.

But even if not one cubic foot of sand, clay, or loam does escape from its due place in the measures, yet nevertheless there may be such a loss of water as to result in a surface settlement. It is said that the cause of the weakness of the foundations of St. Paul's Cathedral in London, England, is to be found in the shrinkage of the London clay as a result of the building of the underground railroads, a work which has abstracted much water from that measure. The London clay, laid down immediately after the Cretaceous period, is in London only 64 feet thick, though in the vicinity it reaches 500 feet. It is a well recognized fact, that the lowering of ground water makes old foundations insecure, as the supports shrink from under them when the water is removed. Similarly when sand is drained, it furnishes a better foundation, than when wet, for any structure put on it after draining.

It might be well to examine the investigations of Seelheim, King, and Slichter, in this connection.

Seelheim[5], in an article on the methods of determining the permeability of bodies, that is, their power of permitting the transference of liquids and gases through their pores, has shown that when a mixture of very fine clay and water is allowed to stand quietly for some time, under conditions where no jarring can take place, the clay settles in layers, but contains a large amount of water. He found that, where no jarring took place, the upper layers contained more water than the lower ones; the proportion being one volume of clay to 3.84 volumes of water in the upper strata and one volume of clay to 1.78 volumes of water in the lower strata. That is to say in the loosest settling 79.34 per cent. of the volume of sediment was water and in the closer packing, there was still 64.03 per cent. of pore space.

Where the settling was caused to take place under frequent jarrings, Seelheim obtained a uniform texture throughout and a greater compactness but there was still a pore space of 54.54 per cent. He further showed that there was no sensible reduction of pore space when the sedimentation was caused to take place under the pressure of 102 feet of water instead of a few feet.

Prof. F. H. King[7], on behalf of the United States Geological Survey, has investigated the proportion of pores to clay in bodies of fine dry clay dropped into place in small lots, tamped and jarred, an operation which results, he has found, in greater density of clay than is obtained from simply pouring in mass, shaking and striking off the surface.

Prof. Chas. S. Slichter[8], also of the Geological Survey, has calculated the pore space resulting from placing rigid and true spheres of uniform size in contact with each other at various angles. Where true and equal spheres are placed immediately over one another in similar manner to the spots on a six-spot playing card but in close order, then the pore space is 47.64 per cent. of the whole and it will be noted that Professor King has found this to be the average space left in dry clay dust, tamped and jarred into place as above described. But it is not likely that we have here the limit of clay density from compaction. Sandstones very readily shake down to a porosity of about 36 per cent. and some even lower, even below the porosity given by Professor Slichter as the result of placing equal uniform spheres, set like the spots on an eight-spot playing card, only in close formation and with 12 points of contact between spheres. The lowest percentage of porosity found by Slichter, obtained as above set forth, was 25.95. Professor King obtained practical

porosities of 25.55 and 25.43 per cent. Here doubtless smaller spheres partly filled the pores between larger spheres.

It is not unlikely that under pressure clay similarly receives a further settling, and, moreover, a degree of distortion may well take place fitting the spheroidal or cubical units to those around them, which distortion after enduring for a long time may become permanent. For a tombstone, resting for years on a head and a foot-stone will bend and become set in its acquired shape so that the curvature is only slowly removed when the strain on the stone is reversed by turning it over. In final analysis, we find that clay only absorbs 8 to 15 per cent. of its bulk of water and passes little or none.

Clearly such a pore is not open or it would allow water to pass, and the clay also is far denser than any theory of elementary units of the nature of spheres and in mere point contact would indicate. True, part of the loss of pore space is due to coatings of these elementary units, the action of cementation and filling tending to continue till it has progressed so far that further penetration of water through the clay becomes impossible. It is therefore necessary to warn the reader of these remarks that the last line in the accompanying Table 1 would only furnish a valuable guide to the possible shrinkage from drainage and pressure alone, if the whole of the loss of porosity in clay could be ascribed to those causes.

Table 1. Showing Volumetric Shrinkages of Clay Slimes

Nature of Material	Clay : Water or Clay Pores	Water Space or Pore Space Per Cent.	Comparative Volume	Authority
Upper layer of subsided clay in water........	1 : 3.840	79.34	100.00	Seelheim
Lower layer of subsided clay in water........	1 : 1.780	64.03	57.43	Seelheim
Same after frequent jarrings............	1 : 1.200	54.54	45.45	Seelheim
Fine dry clays.......	1 : 11.000 to 1 : .818	50.00 to 45.00	41.32 to 37.56	King King
Perfect spheres of equal diameter closest arrangement...... ...	1 : .354	25.95	27.97	Slichter
Stiff clay..........	1 : .177 to 1 : .087	15.00 to 8.00	23.76 to 22.31	Fanning Fanning

It should be noted that the decrease in volume in a slime, especially when under pressure of overlying measures or other slimes, affects only the depth, unless the basin is small and has shelving sides. For the area of the stratum remains constant, only the depth varies for the weight will spread the slimes as fast as they shrink, so that the whole stratum remains continuous. The vertical shrinkage is equal to the shrinkage in gross volume.

A clay slime, 200 feet thick, will reduce to 50 feet and less, as a result of drainage, and though such a result is rare, for most bogs are more concentrated than Seelheim's upper slime, yet the figures above suggest what an action drainage has in shrinking roof coverings of mines and how even clays of great age may lose bulk by mining operations and let down the rock or surface with its buildings above them.

German and English investigations[10] have been made of the shrinkage in air of flint clays. A flint clay drying in air will shrink in all directions 5 per cent., so that it will measure linearly only 95 per cent. as much as before shrinkage. Its volume will be only as the cube of 95 or 85.74 per cent. The loss in drying is therefore 14.26 per cent., and this, if the clay were plastic, so as to give laterally with freedom, would reduce the thickness of the bed 14 feet 3 inches in every 100 feet of depth of measure.

A measurement of the iron ore deposits in what was once the channel of a running stream in a coal mine or of the sun cracks in a bog or road puddle will immediately convince us that the linear contraction of the deposit, bog, or puddle, from a condition, not of fluidity, but of incipient cohesion, to a state of partial dryness is not less than $\frac{1}{15}$ or 6.5 per cent. The volumetric contraction will therefore be not less than 18.25 per cent. Such a reduction in roof or floor of a mine would powerfully modify conditions.

CEMENT-LINED PUMPS AND COLUMN PIPES

Written for Mines and Mineral

Next to drilling and blasting the most important item of cost in mine operations is that of pumping water. The cost is increased by the acids and acid salts which are frequently found in the water in metal and coal mines. If sulphate of copper is in the water it will attack the pump and the pump-column pipes, replacing the iron of those pipes with what is termed cement copper, according to the reaction $CuSO_4 + Fe = FeSO_4 + Cu$. If sulphuric acid is in the water it will attack the iron of the column pipes and corrode them badly, according to the reaction $H_2SO_4 + Fe = FeSO_4 + 2H$.

In those mines where mineral salts are in solution it may be necessary to use column pipes of bronze which are not attacked by acid water so readily as iron pipes. The cost of these pipes, however, is high, and generally wherever possible wooden pipes or wooden linings are substituted. There are occasions when the cost of pumping water alone will be the most expensive item of mine operation, but this is one of the difficulties imposed by nature and can only be overcome by the use of drainage tunnels, which are not only expensive but would be impossible in many instances.

Where several coal mines are owned by the same company the cost of pumping may be reduced by having a central pumping station into which all the water is drained, and at these pumping stations large pumping plants are installed.* The evolution of mine pumps extends over a long period and has included almost every known means of raising water, from baling by hand and carrying the water in leather bags up a ladder, to more recent cement-lined electric-power pumps. Mine pumps, like every other class of machinery, should be made as simple as possible, owing to the fact that they are liable to be injured and do not have the same care that pumps on the surface would receive. They must also be constructed

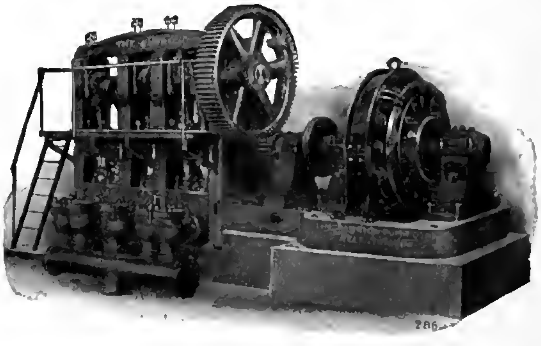

Fig. 1. Quintuplex Electric Pump

* Mines and Minerals, Vol. XXVI, page 205; *Ibid*, Vol. XXX, page 457

with a water end that will not corrode or be cut out by small particles of grit which are sure to pass through the valves in course of time. To prevent this latter trouble as much as possible there should be sand traps in the ditches leading to the sump which should be made large; and all chips and dirt, as far as possible, should be prevented from going into the sump; otherwise a snorer should be placed on the tail-pipe.

One of the latest power pumps for use in mines is shown

Fig. 2

in Fig. 1. This is a power pump driven by an electric motor. It has a number of features which add to its convenience and usefulness in mines, since its adoption eliminates steam-pipe lines in shafts or slopes leading to the pump which greatly affect the atmospherical conditions as well as the timbers and roof. It also eliminates the exhaust steam and the apparatus which is usually needed to condense the exhaust and which increases the temperature of the sump water. If the water is acidulous, an increase in temperature usually makes it more corrosive on pumps and column pipes. By the use of electricity and the electric pump with two or three wires the cost of pumping and the pump repairs has been reduced.

The Aldrich Pump Co., which specializes on electric mine pumps, has discovered a process of lining the water cylinder of its power pump so that water carrying as much as 75 grains of free sulphuric acid to the gallon seems to have little effect on the working barrels, where previous to its introduction a working barrel only lasted about 6 weeks.

The pump shown in Fig. 2 is the one under consideration and is working against a vertical height of 150 feet, pumping 1,000 gallons of water per minute. The pump shown in Fig. 1 lifts 1,000 gallons of water per minute 600 feet, high. It is installed in the coal mines of the Kingston Coal Co., Kingston, Pa. The water cylinders are cement lined and the plungers operated by a 200-horsepower motor. The Aldrich Pump Co. claims that its cement-lined pipes will give a service equal to that of bronze water pipes, and at the same time are very much cheaper to install.

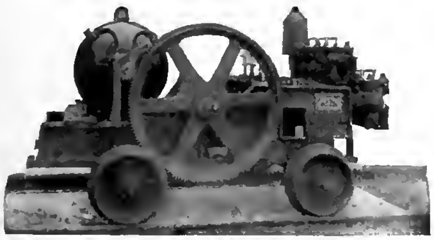

Fig. 3

In the anthracite region one company at least has had its triple-expansion wood-lined pump, that was manufactured by another company, relined with this cement. The cement lining can be applied to any type of water end without making special castings, and it can be applied to any surface whether spherical or not.

Fig. 3 shows a portable power pump whose water end is lined with cement. This pump will deliver 300 gallons per minute against 350 feet head, and is at work in the mines of the Consolidated Coal Co., Fairmont, W. Va.

Cement lining may be applied to column pipes and protect them from corrosion the same as the water cylinder, and it is claimed that it will give better service than wood lining in the same positions.

ELECTRIC CIRCUIT PROBLEMS

The application of electricity to mining operations is so varied and extensive that electric circuits form an important part of the equipment of collieries and some metal mines.

In mines, especially where electric haulage is used, the installation of a circuit costs more than the rest of the plant, and in addition is as expensive to keep up unless carefully watched. Fortunately the capacity and resistance to the circuit can be readily calculated; unfortunately the insulation can not, and becomes therefore a serious problem that can be solved only by the electrical worker on the spot. This is the more to be regretted, for the efficiency of the plant,

Fig. 1. Trolley-Wire Hanger in Roof

and in some cases the safety of miners, depends on the insulation. In Circular No. 23 of the United States Bureau of Standards and in the Report of the American Mining Congress Commission on the Standardization of Electrical Equipment in Mining, no mention whatever is made of trolley-wire hangers, which are about as important as any other part of an electrical haulage system. Wherever possible, the trolley wire must be placed to one side of the track, and the hangers may be fastened directly to the roof, to brackets, to overhead timbers, or in some other suitable way. In Fig. 1 is shown a Jeffrey electric locomotive pulling a coal train. In the illustration, the trolley wire is suspended from the roof by a combination of expansion bolt, hanger, and trolley clamp. One of the two methods of fastening the trolley wire to the roof is by means of a hole drilled in the rock in which is driven a wooden plug, and then by means of a screw the hanger is attached to the plug. While this may be slightly more economical, it is hardly so sure a support as the expansion bolt, and since safety and efficiency are more to be considered than slight economy in first cost, the latter is to be preferred. Both the screw and the expansion bolt terminate in a stud bolt to which the hanger shown in Fig. 2 is screwed. Apparently the hanger is a simple appliance and anything in that line would answer the purpose, when as a matter of fact it is the most important device entering into the trolley system of underground haulage. In the first place it is an insulator and in the second place it must support the trolley wire which has some weight

and considerable vibration. If these were the only considerations it would not be necessary to give the hanger such a complicated shape as that shown in Fig. 2. The Ohio Brass Co. has been making hangers a number of years and this is the outcome of their experience and not a mere guess. The skirt is constructed so that water will not trickle on to the wire to cause short circuiting; or if any does run over, it will on account of the double groove in the petticoat, fail to make connection. In some mines headroom is of great importance and this is minimized by the hanger being but 1½ inches in height. In high haulways this length adds strength to the connections. Inside the hanger the insulating material known as "Dirigo" cements the bolt in place and from the peculiar construction of the hanger cannot be worked out. Another feature is the hexagonal arrangement on the skirt which permits of quick attachment to the roof bolt and the use of a wrench. If this hanger is to be attached to a roof timber the mine hanger screw only is needed. In Fig. 3 is shown the hanger attached to the collar of a timber set. In such cases either the hanger shown in Fig. 2 or that in Fig. 4 may be used; in either case the fastening requires less careful attention and workmanship than when attached to the roof rock. Both lugs in Fig. 4 project far enough so that the skirt does not interfere with the 2½-inch lag screws by which it is fastened to the mine timbers. To the stud bolt pendant from these hangers the trolley clamp is attached. The galvanized malleable iron clamp, shown in Fig. 5, known as the Modoc trolley wire clamp, consists of a suspension casting,

Fig. 2. Screw Trolley-Wire Hanger

Fig. 3. Hanger Attached to Timber

a conical sleeve provided with a hexagonal nut for the application of the wrench when installing, and two interlocking jaws. All parts are held together by two lugs on one of the jaws which engage projections on the other. These jaws are intended to hold the parts together before installation and are not under strain when the clamp is in service. The height of the clamp is 2 inches, making it desirable for use in low-bed mines, while the length of the jaws being 3½ inches, a firm grip is had on the trolley wire. This clamp is also the product of the Ohio Brass Co., of Canton, Ohio, and has been designed by experienced men with a view to overcoming obstacles met with in practice.

The jaw castings are attached to the suspension casting by a flange at its lowest point and by revolving the conical operating sleeve, which is mounted upon it, the suspension casting is screwed upon the hanger stud bolt and draws the jaw castings over the conical portion of the operating sleeve which, in turn, causes a spreading action on the upper faces of the jaws and exerts a very powerful leverage or gripping upon the trolley wire.

It is possible to attach the clamp to the trolley wire just tight enough to hold the wire in position until it has been stretched.

The clamps can then be tightened permanently upon the wire and in perfect alinement with it, thus eliminating backing off the clamps to line them up, which is often necessary with other styles of clamps.

Fig. 4. Lugged Mine-Wire Hanger

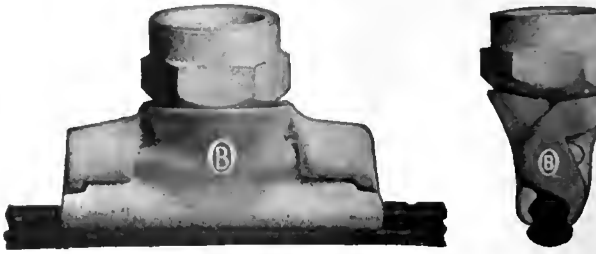

Fig. 5. Modoc Trolley-Wire Clamp

The clamp jaws are so narrow there is ample clearance for the flanges of the trolley wheel.

TRADE NOTICES

The Westfalia Engineering Co., of 42 Broadway, New York City, will keep in stock what is known as the Westfalia Rescue Apparatus. This agency is the only one authorized to give quotations, fill orders and supply duplicate parts.

Catalog No. 26 of the Jeffrey Mfg. Co., Columbus, Ohio, is on fans for ventilation of mines. It is worth owning.

The Sullivan Machinery Co., of Chicago, Ill., have opened a branch office at Spokane, Wash. Stocks of Sullivan machinery will be carried as in Seattle, Wash., and Nelson, B. C.

The Sanford-Day Iron Works, of Knoxville, Tenn., have manufactured a large double sheave drum that is said to be the largest in Tennessee and can be used on an incline 5,000 feet long. The main shaft is 7 inches in diameter, with 21-inch bearing on each side.

The New River Collieries Co., a subsidiary of the American Smelting and Refining Co., has placed orders for three coal tipples for their No. 1, No. 5, and No. 6 mines, at Eccles, W. Va. Each equipment is complete, consisting of "Link-Belt" dumping hoppers, shaking screens, picking bands, chutes, etc., and are excellent types of modern West Virginia tipple practice. The machinery—electrically driven—will be designed, constructed, and erected by the Link-Belt Co.

ANSWERS TO EXAMINATION QUESTIONS

Written for Mines and Minerals, by J. T. Beard

NOTE.—By special request of a number of subscribers the remaining questions of the last examination in the bituminous regions of Pennsylvania are answered at this time. The mine-foremen, second-grade questions of this examination were answered in MINES AND MINERALS in July, 1910, but owing to lack of space the first-grade questions and the fire bosses' examination were omitted.

Pennsylvania Bituminous Mine Foremen's and Fire Bosses' Examination Held April 5-8, 1910

MINE FOREMEN'S EXAMINATION

(*Second-Grade Questions.—Continued*)

QUES. 22.—What method would you adopt in drawing pillars in order to insure the greatest safety to the men and the most complete extraction of the coal?

ANS.—Much will depend on the kind of roof, floor, and coal; the thickness, depth, and inclination of the seam; and other conditions affecting the work. Pillar work should be done by experienced miners; the work should be kept in line, and places not allowed to stand idle; the roof should be carefully examined for fault lines and slips each day, and necessary timber be used to make the place safe. All posts should be drawn regularly as the work progresses and no timber be left standing in the waste.

QUES. 23.—Describe the kind of explosives best adapted to blasting different kinds of coal and rock, keeping in view the safety of the workmen.

ANS.—In any case, the size of the grain, which determines largely the quickness with which the powder acts, should be suited to the hardness of the material to be blasted. The smaller the grain the quicker the powder acts. Rock and hard coal require a quicker powder than a loose shale or soft coal. A deflagrating powder, as black powder, is slower and better adapted to blasting coal, while the detonating powders of the nitroglycerine class, as dynamite, are better adapted to rock. A quick powder breaks the coal too small and produces much fine coal and dust. Where the coal or adjacent strata contain gas, or the coal is friable and produces much fine dust, flameless powders should be used.

QUES. 24.—State in detail what should be done to remove or reduce to a minimum the dangers due to coal dust.

ANS.—Adopt a powder that is suited to the coal and allow no other powder to be used in blasting coal. Take proper precautions to avoid any excessive use of powder. Have all fine coal and slack loaded out with the coal, and permit no accumulations of fine coal and dust at the face. Use tight cars in the mine and do not overload them. Have the roadways cleaned regularly, and, if necessary, sprinkle them with water often enough to lay the dust. If the mine is dry and dusty, especially if some gas is present and the coal friable or highly inflammable, each place should be tested for gas and sprinkled before firing a shot therein. If necessary appoint competent men and authorize them to examine all shots and condemn any that, in their opinion, are unsafe. If the conditions further require, employ shot firers to examine and fire shots after the men have left the mine.

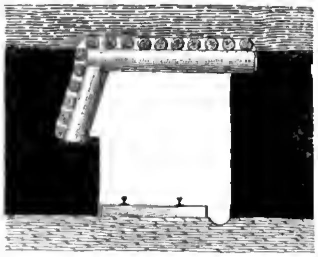

FIG. 1

QUES. 25.—What precautions would you use in timbering haulageways in a mine to prevent the timbers from being knocked out should cars leave the track?

ANS.—If the coal is firm and strong, short legs may be used to support the collars, the foot of the leg being set in a hitch cut in the coal, as shown in Fig. 1, or above the coal where roof slate is taken down to make headway for the cars. In some cases, no legs are used, but the ends of the collar are set in hitches cut in the coal, as shown in Fig. 2. When this is done one of the hitches must be cut so as to allow the stick to be ended into place and wedged. Where the coal is too brittle to support the timbers, long legs must be used standing on the floor, each leg being recessed into the rib beyond the reach of a derailed car.

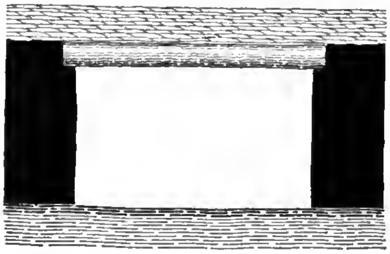

FIG. 2

QUES. 26.—If a water gauge of 1.2 inches produces a velocity of 500 feet per minute in an airway 6 ft. × 8 ft. and 1 mile long, what water gauge will be required to produce a velocity of 750 feet per minute in an airway of the same section and 2 miles long?

ANS.—The two airways being of the same section will have equal perimeters and areas, and, in that case, the pressure as shown by the water gauge will be proportional to the length of the airway and the square of the velocity of the current; or, in other words, the water-gauge ratio will be equal to the product of the length ratio and the square of the velocity ratio. Thus, calling the required water gauge x,

$$\frac{x}{1.2}=\frac{2}{1}\times\left(\frac{750}{500}\right)^2=2\left(\frac{3}{2}\right)^2=2\times\frac{9}{4}=4.5$$

and $$x=1.2\times 4.5=5.4 \text{ in.}$$

NOTE.—When a question is stated absolutely, as above, care should be taken that the statement is correct. As a fact, by the usual method of calculation and the average results of mining practice, it would require a water gauge of practically 3 inches to produce a current velocity 500 feet per minute in an airway 6 ft. × 8 ft. 1 mile long. Some candidates would calculate at once the required water gauge to produce a velocity of 750 feet per minute in the same airway, 2 miles in length, as follows:

$$\text{water gauge}=\frac{.00000002\times 10,560\times 28\times 750^2}{48}=13.3 \text{ in.}$$

which is the case practically, but is not the correct answer to the question asked. The question is unintentionally a catch question.—ED.

QUES. 27.—What method would you adopt for timbering a room having a tender roof when chain and puncher machines are to be used, to insure the safety of the workmen?

ANS.—Posts should be set in regular rows a specified distance apart, and the distance of the first row of posts from the face of the coal should not exceed this amount unless temporary lagging is used to support the roof above the machine. In order to allow the machine to move along the face, each post in the first row should be taken out in turn and reset as the machine passes the place. Sprags should be set or wedges be driven under the coal as the machine advances.

QUES. 28.—If an airway is 6 ft. × 8 ft. and 2,000 feet long and the velocity of the current 500 feet per minute, what is the power producing the ventilation?

ANS.—

$$H=\frac{.00000002\times 2,000\times 28\times 500^3}{33,000}=4.24 \text{ H. P.}$$

QUES. 29.—What general conditions would guide you in determining the width of rooms and the dimensions of room pillars?

ANS.—First, the maximum width of opening or width of rooms in a mine is determined by the depth of cover or roof pressure, the kind of the roof, floor, and coal, and the length of time the rooms must be kept open. The proper width of pillar is then decided, and depends on the width of the rooms, depth

of cover, kind of roof and floor, strength of coal, thickness and inclination of the seam. The length of room pillars will depend chiefly on the inclination of the seam and the requirements of ventilation.

Ques. 30.—Which method do you prefer, the timbering of the working places by the miners employed therein, or by practical timbermen employed for that purpose? Give reasons.

Ans.—Every miner should learn how to set a post where it is most needed, and be required to timber his own place; as this would make him more watchful and careful of his own safety. When a post is needed it should be set at once, and any delay is dangerous. The miner should do the work, because, if compelled to wait for a regular timberman, he would, in practically every case, continue to work in the danger and risk his life.

FIRST-GRADE QUESTIONS

Ques. 32.—In a mine giving off 2,500 cubic feet of marsh gas per minute the volume of air entering the intake opening is 4,500,000 cubic feet per hour; what is the percentage of gas in the return current? Would you consider this percentage of gas dangerous?

Ans.—Assuming that the temperature of the return air is the same as that of the intake, the volume of the return current of air and gas is $4,500,000 \div 60 + 2,500 = 77,500$ cubic feet per minute. The percentage of gas in this current is $\frac{2,500 \times 100}{77,500} = 3.22$ per cent. This would be a dangerous percentage of gas for general working conditions in bituminous mines.

Ques. 33.—Why is afterdamp a variable mixture?

Ans.—Because it is the product of the explosion of variable mixtures of gas and air, often involving quantities of fine coal dust and other gases than marsh gas. The products of the combustion (afterdamp) will depend on the kind of gases burned and the relative proportions of air and dust present. Hence, afterdamp is always a variable mixture, depending on conditions that are never wholly alike in any two cases.

Ques. 34.—What method of timbering and drawing timber would you adopt in pillar work to insure the best results in respect to both safety and economy; and when, where, and how would you instruct the workmen?

Ans.—In pillar work posts must be set as experience shows they are needed. No rule can be laid down, as the roof and pillar conditions vary widely. The condition of the pillar coal and the movement of the roof must be closely watched by the effect on the posts stood behind and about the workmen for their protection. Sufficient timber must be always on hand. Posts must be drawn regularly as the work proceeds so as to induce falls and relieve the roof pressure on the pillars. To draw posts the chain and dog should be used instead of trying to knock out the post with a sledge. The men should be instructed, before attempting the work, by those who have had experience, and this should be done at the time and place.

Ques. 35.—What method would you adopt in drilling, charging, and firing shots to insure the greatest safety to the workmen and the mine?

Ans.—The miners should drill their own holes according to their best judgment and experience. Each hole should be inspected and passed or condemned by a duly authorized and competent inspector before the same is charged. The inspector should determine the weight of charge to be placed in each hole at the same time, and make a full record of each examination. In most cases, no shots should be fired till a fixed time arrives, and then only in regular order of rotation beginning on the end of the air and proceeding toward the intake. Violation of this rule should be punished. Where the conditions require, all shots should be fired by shot firers after the men have left the mine.

Ques. 36.—Which gas diffuses the more rapidly, CH_4 or CO_2? Give the ratio of diffusion of these two gases.

Ans.—Marsh gas (CH_4) diffuses more rapidly than carbon dioxide (CO_2). The relative rates of diffusion of the two gases are expressed by the ratio

$$\frac{1}{\sqrt{8}} : \frac{1}{\sqrt{22}}; \text{ or } 1 : .603$$

in which 8 and 22 are the densities, respectively, of marsh gas and carbon dioxide.

Ques. 37.—What gases are commonly found in the bituminous mines of Pennsylvania?

Ans.—Marsh gas (CH_4), carbon monoxide (CO), carbon dioxide (CO_2), olefiant gas (C_2H_4), and hydrogen sulphide.

Ques. 38.—What instructions would you give shot firers before permitting them to enter upon their duties?

Ans.—Allow a sufficient time after the men have left the mine for the return air to become clear and free from dust. Ascertain that the air-current is traveling with its usual velocity. Begin work on the last of the air in each section or air-split of the mine. Examine each shot carefully, and do not fire a shot that appears to be doubtful or in any way unsafe. Never fire more than one shot at a time in a close heading or room, and always give time for the air to clear before firing a second shot in a close room. Where gas is generated it is necessary to test each place for gas before firing a shot therein.

Ques. 39.—Give the specific gravities of the gases common to the bituminous mines of Pennsylvania and state where each gas is to be mostly found.

Ans.—Marsh gas, specific gravity .559; found mostly where it issues from the coal or strata, or where it has accumulated in rise workings, or at the roof of rooms or entries. Carbon monoxide, specific gravity .967; found mostly in abandoned rooms and other badly ventilated places, or in the vicinity of gob fires, or where shots have been fired in a close room or heading. Carbon dioxide, specific gravity 1.529; found in low places, dip workings, and at the floor of rooms or entries that are poorly ventilated. Hydrogen sulphide, specific gravity 1.1912; rarely found in troublesome quantity, except in some damp low places where sulphide of iron (pyrites) occurs in the coal and the ventilation is poor.

Ques. 40.—When and where should regulators be used in conducting air-currents in mines?

Ans.—Regulators are required whenever the air is to be divided in other proportions than the natural division of the current as determined by the potential of each split. A regulator should be placed, if practicable, at the mouth of the split where the air is divided, but not on a haulage road.

Ques. 41.—What precautions would you take when driving entries through gaseous and faulted territory?

Ans.—Use only safety lamps and make a test before beginning each shift to ascertain the first signs of an increase or decrease of gas at the head of each entry. Any change in the percentage of gas for the same quantity of air passing would indicate a corresponding increase or decrease in the outflow of gas from the strata; and, in most cases, if this continued, it would indicate the near approach to a fault. To make such a test a sight-indicator should be used in a lamp burning a non-volatile oil. Volatile oils, as gasoline or naptha, heat in gas and do not, on this account, give reliable readings. It is well, also, to keep a drill hole, say from 3 to 5 yards in advance of the face of each heading, and watch closely for any increase in amount of water draining from the strata.

Ques. 42.—Describe in detail what examination you would make before firing shots.

Ans.—Always examine the place for gas, both at the roof and in any places not reached directly by the air-current. Observe also if the usual quantity of air is passing, and that the same is fairly clear or free from dust. See that all tools and powder are removed to a safe place and that there is no accumulation of fine coal and dust in the vicinity of the shot.

FIRE BOSSES' EXAMINATION

Ques. 1.—When and where would you expect a sudden inflow or outburst of explosive gas, and how would you guard against danger therefrom.

Ans.—When driving headings or rooms to a fault line or toward abandoned workings, or when drawing back pillars, or during a heavy squeeze or creep, or accompanying a heavy fall of roof. To guard against this danger safety lamps should be used exclusively when driving rooms or entries in faulted strata, or drawing back pillars, or when approaching abandoned workings, or during the progress of a mine squeeze, if there is any reason to suspect gas being in the strata. The danger arising from heavy roof falls is best avoided by reducing the amount of standing area by drawing timber and allowing worked-out places to close.

Ques. 2.—What precautions would you take with your safety lamp before entering the mine, and how would you proceed with its use in the mine to insure the greatest safety?

Ans.—The lamp should be thoroughly cleaned, filled, and trimmed, the gauzes examined, and the parts put together carefully. If possible, before being taken into the mine, the lighted lamp should be tested by exposure to an explosive atmosphere in a box or test chamber so arranged that the lamp can be observed during the test. When using the lamp in the mine, it should be held erect, should not be swung or allowed to fall. The lamp should be observed constantly, and the flame should not be carried too high, or the lamp allowed to smoke. It should not be exposed to gas longer than to determine the kind and amount of gas present; it should be carefully shielded from a strong air-current or blast. In case the lamp flames, it should quietly but promptly be lowered and removed from the gas. No quick motion should be made.

Ques. 3.—What qualifications, other than those required by law, are necessary to make a good, efficient fire boss?

Ans.—The fire boss must be intelligent, faithful, and conscientious in his work; must have a good theoretical and practical knowledge of mine gases and their behavior in mines, the atmosphere, and the effect produced in mines by changes in atmospheric pressure, temperature, and moisture; the principle, construction, and use of the safety lamp, barometer, anemometer, water gauge thermometer, and hygrometer, in mining; the principles of mine ventilation, and the means and methods of generating and conducting air-currents in mines.

Ques. 4.—When does a safety lamp become unsafe?

Ans.—When the lamp is not clean, or not properly put together, or has been injured in some part, or is improperly or carelessly handled by an incompetent person; when exposed to a strong air-current, or allowed to fall, or is swung, or carried too rapidly against the air, or exposed for too long a time to gas; and lastly, when the lamp is improperly designed.

Ques. 5.—What protection is secured in a mine worked exclusively with locked safety lamps that cannot be expected in a mine worked exclusively with open lights?

Ans.—The mine using safeties exclusively is protected against sudden outbursts of gas due to a heavy fall of roof, or the sudden tapping of a large feeder, or a sudden fall of barometric pressure where large abandoned areas exist containing gas. Such a mine is also protected against the sudden disablement of the fan or other means of ventilation.

Ques. 6.—Name the gases usually found in bituminous mines; state where they are found, and give briefly their injurious effect on the workmen.

Ans.—This question is partly answered in reply to Ques. 37 and Ques. 39 of the mine foremen's examination. Marsh gas has no injurious effect when mixed with air and breathed, but is injurious by reason of its inflammability and because it forms an explosive mixture with air. Carbon monoxide and hydrogen sulphide are each extremely poisonous when breathed, even in small quantities; they are also, like marsh gas, inflammable and explosive in air. Carbon dioxide is not poisonous but suffocates when breathed in sufficient quantity.

Ques. 7.—When, where, and how would you instruct the men as to the use of danger signals to get the best results?

Ans.—All men should be informed and instructed as to the use of danger signals before they are allowed to enter the mine. This should be done as far as possible at the mine before they enter; but in order to make these danger signs and signals better understood by all, they should be further explained and their operation shown underground and before beginning work.

Ques. 8.—Could an explosion occur from a sudden outburst of marsh gas under a high pressure; and, if so, under what circumstances?

Ans.—A sudden outburst of marsh gas in any part of a mine often fills the adjoining workings with an explosive atmosphere before the men can be notified to put out their open lights and withdraw. Where open lights are used it is possible that an explosion may occur under these circumstances.

Ques. 9.—If an explosion occurred in a safety lamp, or if the lamp should suddenly fill with flame, what would you do to insure your safety?

Ans.—Lower the lamp promptly but slowly to the floor; and, if possible, if the flaming ceases, withdraw quietly carrying the lamp low and making as little commotion as possible. If the lamp continues to flame after it is on the floor, it may be possible to smother the flame by wrapping the lamp in a coat; but this must be done carefully to avoid forcing the flame through the gauze by the wind caused in folding the coat about the lamp.

Ques. 10.—As a fire boss, what instruction would you give the men in your section in regard to the use of safety lamps, assuming they are not familiar with the same, and when and where should such instructions be given to secure the best results?

Ans.—A safety lamp should never be given to a man till he has been made fully acquainted with all the points mentioned in reply to Ques. 4, which instruction should be illustrated practically with a lamp. This should be done at the mine before entering, and special attention should be given these men underground by the fire boss till they understand fully how to handle and use a lamp.

Ques. 11.—What duties should be assumed by a fire boss, acting as assistant mine foreman, while on his second visit through the mine or any part thereof?

Ans.—On his second visit he should carefully inspect each working place to see that the same is properly timbered, a sufficient amount of posts and caps on hand, the coal properly mined and spragged, the lamps used properly, and the place properly ventilated, etc.

Ques. 12.—Are you in favor of mixed lights in a mine? Give reasons for your answer.

Ans.—No. Because the conditions requiring the use of safeties often arise suddenly and without warning; and because an accumulated body of gas may be suddenly disturbed by a heavy fall of roof or by a windy shot, or other cause; and render the mine air in that vicinity explosive. Moreover, the general miner is too willing to run risks with open lights that expose himself and others to grave danger. If the conditions require the use of safeties in any section of a mine, they should be used exclusively in that section.

Ques. 13.—In testing for explosive gas, how would you satisfy yourself that there was not sufficient gas to indicate its presence on the flame of a lamp?

Ans.—The more sensitive test is to lower the flame to the smallest possible size and elevate the lamp slowly to the place where the gas is suspected or may be found. Some prefer testing with the normal flame. Good eyesight is required and the eyes must be screened with the hand to detect the first indication of gas. Many fail to detect gas when present, because they proceed hastily and disturb the gas too much before the

test can be made, and then pass on, leaving the gas undetected, while more deliberation would have revealed its presence. The best and surest test is with the sight indicator, which shows clearly the exact condition without guessing.

Ques. 14.—Do you think it advisable to report gas on the fire bosses' record book when you would have to hold your safety lamp against the face of the coal to detect it, and could not get a showing in the lamp by holding it up to the roof?

Ans.—Under the present system, to report "gas" in a working place would mean a dangerous quantity of gas, and would debar men from working there till the danger was removed. Therefore, the report should only show the finding of sufficient gas to make the place unsafe for work. Where extra caution is required, owing to a free outflow of gas from coal or strata, or from lack of efficient circulation of air at the face, or other cause, the report should show such condition. Every fire boss should be equipped to show the exact gaseous condition in every place examined. On his second round he should give this matter closer attention than he is able to do when making his first early morning examination, because it is when the mine is working that the greatest danger exists. The fire boss should keep his own private record showing the exact percentage of gas each day at certain points in the mine

Catalogs Received

In writing for catalogs, please mention Mines and Minerals

The Jeffrey Mfg. Co., Columbus, Ohio, Catalog No. 26A, Jeffrey Mine Fans, 36 pages.

Allis-Chalmers Co., Milwaukee, Wis., Bulletin No. 1432, Stamp Mills and accessory machinery for free-milling gold ores, 60 pages

The Bristol Co., Waterbury, Conn., Bulletin No. 152, Bristol's Patent Steel Belt Lacing, 12 pages.

The Cutler-Hammer Mfg. Co., Milwaukee, Wis.. Elevator Controllers, Schureman Types, 63 pages.

De Laval Steam Turbine Co., Trenton, N. J., Catalog A, De Laval Steam Turbines, Single-Stage Type, 120 pages.

S. Flory Mfg. Co., Bangor, Pa., Flory Hoisting Engines, Steam and Electric, 120 pages.

General Electric Co., Schenectady, N. Y., Bulletin 4685, Belt-Driven Alternators, 12 pages; Bulletin 4804, Direct-Connected Generating Sets, 12 pages; Bulletin 4810, Portable and Stationary Air Compressor Sets, 8 pages.

New Inventions

Complete specifications and drawings for any of the following patents can be obtained from the Commissioner of Patents, Washington, D. C., at the following rates

Single copies	5 cents each
Copies by subclasses	3 cents each
Copies by classes	2 cents each
At entire set of patents	1 cent each

Patents Pertaining to Mining Issued January 3 to January 31, 1911, Inclusive

No. 980,776. Drill coupling, Martin Hardsocg, Ottumwa, Iowa.

No. 980,196. System of mining coal, Charles Arnold Cabell, Carbon, W. Va.

No. 980,244. Ore classifier, John P. Ginivin, Seattle, Wash.

No. 980,202. Ore concentrator and sliming table, Christopher A. Christensen, Portland, Ore.

Nos. 980,890 and 980,891. Process for dry ore separation, William W. Bonson, Dubuque, Iowa.

No. 981,344. Coke and gas oven, Louis Wilputte, Joliet, Ill.

No. 981,170. Method of preventing mine explosions, John W. Coleman, Maybeury, W. Va.

No. 981,226. Mine roof support, James Gardner Sanderson and Clarence B. Sturges, Scranton, Pa.

No. 981,243. Mining bit, William W. Bittenbender and Elias G. Bittenbender, Nanticoke, Pa.

No. 981,201. Method of mining coal, Harry A. Kuhn, Pittsburg, Pa.

No. 981,306. Mining tool, James Pollock, New York, N. Y.

No. 981,230. Apparatus for classifying and concentrating ores, Rene Emile Trottier, Hussein-Dey, France.

No. 981,172. Sand trap for pumps, Rudolph Conrader, Erie, Pa.

No. 981,073. Chemical shot firer, John Dowd, Chicopee, Kans.

No. 981,732. Leveling ram for coke ovens, Louis Wilputte, Joliet, Ill.

No. 981,908. Safety mechanism for mine cages and elevators, Thomas G. Baird, Ladd, Ill.

No. 982,095. Safety appliance for mines, Henry William Scheiler, Lawndale, Ill.

No. 981,681. Centrifugal ore-separating apparatus, Philip F. Peck, Tacoma, Wash.

Nos. 981,679, 981,680 and 981,682. Centrifugal ore-separator, Philip F. Peck, Tacoma, Wash.

No. 981,880. Process for roasting sulphide ores, Charles W. Renwick, Isabella, Tenn.

No. 982,765. Apparatus for determining water in coke, etc., James A. P. Crisfield, Philadelphia, Pa.

No. 982,625. Spraying mechanism for coke ovens, Thomas J. Mitchell, Uniontown, and James A. McCreary, Connellsville, Pa.

No. 982,590. Apparatus for quenching, screening, and loading coke, Albert Goodall, Spennymoor, England.

No. 982,612. Miner's lamp, George Laws, Philipsburg, Pa.

No. 982,583. Hydraulic classifier for ores, James N. Flood, Denver, Colo.

No. 982,243. Desulphurizing apparatus for refractory ores, Charles Anderson Case, New York, N. Y.

No. 982,245. Process for reducing and desulphurizing refractory ores, Charles Anderson Case, New York, N. Y.

No. 982,983. Gas burner for coke ovens, Robert Muller, Essen-on-the-Ruhr, Germany.

No. 982,899. Crushing machine, Josiah E. Symons, Chicago, Ill.

No. 982,785. Ore concentrator, Samuel K. Behrend, Denver, Colo.

No. 983,067. Ore pulverizer, John J. Knight, Alameda, Cal.

Nos. 983,068 and 983,069. Tube mill, Povl T. Lindhard, New York, N. Y.

Mines and Minerals

Vol. XXXI—No. 9. SCRANTON, PA.—APRIL, 1911—DENVER, COLO. Price, 25 Cents

THE PECK'S SHAFT BREAKER

Written for Mines and Minerals, by E. B. Wilson

Process of Preparing Anthracite by a Combination of Wet and Dry Methods

It has been the custom in the Lackawanna anthracite field of Pennsylvania to prepare coal by the dry process, while in the Middle and Schuylkill anthracite fields it has been the custom to use the wet process. One of the most up-to-date breakers in the Lackawanna valley is that at the Peck's shaft of the Mt. Jessup Coal Co. at Peckville, which combines many of the approved old and new features in breaker construction, and has adopted both the dry and the wet preparation of coal.

In addition to this improvement, the old method of hoisting the coal to the top of the breaker in cars, then dumping, has been discarded, and the new method of dumping at the surface and using an inclined conveyer substituted. Another of the many features worthy of particular notice is the absence of revolving screens—there not being one in the building—that style having been discarded for the shaking variety. The toothed rolls are made of manganese steel and in segments, not individual teeth. At first the advantage of this move is not so apparent until it is understood that the manganese teeth are less liable to breakage and continue to remain sufficiently sharp to crack the coal long after the replaceable steel tooth has dulled and commenced to pulverize the coal. The economy of throwing away an entire segment of manganese steel when a tooth becomes broken, where in the older style roll it is only necessary to knock out a tooth and replace it with another at first seems doubtful. The economy is figured out as follows: The teeth of a manganese roll do not break, but wear uniformly; the labor involved in removing and repairing a broken tooth frequently costs more than a segment, which can be placed in a short time; finally, the wear is greatly in favor of manganese, not to mention the better cracking ability of the solid tooth.

All coal previous to going to the boy slate pickers passes through one of the two kinds of spiral pickers. The wet coal goes to a picker designed for the purpose, while the dry coal goes to another kind. It can be readily understood that wet coal will slide on an incline differently from dry coal, and this difference is sufficient to require special construction for wet-coal spiral pickers. At this breaker the jigs are run on the bony coal that comes from the slate pickers.

The advantages to be derived from the wet preparation of coal are as follows: Dust is kept down; the mechanical separation of coal and impurities is readily performed through the medium of water; and finer material can be treated than by the dry process, since by the abundant use of water the screens do not clog.

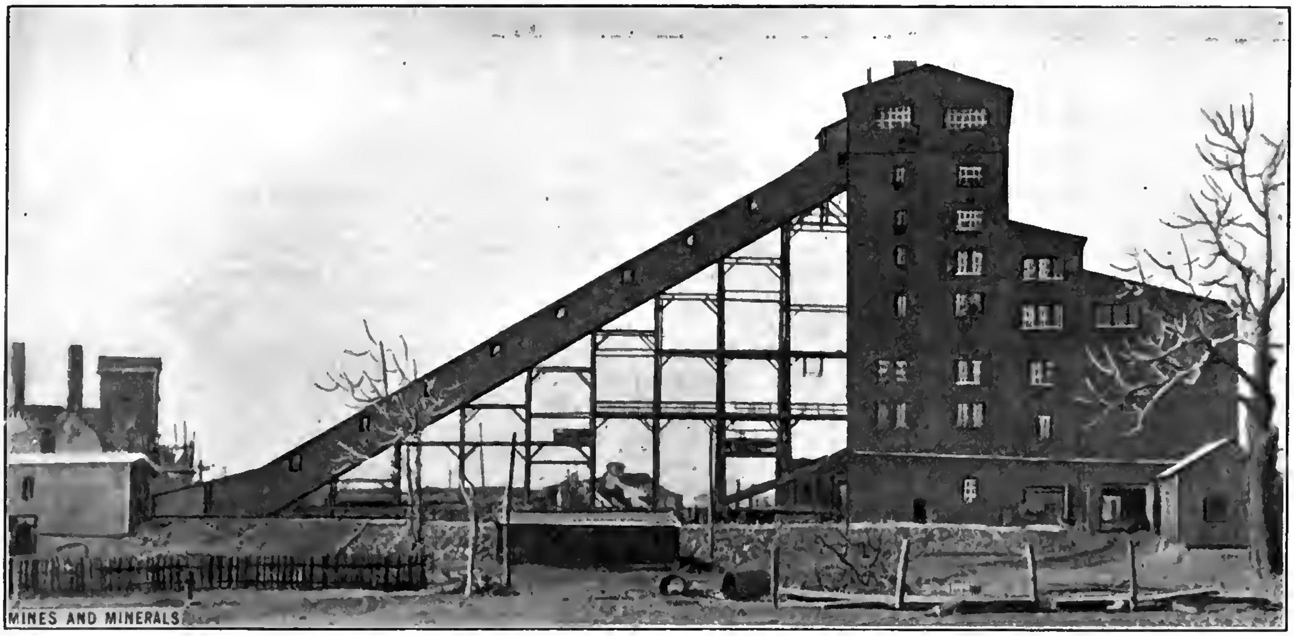

Fig. 1. Peck's Shaft Breaker, Mt. Jessup Coal Co.

The disadvantages are the expense of pumping, the sloppy condition of the breaker, and the disposal of the refuse. From the advantages and disadvantages mentioned it does not require more than average discernment to note that a compromise between the two systems of preparation is better under present-day markets than either separately when small coal was unsalable. To obtain a general idea of a modern compromise breaker, a description of the Peck's shaft breaker shown in Fig. 1, is ideal.

The long incline is for the scraper line which lifts the coal from the tipple house at the bottom to the very top of the breaker. To the rear of the tipple house is the Sterling boiler plant.

While the breaker is constructed of wood it is equipped with sprinkling and fire-extinguishing apparatus from the top to the bottom, so that any or all floors can be deluged with water if necessary. The sprinklers can be turned on in several places at the bottom of the breaker, while the water in the fire

plugs is always under pressure and cannot be turned off anywhere except at the plugs on the various floors. This arrangement makes the system positive, with no possible chance of any one tampering with the valves; consequently it is always ready for immediate use.

The coal comes from the Dunmore and from the Clark beds. It is hoisted in cars up an underground incline about 2,400 feet long, and then the cars are run by gravity a short distance to the foot of the shaft in the Clark bed. From the Clark bed, which is about 430 feet under cover, all coal mined is hoisted in cars through a vertical shaft to the surface. From the shaft collar the coal cars run by gravity in a semicircle to the dump house, where the tipple shown in Fig. 2 is installed. As a loaded car approaches this dumping device, it is assumed for description that there is an empty car standing on the movable and pivoted rails, held there by two tipple horns. When the loaded car reaches the lever, shown between the rails to the rear, its weight presses it down, thereby spreading the horns which held the empty cars stationary. As the loaded car moves forward it strikes the rear of the empty car, setting that in motion, so that it runs down an incline around to the car haul, shown indistinctly in Fig. 1 between the middle bent under the incline, and then back to the shaft collar, completing the circle.

Fig. 2. Car-Dumping Arrangement

So soon as the loaded car passes over the lever the horns of the tipple assume an upright position, and catching the forward wheels, bring the approaching car to a stop Underneath the floor of the tipple there is a steam cylinder whose piston is attached to the rear of the tipple rails by a yoke. When steam is admitted to the cylinder the piston lifts the pivoted rails and the rear of the car so that the car is tilted at the proper angle for discharging its load, after which the steam is turned off and the tipple and car return to their normal position.

There is a lever on the post shown to the left of the tipple which works the throttle valve leading to the steam cylinder, thus allowing the dumpsman full control. As the car commences to tip, a weight is disengaged which spreads the rails in front of the tipple so that no coal strikes them, and as soon as the car commences to go back to its normal position the rails return to their original place for the empty car to cross over them.

The coal is dumped in a hopper from which it is fed automatically by a revolving wheel to the scraper line, which is 228 feet long between centers and pitched at an angle of 30 degrees. The flights in this line are rigidly fastened to flat-linked Wilmot chains and do not come in contact with the trough. The chain moves on hard-wood rails without a squeak, and the rails being properly lubricated, there is little friction or wear.

The conveyer delivers the coal directly to the chute at the top of the breaker leading to the lump-coal shakers shown in Fig. 3. Large wooden fingers placed at the bottom of the chute prevent the large pieces rushing on the screen with momentum sufficient to injure it. This arrangement does away with a gate, and as there is no intermittent rush of coal the screen is never flooded. From the lump shakers the coal goes to the traveling picking belt, where the rock and coal frozen to rock are separated by hand as shown. The coal remaining on the belt is comparatively clean and is delivered by the belt to the crushing rolls. The rolls crush dry, but they, with the natural ventilation, create sufficient air-current to carry the little dust made out of the chimney shown in the top of the breaker, Fig. 1. The rolls in this breaker are run at about 125 revolutions per minute, or at about one-half the speed most rolls are driven. It has been found that by driving large rolls slowly better crushing results are obtained on anthracite than by running small rolls fast. This system would not apply to crushing bituminous coal fine. From the rolls the coal goes by gravity to the dry-coal shaking screens where it is sized into stove, egg, and nut, the undersizes going to the small-coal screens. From the dry-coal screens the stove, egg, and nut go to the spiral slate pickers shown in Fig. 4, there being a picker for each size. Attention is called to the fact that in this breaker all moving parts of machinery are fenced, and in order to get to the machinery the person must go out of his way. All the screens in this breaker are of the shaking variety, even to the finest material, but are so arranged that there is less vibration than in breakers using rotary screens. It will be noticed also in Fig. 4 that the timber frame is bracketed and tie-braced, a system of framing that is followed throughout the structure. Where this system of framing is used the timber legs must be perpendicular; and the cross-beams be made flush with the posts and tied so that there will be no spaces between timbers. In this particular breaker the machinery is arranged so that it fails to get in step, but this advantage is due as much to the delivery of the coal by means of the scraper line as to the bent construction.

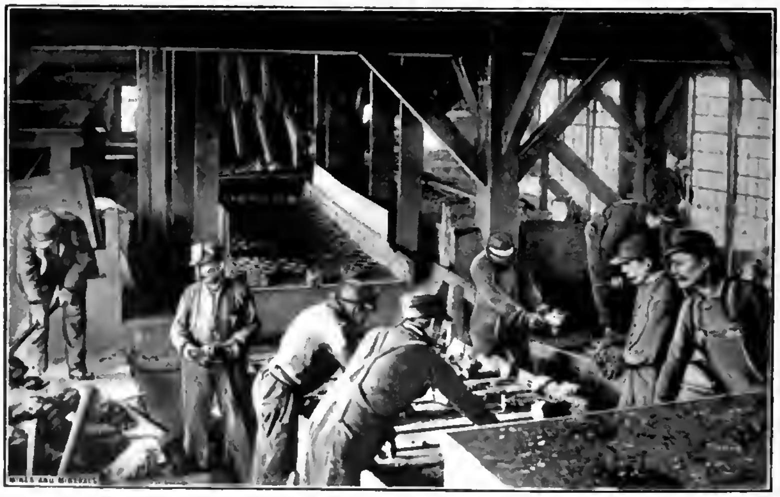

Fig. 3. Lump-Coal Shakers and Picking Table

From the spiral slate pickers the clean coal goes to the slate picker boys shown in Fig. 5. Breaker boys are artists in their line, being able to spear slate or bony coal with either hand, and without lifting their eyes place either in its proper chute. The bony coal picked out by the boys and that from the spiral pickers is delivered to Hazleton jigs, where a further separation of bony coal and slate occurs.

Part of the coal that passes through the lump-coal screens goes to 27″×36″ rolls, the remainder to the mud coal screens where egg, stove, chestnut, and pea are separated, also flat pieces of slate and bony coal. These sizes are sent direct to the spiral pickers and the undersizes to the small-coal shaking screens. From the spirals the coal goes to the boys' picking chutes, while the bony coal goes to the jigs. These rolls can also be employed if it is desired to break down coal to smaller sizes. At this breaker the lip screens are arranged so that they deliver to a trough pitched from each side to a pocket situated about in the center of the breaker, but below the broad-gauged track. Whenever there is a rejected car of coal it is dumped into this pocket and carried by a scraper line to the elevators, hence to the dirty-coal screens at the top of the breaker and so back through the breaker.

Fig. 5. Boy Slate Pickers

When the writer was actively engaged in anthracite mining it was the custom to construct a flow sheet and build the breaker to conform; at the present time the custom is reversed, with the result that innumerable changes and adjustments are made before the plant works satisfactorily. One operator remarked that the flow sheet was the last thing considered. As he was a mining engineer—well, those who know say the writer is not altogether politic.

The Peck's shaft breaker was constructed by Kingsley & Wescott, of Scranton, after ideas deduced from the experience of K. M. Smith, vice-president of the company, for which reason there will be few changes made, if any, in the flow sheet of this breaker.

A detailed account of the coal preparation is subtended.

The flow sheet of this breaker is shown in Fig. 6. The incline conveyer delivers the coal to the lump-coal screen *a*; all that goes over is carried away by picking belt *b* and delivered to 32″×36″ crushing rolls *c*.

Fig. 4. Spiral Pickers

The coal that passes through the rolls is elevated by *d* to the dry-coal shakers *e*, where it is sized into egg, stove, and nut, the undersize going to shaker *f*, where it is sized into pea and Nos. 1, 2, and 3 buckwheat.

The coal which passes through *a* and rests on grate-coal shakers *g* goes to a pair of 27″×36″ rolls *h* and is elevated and prepared over dry shakers *e* into egg, stove, nut, and pea. From *e* all coal goes to the dry-coal spiral pickers *i*, and from them to the boys' picking chutes *j*, and to the bins.

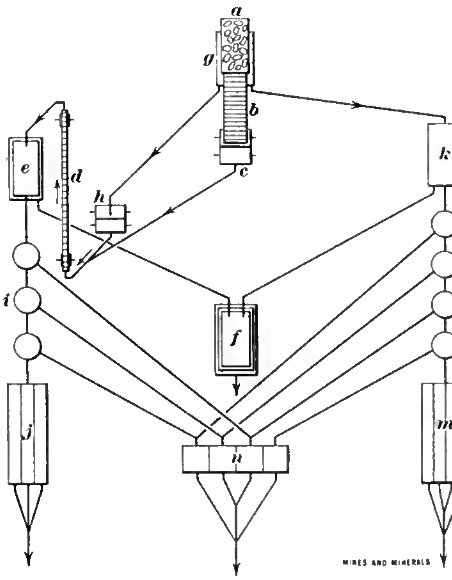

Fig. 6. Flow Sheet

That coal which goes through grate-coal shakers *g*, goes to the mud screens *k*, which are sprayed with water, and is sized into egg, stove, nut, and pea and sent to the wet spiral pickers *l*. The undersize from the mud screens goes to table *f* and is sized wet to pea and Nos. 1, 2, and 3 buckwheat. From the spiral pickers the coal goes to picking tables *m*. The bone from the dry pickers *i* goes to egg, stove, and nut coal jigs *n*, that from the wet spiral pickers, to egg, stove, nut, and pea coal jigs. The product of the jigs goes to bins.

The writer is indebted to P. A. Murphy, outside foreman, for the information relative to the details of this breaker that are contained in this article.

STEEL MINE SHAFT CONSTRUCTION

*By R. B. Woodworth, C. E.**

The circular shaft lined with brick or cast iron is extremely common in England and on the Continent. Meyer in discussing English practice remarks that the rectangular shaft is rather common in Cumberland, indicating that elsewhere its use is rather uncommon, and it is noteworthy that of the 14 shafts described in his book on "Mining Methods in Europe," all are circular with the exception of one, and that one is elliptical. It is also worthy of note that of 150 shafts listed by J. Riemer in his book entitled "Shaft Sinking Under Difficult Conditions," all but five are circular. Meyer also notes that there is a circular shaft in a Grundy County coal mine near Coal City, 60 miles west of Chicago. Outside of this the writer recalls but one other instance of a circular shaft which has come under his own observation, and certainly the common form in the United States is the rectangular.

Conditions Influencing the Material for Shaft Lining. Forms of Steel Linings and Supports

The advantages of the circular shaft as compared with the rectangular are stated by R. A. S. Redmayne in Vol. 2 of his work on "Modern Practice in Mining," to be:

1. The decreased cost of sinking due to the elimination of corners.

2. The smaller cost in lining, a rectangular shaft lined with timber costing £2 5s. per foot, whereas a circular shaft lined with brick at 20 shillings per 1,000 would cost £1 4s. 2d. per foot.

3. The greater difficulty of shutting off water in the square shaft.

4. The greater difficulty of placing a rectangular shaft in the most suitable situation with regard to surface and underground arrangements, position of railway sidings, etc., it being desirable that the greatest length of a rectangular shaft should be across the cleat of the stone so that the long side may be in the position most easily supported.

5. The increased danger and increased expense in a rectangular shaft when it passes through a fault.

6. The greater durability of cast iron and brick usually employed in lining a circular shaft as compared with the timber with which the rectangular shaft is lined.

These considerations in the ultimate analysis are due largely to differences in mining conditions, and the practice in building shafts in England and on the Continent is different from that which obtains in America largely by reason of the different material through which the shafts are sunk and the materials which are used in their construction. In certain parts of England, for example, and in certain mines on the Continent, the upper strata are of recent geological origin; the shafts are sunk in the valley while the seams of coal or ore mined outcrop on the hills or at the surface, sometimes many miles away. The result of this configuration of the soil is to permit enormous masses of water to percolate into and form reservoirs in the strata lying above the coal or ore. As the shafts are sunk, these strata of course have to be penetrated, causing difficulties in the way of pumping and keeping out the water. By reason of this difference also the pressures on the shaft lining increase approximately in the ratio of the hydrostatic head. In the United States, however, the coal mines are either not of any great depth, or where they are, they almost always pass through strata of Carboniferous time which are approximately horizontal, very hard, free from faults, and relatively free from water. In the iron-mining regions the ore occurs in troughs of slight extent with the strata deeply fissured, folded, and faulted; consequently the shaft is sunk through material which may contain considerable quantities of water, with sand, gravel, shales, etc., but after bed rock is reached its extremely hard nature eliminates difficulties of the kind met with in England. In England, and on the Continent also, suitable brick for lining shafts is not very much more expensive than wood, and what little difference there is in expense of first cost is overweighed by the considerations of durability and maintenance, which are paramount in English and Continental construction. For these reasons the English and Continental coal deposits are usually worked through circular shafts which offer a high degree of resistance through arch action to the pressure from the surrounding material. These shafts when shallow and through firm strata are usually constructed of brick, and Fig. 1 shows what may be considered common practice in English shaft and heading construction and indicates the solid and fireproof construction of the shaft itself with the strength and stability of the gangway supports. The mines owned by the Hulton Colliery Co., in the Lancashire coal field have a total output of about 500,000 tons per annum, the bulk of which is raised from two shafts known as Atherton No. 3 and Atherton No. 4, which were sunk in 1900 and are each 24 feet in diameter in the clear. The shafts are lined with brick and the gangway approaches to shafts for the upper seams and at the bottom of both shafts are formed on a method now much approved in this coal field. Strong steel beams are set upon side walls of brick; two beams 12 inches wide by 7 inches deep are placed immediately under the last bricking ring of the shaft and are repeated at intervals of 12 inches, the single beams at more frequent intervals. These beams are covered to form lagging with 2-inch pine plank or ⅜-inch boiler plate. Side walls are good brickwork 3 to 4 feet wide. Where the floor is bad, the thickness at the bottom may increase to 5 feet and taper to 2 feet or 2 feet 6 inches at the top.

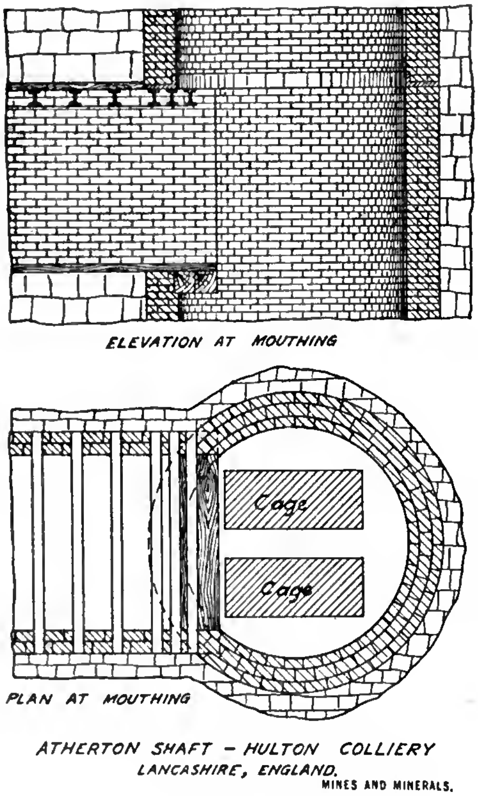

Fig. 1. Brick-Lined Shaft, Lancashire, England

Where the shafts pass through strata such as the magnesian limestone in the north of England, the Permian sandstone of the central countries and the chalk and green sand in the north of France and Westphalia, which carry large quantities of water, the main dependence is on cast-iron tubbing, which is built up in segmental framing rings piled upon each other throughout the entire depth of the water-bearing strata, this kind of lining being also peculiarly adapted to the circular form. The thickness of this lining is usually figured to resist hydrostatic pressure, the minimum thickness being about ¾ inch, and running to 4¾ inches, which is generally recognized as the maximum thickness which can safely be manufactured and readily handled. A new method of lining has been introduced in France which uses an iron ring ¾ inch thick lined inside with reinforced concrete of a thickness and strength to carry the pressure, the iron ring serving merely to protect

*Abstract from paper read before the Lake Superior Mining Institute, August, 1910.

the concrete from the water. In cases where iron rings 4¾ inches thick were formerly in use the saving in metal by the new system was about 20 tons per meter of shaft, the latter being 6 meters in diameter, the iron tubbing being the same thickness for all pressures. In the method of sinking shafts through water-bearing strata adopted by Kind & Chaudron, in Belgium and Germany, shafts have likewise been lined with wrought-iron plate tubes, and as rolled material has come into

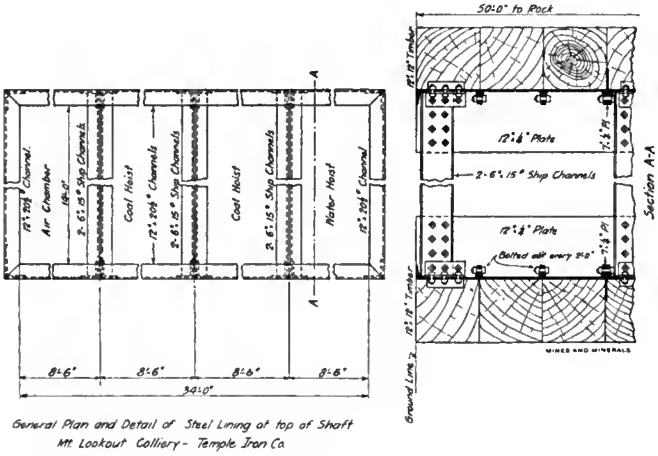

FIG. 2. STEEL-LINED SHAFT

larger use, the cast-iron tubbing has been more and more replaced by steel plates and shapes. So far back as 1894, for example, at the Grimsby iron ore mine in the Siegen district, Prussia, the shaft from the sixth to the seventh level was built of channels. At the Bockswiese mine, in the Harz Mountains, iron lining of I beams was experimentally adopted in place of masonry. The rings were 2 feet 6 inches apart, lagged with tees, the intermediate spaces being filled with stone, at a cost of 6 per cent. less than the ordinary masonry methods of construction.

If, however, the circular shaft is built large enough to carry the rectangular cages which are in almost universal use, there will always be an excess useless area requiring an excess of excavation as compared with the rectangular form, which, in turn, is best adapted for framing in wood or steel and which offers the largest useful area for a minimum amount of excavation. On the other hand, for the same area the perimeter of a circular shaft is less than that of a rectangular shaft. The useless area in a circular shaft may run from 25 per cent. to 45 per cent. and means that much additional expense in excavation and maintenance, which must be offset by cheapness of lining material in order to make it economical as compared with rectangular construction. The rectangular form of shaft conforms to the cages and skips which are used in hoisting men and materials, and represents, therefore, the minimum of excavation, and if properly divided by compartment separators of sufficient stiffness, offers no special difficulties from a technical standpoint. It is the form best adapted for framing in wood, and if framed in wood, steel may be substituted therefor with perfection, these materials being interchangeable and the variations in details insignificant. The cheapness of timber as a lining material has, therefore, made it more satisfactory from the standpoint of American mining practice and the chief advantages of the circular shaft in England and on the Continent do not have very much force under American conditions. The rectangular shaft may, therefore, be considered as the typical and best form of construction. The circular shaft has an advantage over a rectangular one in that it offers less rubbing surface and hence less friction to the air-currents and provides better ventilation. The mining laws, however, almost always require separate air-shafts and this consideration also is of little force.

The elliptical shaft is an endeavor to combine some of the advantages of the circular shaft and the rectangular; namely, strength and economy of space, but has not met with favor in England owing to the difficulty of keeping a deep shaft of that shape plumb and the obstacles presented to effective walling or tubbing. In Redmayne's discussion of this subject, however, the use of concrete seems to have been overlooked. The concrete-lined shaft is almost always elliptical in form and concrete seems to be the material best adapted in the construction of elliptical shafts, though it is possible to use brick. The difficulty in the use of cast-iron segmental lining is due to the fact that special sections would be required, whereas in the circular shaft the sections may be made all alike and interchangeable. In the elliptical shaft there is some elimination of useless space. It is safe to say that the elliptical shaft comes between the circular and the rectangular so far as availability of space is concerned. The elliptical shaft also takes advantage of arch action in the material itself so that the concrete may be made of less thickness than if rectangular. The concrete-lined shafts built in the United States have usually been sunk by the caisson method, the lining being built upon a steel cutting edge from the ground upwards and sunk into position by its own weight, whereas with the cast iron or wooden-lined shaft the extension of a shaft may proceed by building from the lower end downwards or by extensions downward in short sections successively built up on wooden or steel bearers. The caisson method of sinking is limited to about 120 feet. It is satisfactory through soft materials, but not through hard, and below the ground rock level, friction on the sides, the difficulties of excavation, etc., increase enormously.

The various uses of steel in connection with mine shafts may be illustrated by a few representative examples, which

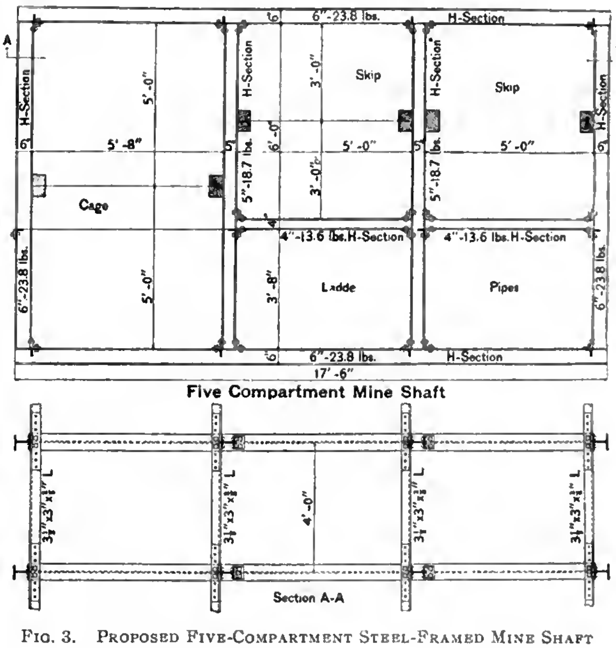

FIG. 3. PROPOSED FIVE-COMPARTMENT STEEL-FRAMED MINE SHAFT

will serve to bring out also its advantage in this form of construction. The writer will not say that there are no cast-iron lined mine shafts in the United States, but only that none such have come under his observation. If there are any, he will appreciate any information as to their whereabouts, dimensions, depths, etc.

A method of lining based on the same idea in steel is to be found at the Mt. Lookout colliery of the Temple Iron Co. Here the original timbered shaft was carried down to rock through quicksand, and when it had decayed it became neces-

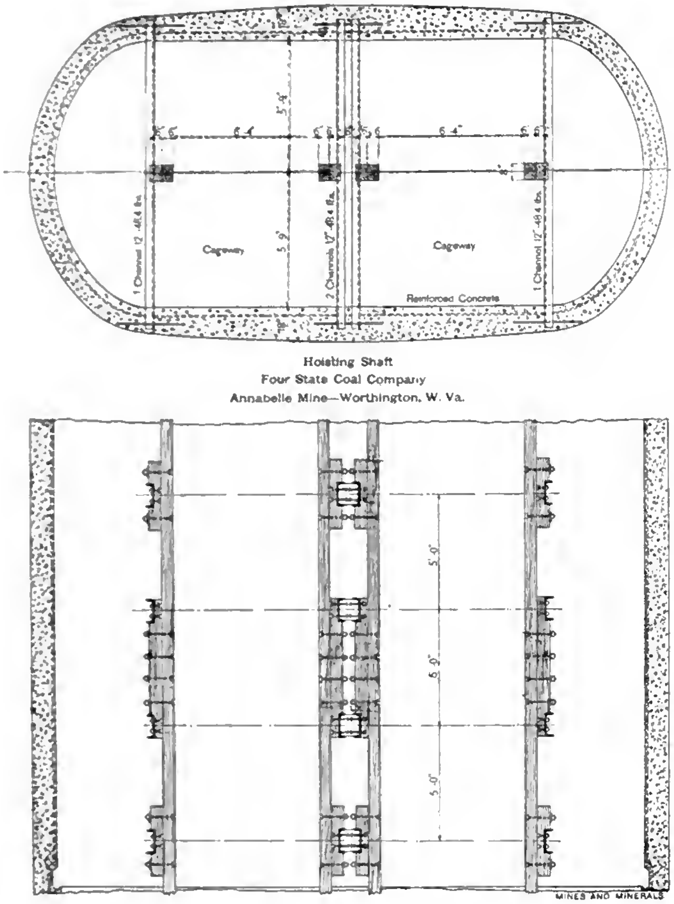

Fig. 4. Elliptical Concrete Hoisting Shaft, With Steel Ship-Building Channel Buntons

sary to put in some material which could be placed without disturbing the original structure and without cutting down the working space in the compartments for coal hoists, water hoists, etc. Fig. 2 shows the details of this construction in which 12-inch channels were used back to back, separated by anchor plates to catch in the wood of the original lining, and double 6-inch channels to take the place of the 10″ × 12″ buntons originally separating the compartments. The construction was very simple and could be made more so by the use of **H**-sections, which are better adapted to resist compressive stresses developed by the earth pressure than the channels, and of less weight as well.

The use of this form of construction in sinking new shafts would avoid the excavation of from 3 to 4 feet additional space around the shaft opening and very materially lessen the original cost of the construction. The lining, after the same fashion, could be constructed for a rectangular shaft by the use of steel beams spaced about 4 feet centers laid with webs horizontal, suspended one set from the other with heavy rods or angles and filled in between with concrete, in which case it would be necessary only to provide forms for the inner faces of the shaft and to have the beams punched with holes sufficiently large for pouring grout through them to fill up the small spaces between the flanges of the beam and the web. In this manner the strength of steel for shaft timbers can very readily be utilized in connection with the desirability of concrete as a permanent lining material.

The very first use of Friestedt interlocking channel-bar piling on a commercial scale was in sinking the shaft of the Johnson City and Big Muddy Coal and Mining Co., Johnson City, Ill., through quicksand 70 feet below the surface.* It has also been used by the Robert Gage Coal Co. at Bay City, Mich., in a similar construction after endeavors had been made to sink three times without success, and at an estimated saving of $35,000 if the piling had been used at the start. It has also been used by the Weaver Coal and Coke Co., at Du Quoin, Ill., Big Muddy Coal and Iron Co., at Murphysboro, Ill. etc. These installations were not all permanent. A noteworthy example of its use as a permanent lining of a rectangular shaft was at New Biggen, England, where piles of mild steel 80 feet long, built up in lengths of 20 and 30 feet, spliced so as to break joints, were driven by an ordinary pile driver through 18 feet of clay, 60 feet of running sand, and 2 feet into sandstone, with entire satisfaction and complete success. This is the greatest depth to which interlocking steel-sheet piling has ever been driven and exposed to view by excavation. The piling can be used either in rectangular or circular shafts, what is known as United States steel-sheet piling being peculiarly adapted to circular construction. The chief difficulty in respect to the use of steel-sheet piling, as also to any kind of piling, is the preservation of its verticality, especially where the clay or gravel contains large boulders. In the installations mentioned, however, the shafts remained plumb to all practical purposes without any special attention more than is necessary in good pile-driving practice. It may be added that great care is to be exercised in driving and instances have occurred, through inexperience, where it was attempted to drive the piling not to, but through, solid rock. With reasonable care in driving, however, this use of steel-sheet piling results in economical construction.

An ingenious system of forcing down piles in lining shafts has been successfully applied on several occasions in England and covered by letters patent taken out in the name of Mr. Charles Walker. It consists, briefly, in erecting a cylinder of tubbing, which is suspended from a surface platform, and

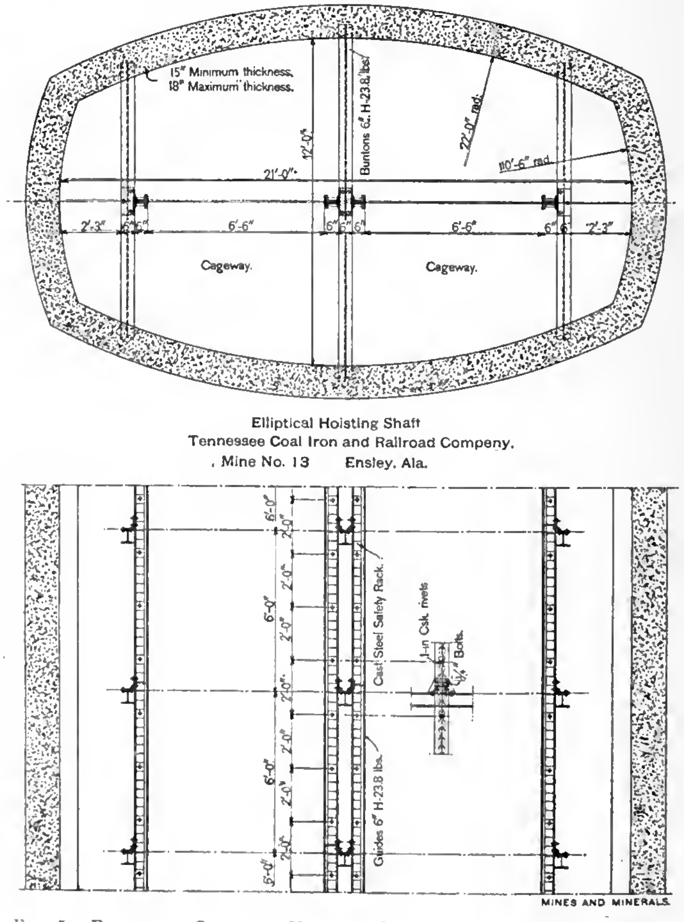

Fig. 5. Elliptical Concrete Hoisting Shaft, With **H** Section Buntons and Guides

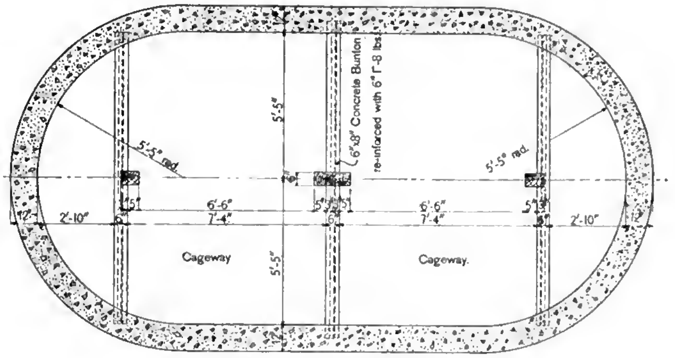
*See Mines and Minerals, Vol. 23, page 72.

utilizing its weight to force down the circle of interlocking piles which are of special type and have riveted to them lugs or brackets against which pressure is exerted by hydraulic jacks. The verticality of the piling is assured by means of a movable or floating ring of tubbing into which they are grooved and which lies at the bottom of the shaft as it sinks into the silt. Full details of this form of construction may be found in Redmayne's "Modern Practice in Mining," Vol. 2, page 197.

The standard typical framing of rectangular shafts in the United States consists of the use of timber sets spaced 4 feet, more or less, centers, as conditions may determine, and lagged between with plank. In the mining districts of Michigan and Minnesota there are quite a number of mine shafts timbered with steel shaft sets lined with plank. These shaft sets are made along the lines of the timber set and are lowered into position by hangers as the excavation proceeds. They have been constructed with **T**-rail wall plates, 3-inch and 4-inch **I**-beam buntons and rail stuttles; also with 4″×5″ **T** wall plates reinforced by angles for proper bearing, 3-inch, 4-inch, and 6-inch double-channel buntons and rail stuttles; also with $4\frac{1}{2}''\times5\frac{1}{2}''\times8''$ Carnegie steel cross-tie wall plates with 4-inch **Z**-bar buntons, and 3-inch **I**-beam compartment dividers and rail stuttles. In the evolution of these sets the strength of steel has sometimes been overestimated by the mine foreman and sections of too small depth and too little strength substituted for the wooden sets previously in use. As an engineering proposition, after the proper size of wooden timber sets has been attained by experience, it is a very simple matter to substitute steel for their use on the basis of their relative strengths, and wherever this has been done, the substitution has been satisfactory.

There is an inclined steel-framed shaft constructed by the Newport Mining Co., at Ironwood, Mich., in which the wall



Elliptical Hoisting Shaft
Bunsen Coal Company
Clinton Coal Fields, near Clinton, Vermilion Co., Ind.

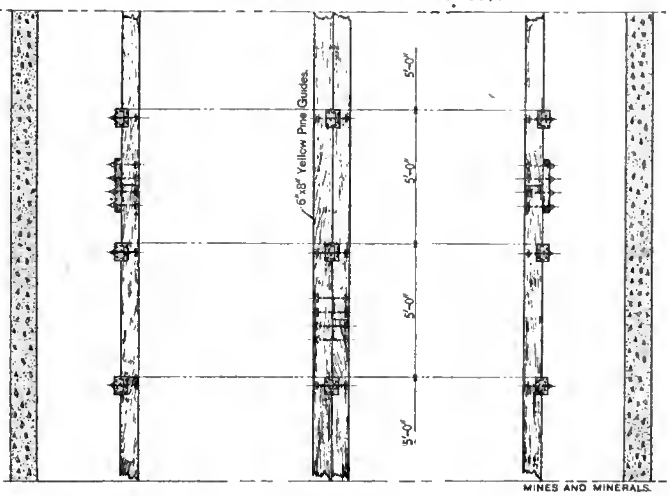


Fig. 7. Elliptical Concrete Hoisting Shaft, With Steel Channel Buntons

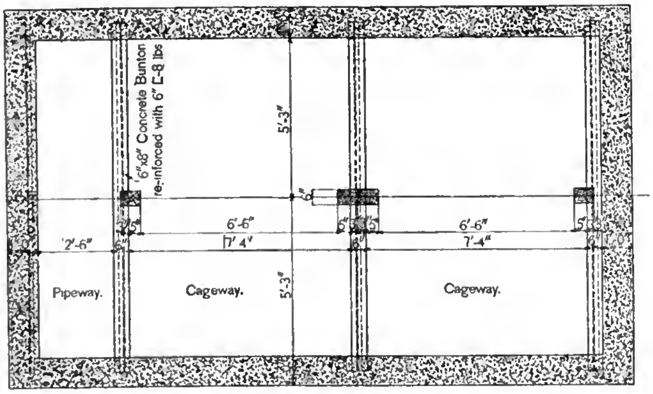
plates are made of 4″×3″ **T**'s, the stuttles are of angles, and the buntons of **H** sections. The use of the angle stuttle is to be recommended, as thereby special hanging rods may be eliminated in the process of sinking, and no material go into the shaft which does not remain in place permanently. With the angle stuttle also the load is divided equally on the bearers above and below, while with the rail stuttle sometimes used, the weight of the shaft comes on the lower bearers only. The **H**-section buntons are also in line with good engineering experience, while the use of **T**'s for wall plates is suitable for the installation, though as a general proposition this is not the proper form of section.

A more ideal form of construction is shown in Fig. 3, which represents a five-compartment mine shaft proposed for use in the mines of the Oliver Iron Mining Co. In this construction the broad bearing surfaces and high compressive strength of the **H** sections are utilized for wall plates, compartment dividers, and buntons, while the stuttles are made of $3\frac{1}{2}''\times3''\times\frac{3}{8}''$ angles. Ten-inch **I** beams were used for buntons instead of 5-inch **H** sections at the Hill mine, Sterling Siding, Minn., so as to allow the use of steel shaft sets in connection with wood, the buntons in the wooden sets being 10 in. × 10 in. and 10 in. × 12 in.; otherwise the 5-inch **H** sections would be much better adapted to the construction.

Recently quite a number of concrete-lined shafts have been recorded in the technical press as either completed or under construction. A representative example is to be seen in the shaft built by the Foundation Company for the Delaware, Lackawanna & Western Co., at the Woodward colliery, about a mile from Wilkes-Barre, where an open concrete caisson was sunk through 79 feet of the water-bearing soil overlying the bed rock. The concrete caisson was constructed with a cutting edge of $\frac{3}{4}$-inch plate 32 inches high, well reinforced with riveted angles, and the concrete in the walls of the shaft



Rectangular Hoisting Shaft.
Bunsen Coal Company
Clinton Coal Fields, near Clinton, Vermilion Co., Ind.

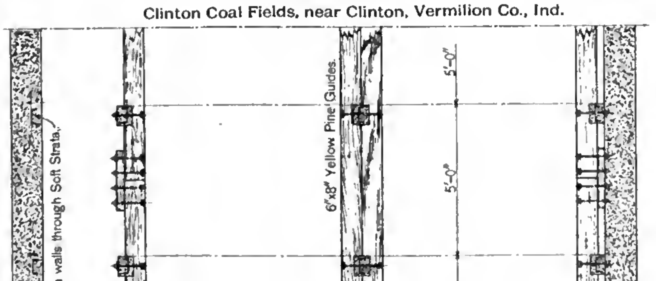


Fig. 6. Rectangular Concrete Hoisting Shaft, With Steel Channel Buntons

was likewise reinforced with 1-inch and 1¼-inch steel reinforcing rods amounting in weight to 140 tons. Instances of the same kind are the two concrete shafts built by the H. C. Frick Coke Co. at its new mines, Filbert, Brownsville, Pa.; and in the iron-mining regions may be cited the circular reinforced-concrete shaft sunk at the Morton mine, Hibbing, Minn., by the Foundation Company for the Todd-Stambaugh Co., Cleveland; also the shafts sunk by the same company for the Cleveland-Cliffs Iron Mining Co. at their Smith and Kidder mines near Princeton, Mich. The caisson at the Kidder shaft was built upon a fabricated steel shoe 24 feet outside diameter riveted to a steel-cone plate on the inside, the slope of which extended up to a height of 10 feet, making the working chamber on which were bolted steel sections 10 feet in diameter as the structure sunk.

The use of steel buntons and interior framing has much to recommend it in connection with the concrete-lined shaft,

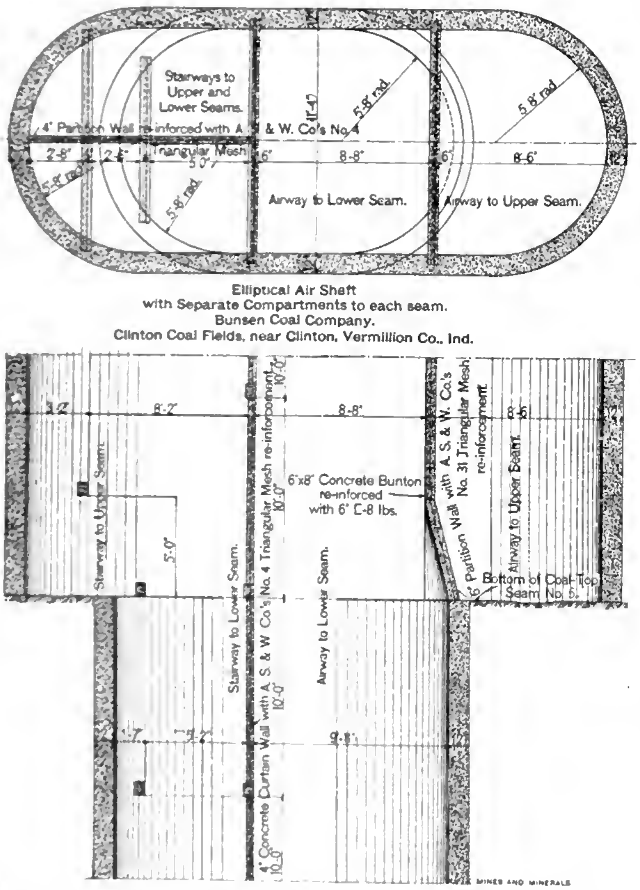

Fig. 8. Elliptical Concrete Air-Shaft, With Two Compartments, Steel Channel Buntons, and Wire Mesh Reinforcement

as it is strictly in line with observations already made as to the relative uses of these materials. Fig. 4 shows an elliptical concrete hoisting shaft under construction at Annabelle Mine, Worthington, W. Va., by the Four State Coal Co., a subsidiary of the Pittsburg-Buffalo Co. This shaft is 340 feet deep, lined with reinforced concrete. The buntons are made of 12-inch ship channels 48.4 pounds per running foot, anchored at their ends into the center of the shaft lining, but without special bearing plates. The two channels at the center of the shaft are fastened together by bolts and separators. The wooden guides are furnished in spliced lengths with broken joints, though this feature is not very plainly shown in the illustration.

Fig. 5 shows a plan and vertical cross-section of the elliptical hoisting shaft now under construction by the Tennessee Coal, Iron, and Railroad Co. at Pratt mine No. 13, near Ensley, Ala. In this case the concrete is massive and not reinforced, with a minimum thickness of 15 inches through firm material and 18 inches through soft. The buntons are made of 6-inch H sections weighing 23.8 pounds per foot, spaced 6 feet apart. The guides are likewise made of 6-inch H sections and carry bolted to them cast-steel safety racks, insuring great stiffness and rigidity in the structure, and in consequence a minimum of lost motion in operating the shaft. The shaft is located near a fault and the measures are much disturbed. It is, therefore, the intention to use steel beams for roof supports in the main gangways and tunnels around the shaft.

The Bunsen Coal Co., mining coal in the Clinton coal fields, has a shaft under construction near Clinton, Vermilion County, Ill. Two designs of this shaft are shown in Figs. 6 and 7, one rectangular and the other elliptical. The buntons in either case will be constructed of 6″×8″ concrete beams reinforced with a 6-inch 8-pound channel. Where the shafts pass through soft strata, it is the intention to reinforce the concrete at the ends also with 6-inch 8-pound channels. The thickness of the lining will be 6 inches through firm material and 12 inches through soft. The guides in both cases will be made of 6″×8″ yellow pine timbers securely bolted to the reinforced concrete buntons. It may be noted in illustration of the observations made as to the advantages of the rectangular shaft that the shaft shown in Fig. 6 has an inside area of 176 square feet with an area of excavation for a 6-inch thickness of lining of 226 square feet, while the inside area of the elliptical shaft shown in Fig. 7 is 211 square feet and the area of excavation for a 6-inch wall thickness 240 square feet.

A most excellent illustration is shown in Fig. 8, the plan and cross-section elevation of an elliptical air-shaft also under construction by the Bunsen Coal Co. in the Clinton coal fields. Two seams of coal are mined and the shaft has separate airways to each seam, as shown in the figure. The inside area of the upper shaft is 305 square feet, and of the lower shaft 165 square feet; the outside area for a 6-inch wall thickness, 341 feet for the upper shaft and 189 feet for the lower shaft. The shaft is about 400 to 500 feet deep, as also is the hoisting shaft just described. The partitions in the shaft are reinforced concrete built with the American Steel and Wire Co.'s No. 4 triangular mesh reinforcement on 6″×8″ concrete buntons reinforced with 6-inch 8-pound channels. These partitions, however, will be made 8 inches thick instead of 4 inches, as shown in the figure.

In the design of mine-shaft timbers the thing of prime importance is simplicity, which lessens the cost of fabrication and contributes to ease in erection. This simplicity is a thing which has always characterized the rectangular wooden shaft. It is a thing which just as well characterizes shaft timbers of steel. Bolts should always be used for erection rather than rivets and the hangers should be, preferably, of the angle type so as to add stiffness and facilitate plumbing. For bearers nothing better can be devised than the standard steel I beam.

An objection has been raised to the use of steel on account of its danger to corrosion. It need only be said that both the light of experience in this country and abroad and laboratory tests demonstrate amply that the subject is one of very little importance. Underground conditions are not nearly so severe on the steel as above ground conditions, and certainly painted material in the mines is not exposed to those alternating conditions of high and low temperatures, dryness, and wetness, strong light and darkness, with which above-ground construction has to contend and which are especially accelerative in the deterioration of a protective coating. The steel should be painted before it is placed in service. If the paint is well chosen and applied with care, there need be no fears as to its durability. Experience and theory all indicate that only the simplest means are necessary for the absolute guarantee of an extremely long life for steel in underground mining conditions.

The first coat applied at the shop should consist of a practically inhibitive pigment to prevent the inception of corrosion in the steel, and the second coat should be put on in

the field to protect the first from atmospheric and temperature conditions, to fill up thoroughly any voids that may occur therein, and to cover surfaces abraded in shipment. To meet these requirements a good grade of red lead or a natural oxide of iron well applied will be sufficient for the first coat. For a second, or excluding coat, there seems to be nothing better today than a first-class graphite.

It appears eminently appropriate that steel should be used in the timbering of iron mines, whether in horizontal headings or in shafts, as its use simply means putting back in finished form that which has already been dug out of the mine in order to dig out more. This is not exactly a parallel to the classical problem of a man pulling himself over a fence by his own boot straps, but is, beyond question, a step toward the solution of that problem

THE AEROLITH RESCUE APPARATUS

Written for Mines and Minerals

In the 1910 Proceedings of the Australian Institute of Mining Engineers there is an article on "Breathing Apparatus for Use in Mines," by R. T. Slee, to which he appends the table that follows, showing the conclusions of the British Royal Commission appointed to test breathing apparatus.

Results of Investigations on Use of Apparatus Carrying Liquid Air for Breathing Purposes

The common object of the various types of breathing apparatus is to enable the wearer to remain at work for varying periods of time in an atmosphere which is either deficient in oxygen or is poisonous, like the afterdamp of a coal mine explosion.

To ascertain the value attached to oxygen helmets as life savers in England, inquiries were made, and the following reply received: "I do not think it can be definitely said that the oxygen helmet has ever been the means yet of actually saving life, unless indeed the operations following the fire at Nova Scotia a year or two ago can be construed to this effect. Over here we are coming to regard the rescue apparatus in what I think has always been its proper light; viz., as the means of assisting in 'recovery work,' such as restoring ventilation, removing falls, and fighting mine fires."

Comparison of Breathing Apparatus

Apparatus	Weight in Pounds	Oxygen Capacity in Liters and Cubic Feet	Removal of Carbonic Acid	Supply of Oxygen	Air-tightness	Comfort and Convenience
Pneumatogen (Type II)	14½	163* (5.8)	Good	Poor	Good	Very good
Draeger........	36–39	251 (8.9)	Good	Good	Good	Bad
Shamrock	36	274 (9.7)	Bad	Good	Good	Good
Fleuss..........	31	228 (8.0)	Good	Good	Good	Good
Weg...........	about 30	150 (5.3)	Good	Good	Good	Good
Aerolitb........	22	?	Fair	Good	Good	Very good

*Maximum theoretical yield; 80 to 100 liters is the more probable figure in actual practice. (163 = liters, 5.8 = cubic feet.)

There are many on this side of the water who hold similar views and it has been suggested, owing to the fact that the operators encumbered with heavy helmets are unable to carry helpless men more than a short distance, that the name rescue apparatus be changed to "recovery apparatus," thereby more appropriately defining it without misleading the general public. Commenting on recovery apparatus, to be efficient, it must fulfil the following conditions:

1. It must be air-tight as regards the passage of the air from the outside to the inside. In atmosphere containing carbon dioxide a slight leak would not render the apparatus useless; but where irritating vapors, such as the smoke from burning sulphides, is met with, even the slightest leak must be avoided.

2. The oxygen supply must be ample, and so supplied that it is not checked by expiration.

3. Expiration and inspiration must not be retarded.

4. The carbon dioxide generated must be quickly and efficiently absorbed.

5. As salivation is much increased when wearing some types of breathing apparatus, effective saliva catchers should be provided in order to prevent contamination of the inspiratory air.

6. The apparatus must not be too heavy, must not impede the wearer's movements, nor impair his powers of observation. Its volume should be such as to render it easy of transport in the workings of a mine.

Modern types are constructed on the following principles:

(*a*) The expiratory air is purified by the use of a chemical which absorbs the carbon dioxide and moisture exhaled.

(*b*) The oxygen consumed in breathing is replaced from reservoirs containing the gas in a compressed or liquid form, or from chemicals liberating oxygen by means of chemical reactions taking place during the use of the apparatus.

Breathing apparatus as now used falls under one or other of the following types:

1. A helmet through which a constant current of air is passed, either from a pump or from the compressed air main being connected with the helmet by a length of hose, or from a reservoir of compressed air carried by the wearer.

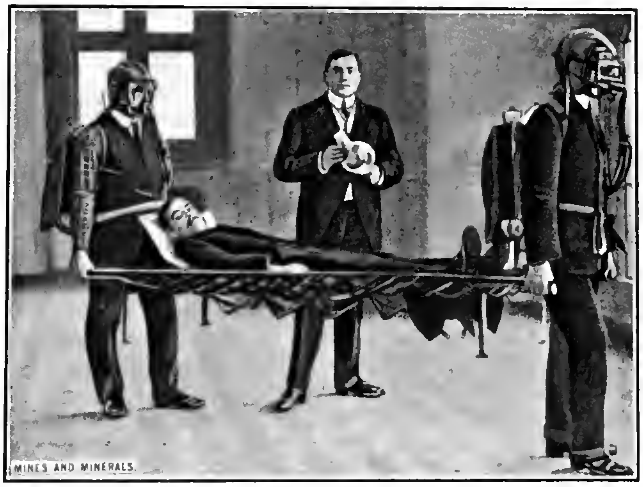

Fig. 1. The Aerolith

2. In this type the wearer breathes into and out of a bag provided with arrangements for absorbing the carbon dioxide and moisture contained in the exhaled air, while highly compressed oxygen from steel reservoirs passing through suitable mechanical arrangements replaces that consumed by the wearer, and as far as possible, assists the wearer in the act of inspiration.

3. In the third type the exhaled air passes through a cylinder containing peroxide of sodium and potassium. These compounds not only absorb carbon dioxide, but theoretically liberate sufficient oxygen to make up for that used by the wearer.

4. In this type the oxygen is derived from the evaporation of liquid air.

From the table it is seen that the Draeger apparatus affords an abundant supply of air, and that the carbon dioxide is absorbed thoroughly. On the other hand the apparatus is heavy and hung so that it is uncomfortable, tiring in use, and liable to catch on projecting timbers, etc. Also the heat is intense, which greatly detracts from the comfort, convenience, and utility of the wearer. Recognizing that vigorous action and comfort were requisites in recovery work, the aerolith has been investigated. Mr. Guy Simmonds, chief of the Durham and Northumberland Collieries Fire and Rescue Brigade, of

Elswick, Newcastle-upon-Tyne, writes as follows: "The reason we adopted the aerolith apparatus was that we found it less than half the weight of the oxygen apparatus, and the air supplied remains cool till the very end, whereas the air in the oxygen apparatus becomes very hot and unpleasant after it has been worn for a time. We have been experimenting for the last 6 months with this apparatus and find that the men are able to use it when carrying out heavy work with very little discomfort. One of the greatest difficulties we have been faced with is the transport of liquid air in glass thermos bottles. This we now think has been got over by using metal containers. I would further point out that the manufacture and storage of liquid air renders it more suitable for this rescue station than any of the others, as it is proposed in this district to use permanent men quartered at one or more stations and not attempt to keep rescue apparatus at every pit. In other districts where the supply of rescue apparatus is contemplated for every colliery the liquid air system might not be so suitable."

"The liquid air plant, which cost about £800, is capable of producing 10 liters of air an hour. With the large stock of air on hand, this plant will enable us to keep 20 aeroliths in constant

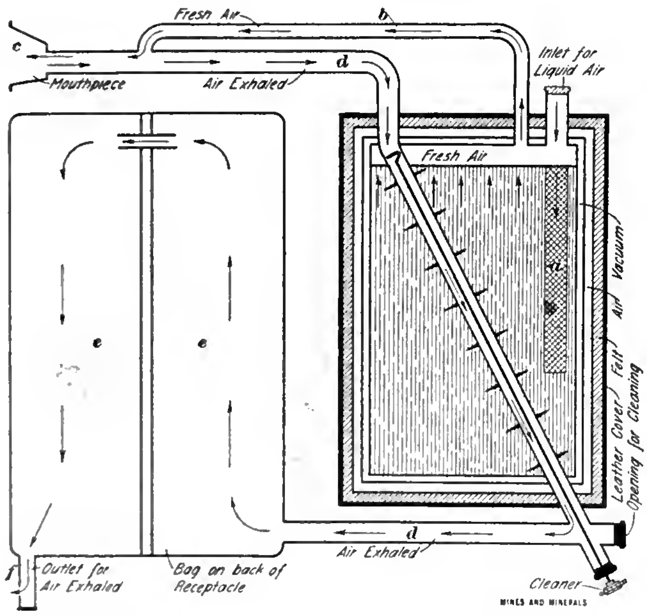

Fig. 2. Diagram Showing Circulation of Air in Aerolith

use for about 48 hours, and in that time we shall be able to get manufacturers to supply us with air in unlimited quantities."

At the central rescue station of the coal mines at Witkawitz, Austria, there are two liquid air plants, one for a normal capacity of 10 pounds of air, which may however be increased to 20 pounds per hour, and the other having a capacity of 50 liters of liquid air per hour. The smaller plant was started in May, 1907, the cost exclusive of buildings being $7,500. The larger plant was installed at a cost of $15,000, exclusive of buildings. The size of the liquid air plant is chosen according to the number of apparatuses dependent on any one center The air is compressed up to about 120 atmospheres or 1,760 pounds per square inch and purified, then through sudden expansion cooled below the critical point, thus turning it into liquid which is stored in vacuum vessels. The vacuum receptacles form such excellent insulators that the loss through evaporation is reduced to about 5 per cent. per day. A stock of air for emergency must of course be kept, but as 1 gallon of liquid air costs less than 25 cents the loss in evaporation amounts to less than 1¼ cents per gallon per day. Assuming that at a certain station the men practice 40 times weekly, and at each practice of 2 hours 1 gallon of liquid air is used, then the cost would be $10 per week. It is probable that a similar number of practices per week with an oxygen helmet would cost nearly five times the money. The composition of the gases given off by liquid air varies in a particularly convenient manner in aeroliths; for instance, the nitrogen boils off more easily than the oxygen, hence the liquid air that has been kept some time before use is richer in oxygen, and the gas received by the users toward the end of a 2-hours practice contains relatively more oxygen than at the beginning.

Plants required for making liquid air need little attention; their product is not explosive and, as used in connection with the aerolith, is harmless. Presuming there are very few in this country who have even a general idea of the appearance of the aerolith, it is shown in Fig. 1 and described by reference to Fig. 2. Fig. 1 shows the aerolith knapsack, as worn in actual work, but the headpiece is now a mask helmet entirely finished in asbestos that covers the head by means of an asbestos flap. The air-tight joint is around the face only, and is formed by a pneumatic cushion attached to an adjustable frame that will fit any type and shape of face. The eyeglasses are large and square and inside cleaners are provided that are operated from the outside. The nickel box shown in Fig. 2 is in the form of a knapsack and is loosely packed with asbestos, besides being well insulated from the outer atmosphere by felt and leather. Into this knapsack 1 gallon of liquid air *a* is poured through the inlet. After charging and closing the inlet the only outlet for the gas produced by the evaporating liquid air is through pipe *b* that opens in an air conduit extending about the knapsack to allow the air to assume a normally cool temperature, then terminates in the mouthpiece *c*, which connects with the helmet. Liquid air has a normal temperature of 180° below zero, and on evaporation expands between 700 and 800 times in volume. The gas given off is cool in temperature and contains about 60 per cent. oxygen. The exhaled air goes through *c* but is unable to enter *b* owing to a constant flow from this pipe, therefore it goes into pipe *d* which crosses the liquid-air chamber before entering the divers-cloth breathing bags *e* and then, as shown by the arrows, to the escape *f*. On the way from *d* to *e* the exhaled air helps to control the air supply by communicating its heat to the liquid air in the box, thus increasing evaporation, in other words, the harder the wearer works the more air he needs and this he receives. Any surplus of evaporated air joins this exhaust and carries its oxygen into the breathing bags. By attaching a mouthpiece to the bags another man, not wearing an aerolith, can be led for a considerable time through poisonous atmospheres.

The knapsack is made of nickel, the outer covering of leather, the breathing bags of divers cloth, and is 15 in.×11 in.×5½ in. over all. When fully charged the outfit weighs 23 pounds, but as the liquid air evaporates, the weight becomes less until when exhausted it weighs 13 pounds. There are no valves, chemicals, or regenerators, which greatly adds to the simplicity of the breathing apparatus, and from the fact that cool fresh air is supplied the operator, there seems to be no hindrance to the aerolith's introduction except the cost of the liquid air plant. The listed price of the breathing apparatus is $115 complete, which is much less than some of the others, and this added to the other good qualities suggests that it receive more consideration in the United States than it has in the past.

GAS IN VERY HOT FLAMES

The products of combustion of gases in very hot flames are not always identical with those generally met with. Thus it has been shown that in the presence of an excess of oxygen the combustion of carbon monoxide gives ozone; under the same conditions the hydrogen flame also contains ozone and a little nitrous oxide; and further, the acetylene flame contains almost 4 per cent. of this same nitrous oxide. The temperatures attained during the combustion of these gases, under the above conditions, are exceedingly high, about 2,600° C. for carbon monoxide, 2,800° C. for hydrogen, and 3,000° C. for acetylene

THE MARIANNA COAL MINES

Written for Mines and Minerals, by Hartley M. Phelps

A Modern Coal Mine Planned for a Daily Output of 5000 Tons From One Tipple

Coal mining after the most improved and modern methods may be seen at the Marianna mines of the Pittsburg-Buffalo Co., in Southwestern Pennsylvania. Practically every labor-saving device of the highest efficiency has been installed in these most interesting of workings; the machinery above ground as well as below is of the best, and no expense has been spared by the enterprising owners to make Marianna what it is, a model coal mine.

Not only is the plant constructed along the latest scientific lines but the town of Marianna must take rank as one of the finest coal miners' settlements in this country. The Jones family, chief owners of the company, are noted for their somewhat altruistic tendencies, having spent hundreds of thousands of dollars to provide many conveniences and comforts and even luxuries, for their employes. Actual uplift work is being done at this mine, The officers of the Pittsburg-Buffalo Co. are John H. Jones, President; Thomas P. Jones, Vice-President; David G. Jones, General Manager; and James Jones, father of the three, Chairman of the Board of Directors.

The Marianna mine taps a vast tract of some 800 square miles underlaid with Pittsburg, Freeport, and Kittanning coal beds, also Waynesburg and Sewickley coal beds of marketable thickness, this latter forming the future fuel supply of Pittsburg. With the exception of several mines on the Monongahela River, Marianna is the only opening in the field. It is situated on Ten-Mile Creek, a branch of the Monongahela and is 6 miles from Millsboro at the junction of the two waterways. The railroad from Pittsburg reaching Millsboro and Marianna is the Pittsburg, Virginia & Charlestown, or the Monongahela branch of the Pennsylvania Railroad. It is about 56 miles by this line from Pittsburg to the mines.

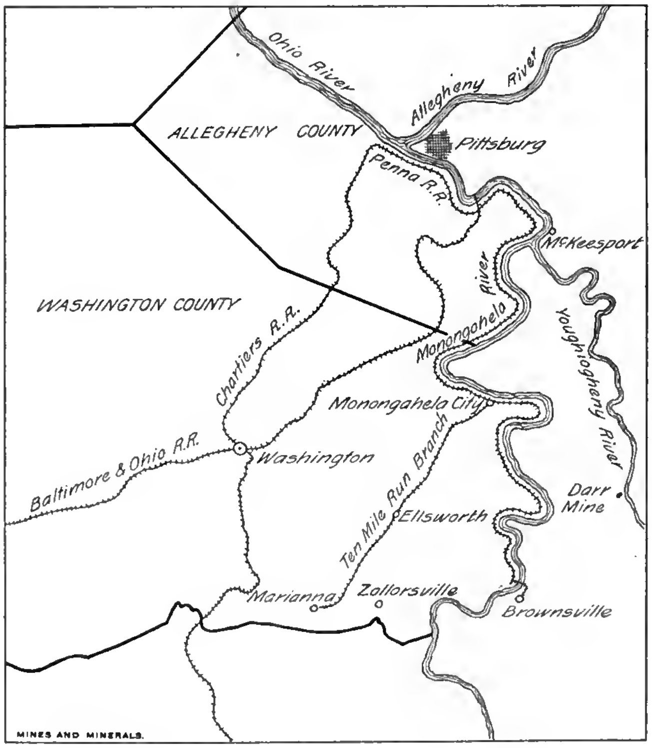

Fig. 1. Map Showing Location of Marianna

The Pittsburg coal bed at Marianna is 440 feet below the surface, is a little more than 6 feet in thickness, and of unusually high grade as gas and coking coal. The land containing the Pittsburg coal held by the company in this field totals more than 6,000 acres, and it is conservatively estimated to contain 50,000,000 tons. The Waynesburg outcropping, largely through southern Washington County, is more than 5 feet thick and makes a good grade of domestic coal. It lies about 70 feet below the surface in the Rachel shaft at Marianna. The Upper Freeport lies about 600 feet below the Pittsburg seam and measures about 5 or 6 feet in thickness. The Lower Freeport is not shown by the oil-well logs, but the two Kittannings have been located, one about 110 feet below the Upper Freeport and the other about 40 feet deeper.

The mine-run coal of the Pittsburg bed has a calorific value of about 14,000 British thermal units per pound of dry coal and cokes with less than 1 per cent. sulphur without washing, while the slack cokes with under 1 per cent. when washed

The Pittsburg-Buffalo Co., as stated, in order to operate economically so large an area, has installed some of the most modern machinery. It is said that 3 cents per ton saved in operation more than covers the entire cost of this equipment. Coal mining is now costing the company less per ton of annual capacity than the average mine in the Pittsburg district, the cost being less than $1 per ton of annual capacity, with amortization less than 3 cents per ton of coal production. The full significance of this can be appreciated when it is borne in mind that many mines having an annual capacity of from 50,000 to 100,000 tons per annum and an area of only 100 acres of coal have equipment costing as much as $100,000 or from 10 to 15 cents per ton of coal produced. The production of the Marianna mine is 5,000 tons a day, or 1,500,000 tons for a year of 300 working days, as against the average daily production of 300 tons for all mines in the United States. The magnitude of the work being done may be realized when it is stated that as much as 18 tons of coal per minute have actually been hoisted at this mine, a rate of 1,000 tons per hour.

There are two main or hoisting shafts 22 ft. × 33 ft. outside the lagging and about 450 feet deep. They were sunk about 4,800 feet apart, and are so located that the coal from the entire field can be delivered to them with the grades almost entirely in favor of the loads. Both shafts have cageways 7 ft. × 20 ft., so two cars may be hoisted on each cage in tandem. They are also provided with an airway 11 ft. × 20 ft. and with stairways from the surface to the coal. One of the shafts, the Rachel, Fig. 2, is the main hoisting shaft and here the cars in tandem holding three tons each are lifted.

The hoisting engine at the main shaft is of an original build having a lever-operated brake on each side of the drum placed in such a manner that either or both brakes may be applied, this method being much safer than the single hand brake usually employed and also more powerful. There is also a steam brake and a steam reverse. Among the other improvements is a method of taking up slack rope and thus keeping the relative positions of the cage so adjusted that there will be no delay in making landings.

The engines are figured to start an unbalanced load of 22 tons divided as follows: Cage, 11 tons; two cars empty, 4 tons; 6 tons of coal; rope, 1 ton. In order to preclude an overwind the hoister is provided with a safety stop. The engine cylinder measures 42 in. × 60 in., and the conical drums 10 ft. × 12 ft. It is possible with this equipment to lower into the mine any piece of machinery that may be necessary without taking it apart, a great advantage. The head-frame at the supply shaft, shown in Fig. 3, is of steel and designed for a load of 20,000 pounds, a factor of safety of 15 being used.

In addition to the two large shafts, known as the Blanche and Rachel, there is a small one, the Agnes, 12¾ ft. × 24 ft., used for taking men in and out of the mine and for handling slate and supplies. By thus relieving the other shafts of such

work, supplies can be lowered in daylight. A fourth shaft, the Miller, 16 feet in diameter and brick lined, is so located as to ventilate the entire mine, thus doing away with brattices and partitions in the shaft, and obviating the air leakage inevitable with such partitions, and at the same time making the air-current absolutely independent of the motion of the cages. As the mines make much water, a Jeanesville pump with a capacity of 1,000,000 gallons in 24 hours has been installed.

Fig. 2. Largest Bituminous Coal Tipple in The World, at Rachel Shaft

In the underground workings is to be seen the same attention to labor-saving devices and methods as characterizes the outside equipment. The main shaft bottom has a capacity of 250 loaded and as many empty mine cars and is arched for 1,100 feet on the rise, and 600 feet on the dip side of the shaft. By means of a chain haul, the loaded cars are fed on to the cages, and by the use of a rope haul the empties are returned to the shaft bottom tracks. The mine cars are of steel and designed with wooden bottoms, lift doors, spring draw-heads and link couplings. The sides are stiffened by bars across the top and by pressed steel stiffeners on the outside. The wheels are of special design and each car is equipped with a powerful hand brake having iron shoes.

Steel track is in all workings and mule haulage is entirely abandoned. On the main haulage road compressed-air locomotives of 15 and 19 tons weight deliver the coal to the shaft bottom. All coal is gathered by means of 6-ton compound gathering locomotives.

Four entries diverge into the mines from the foot of the air-shaft, which has an area of 201 square feet. The main entries extend to the boundary of the property, two for loaded cars, two for empties, and two for return air-courses. The cross-entries are laid out in pairs and entries have been driven from these, the mine being developed in panels. Not more than 50 men work in each panel and each panel has its separate air split. The entries are 9 feet wide and 7 feet high in the clear. All stoppings are of brick or concrete, brattice being carried to within 12 feet of the face and overcasts are built in the rock above the coal. All foul air and gas goes directly to the air-shaft and does not come in contact with the other faces.*

The method of mining is by room and pillar, the semi-retreating procedure being used, butt entries having been driven to the limit of the panel. One-half of the rooms will be turned back from these butt entries at the face end, and these rooms finished, the ribs will be drawn before the remaining half are started. The rooms have a length of 225 feet, but as the pillar-drawing proceeds they are continued across the air-course above and to the next entry, giving a total length of 265 feet.

The entire area to be operated from the two shafts is about 10,000 feet each way from the shafts along the main entries and about 3,000 feet on each side of the main entries. This area is to be divided into four parts, providing for five face entries in each section of the mine from which entries the butt entries will be driven about 1,800 feet long. Each section has its own independent haulage system, making practically four mines.

The tipple, washery, and coke ovens, being correlated in their workings, had to be situated with this end in view, the tipple, Fig. 2, furnishing slack to the washery, from whence the washed coal may be delivered to the ovens, while the bone coal is delivered to the boilers. The boiler house had to be located so waste heat from the ovens could be utilized as shown in Fig. 6.

The tipple at the main hoisting shaft is the largest bituminous mechanism of this kind in the world. It loads 5,000 tons daily with the least breakage in handling, removes impurities from the coal, and is so built that there is the least possible delay by reason of breakdowns. The coal is dumped over four cross-over dumps of heavy pattern, on to 1¼-inch bar screens, the empty cars going from the dumps to the kick-backs and thence to the transfers where they are replaced on the cages by pushers and transfer cars of the company's own design. The dumps operate in the ordinary way but are more quickly returned, being equipped with a pull-back comprising a steam cylinder piston attached by chains to the rear lever of the dump.

* Mines and Minerals, Vol. XXIX, page 272.

Fig. 3. Supply Shaft, Marianna Mine

After going over the screen the lump coal is delivered to the picking table. The impurities removed are sent to the crushing plant where they are made serviceable for use under the boilers, while the coal is delivered into railroad cars with minimum breakage. The picking tables are about 80 feet long, 6 feet wide, and run at a speed of 40 feet a minute. The slack coal falls through the screen on to conveyers whence it is elevated to revolving screens which separate the nut from the slack. Then the nut and slack go by separate conveyers to the shipping bins, the washer, or to the small bins over each picking table. With this tipple it is possible to ship the following grades of coal: Mine run, 3-inch lump, 1¼-inch lump, ¾-inch lump, 3-inch mine run, 3-inch nut, nut and slack, and slack.

The machinery of the tipple being in duplicate the chances of a breakdown throwing it idle are reduced to a minimum. Minor repairs to mine cars are made at the tipple, thus gaining time by not sending them to the shop. Two forges for sharpening heavier bits of the mining machines are located here also. The electric motors on the tipple are built dust-proof and have fans arranged so as to keep the working parts free from dust with clean air from the outside. The roofing and siding of the tipple are of asbestos-coated corrugated iron.

Near the Rachel tipple is a Connellsville fan 35 ft.×8 ft., direct-connected to two Connellsville 26″ × 48″ engines. A new departure comprises two clutches on the main shaft of the fan enabling the disconnecting of one engine and the coupling up of the other without change in speed of the fan. Thus if one engine should be idle it is not necessary to shut down the mine. The fan at 100 per cent. volumetric efficiency delivers 700,000 feet of air at an estimated water gauge of 6 inches. In order that repairs may be made quickly and cheaply, small cranes have been installed over each engine as in all other engine rooms at Marianna. The fan may be quickly reversed and air-locks are provided so the fan chamber may be entered while the fan is running.

The fine-coal washer of the Luhrig type adjoins the tipple and has a capacity of 100 tons per hour. It has 16 primary jigs and four secondary jigs which rewash the refuse from the primary jigs, thus recovering the bone coal. The washer machinery, like that of the tipple, is duplicate, and as much of the conveying machinery for the two is interchangeable a minimum stock of repair parts is necessary. One feature is the 1,500-ton reinforced concrete bin holding three days' supply of washed coal for the ovens in case of idle mines. It can be closed in underneath in winter to prevent the freezing of the slack in the bins. The gates from which the larries are charged are steam-jacketed; the larries can be run in under the bin on cold nights, the doors closed, the steam turned in, and everything put in shape to resume work unimpeded in the morning. Near the washer is a concrete bin from which refuse and bone coal is fed on to a conveyer which discharges into bins over the stokers in the boiler house.

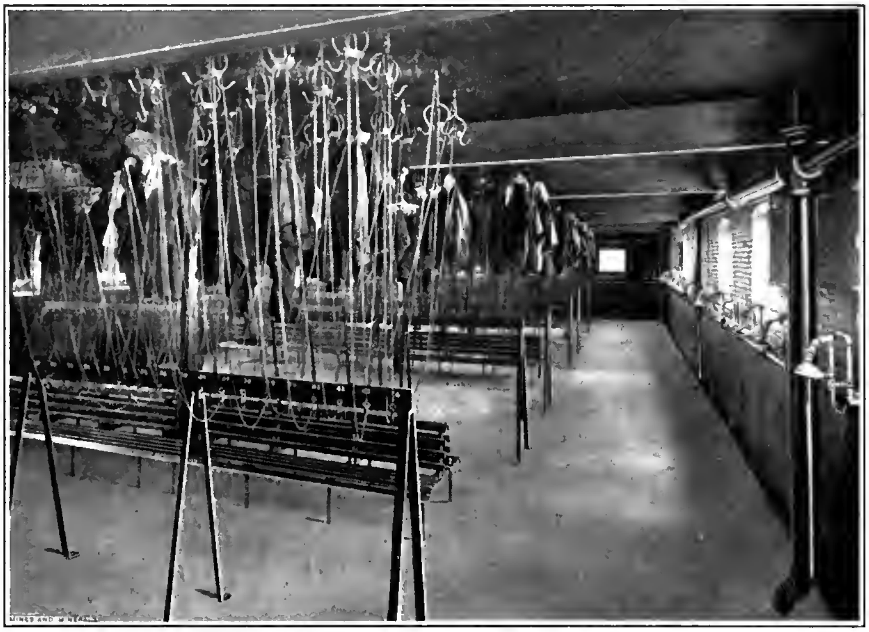

FIG. 5. INTERIOR OF BATH-HOUSE, MARIANNA MINE

The coke ovens are of the beehive type, 12 ft. 6 in.×8 ft. 6 in., equipped with the Kearns patent waste heat flue by which the waste heat is taken from the trunnel head instead of the crown, thus saving two bushels of coke per ton. The larries, having a 75-horsepower railroad motor on each axle, have a capacity of 8 tons of mine-run coal. The oven yard, 30 feet wide, is so arranged that coke-drawing machines can be installed. Provision is also made for loading box cars.

The boiler plant comprises Stirling boilers, 3,619 horsepower, old rating, of which four are equipped with chain grates and three with underfeed stokers, the latter having forced draft and being better adapted to the varying loads caused by the hoisting engine. The chain grate boilers are also fitted with waste heat flues so that coke-oven heat may be used under the boilers to generate steam. The overhead bins have a capacity of about 280 tons or 60 hours supply of coal with full load. It is the intention to install a pneumatic ash disposal plant.

The boiler house, like all Marianna build-

FIG. 4. AMUSEMENT HALL, MARIANNA MINE

ings, is of No. 2 paving brick with steel trusses and cement tile, built in such a manner that no repairs will be needed during the life of the plant.

The power building is back of and on the hill above the boiler house and in order to secure dry steam, there is a large tunnel connecting its basement with the firing floor of the boiler house. It is built of brick, concrete and steel throughout, and has also a 20-ton traveling crane with which all the engines were erected and which is conveniently used in packing, replacing gaskets, and making small repairs. The power house contains the following: One 500-kilowatt Westinghouse generator connected to a 20″×48″ Mesta Corliss engine. One Ingersoll-Rand Imperial compressor 20 in.×34 in.×32 in.×20 in.×30 in. and one Mesta 22″ × 36″ × 20″ × 34″ × 48″ cross-compound compressor, each with a displacement of 3,500 cubic feet of free air per minute, furnish all the low-pressure air required to cut the coal in the mine.

One Mesta and one Norwalk air compressor each 22 in. ×36 in.×28 in.×16 in.×9½ in.×5¼ in.×36 in., with a displacement of 2,200 cubic feet of free air per minute, furnish all the air required by the twenty 6-ton and one 19-ton Porter compound air locomotives which at present haul all coal produced at Marianna. These two high-pressure machines are the largest yet built in this country for this pressure. They are not equipped with receivers as the line itself is sufficiently large for this purpose.

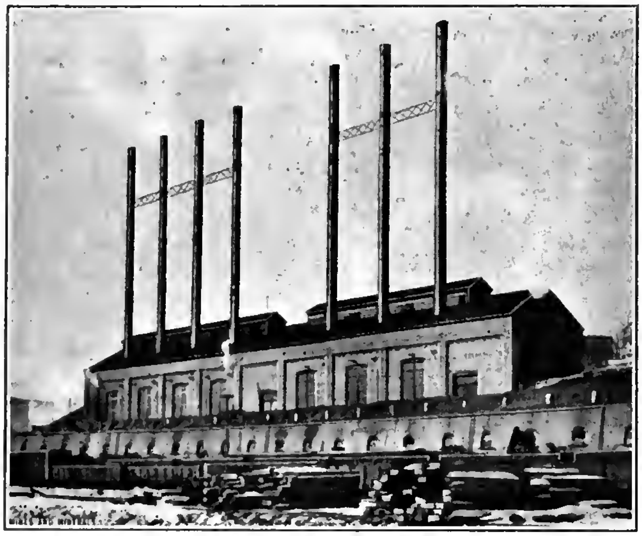

Fig. 6. Power Plant, Marianna Mine

The machine shop is near the Agnes shaft and is connected with it by tracks. In reality it is a collection of shops under one roof, including a carpenter shop, blacksmith shop, car repair shop, brass foundry, and four large storerooms. It is 182 feet long by 66 feet wide and two stories high. The ground floor is of concrete, the second floor of reinforced concrete, the storerooms being separated from the shops by fireproof walls with doors. There is one 25-ton electric traveling crane for hoisting railroad cars, three small traveling cranes and a jib crane. The blacksmith and forge department is large enough to make all manner of forgings for railroad cars, mine cars, and mine machinery.

The company has built about 400 houses in the town of Marianna, most of which are of yellow brick; the others frame. They vary in size from 4 to 14 rooms; are provided with hot and cold water, electric light and, if the tenants desire, with natural gas. They rent for $1.75 a room per month. Fireproof construction has been used where possible. Each house has a garden, the lot being enclosed with a substantial fence.

The streets are 50 feet wide, shaded and have concrete walks throughout, but the streets themselves are not paved. In each lot in the town are fruit trees. There is a sanitary sewage system, and drinking water is derived from artesian wells. The view from the town over the hills of Washington and Greene counties is beautiful.

There is an 8-room public school building under construction, and on the hill is a reservoir of 2,000,000 gallons capacity.

Two of the features at this interesting mine with its 1,500 employes are the bath house and amusement hall, both erected by the company. The former, whose interior is shown in Fig. 5, is modeled after the most advanced German shower or rain baths, is a brick structure 125 feet by 42 feet, four stories high, and is arranged so that men coming out of the mine are landed on a covered bridge leading to the fourth floor, which constitutes the assembly room. Here is the rack containing the safety lamps. Men entering the mine receive lamps prepared by the attendants, and men operating machines receive bits and oil for operating the machines. As the men come out of the mines they are checked by the timekeeper and pass down stairs to the bath rooms, their soiled mine clothing being suspended from the ceiling and ventilated while they don clean dry clothes.

The baths are of the shower kind, as a plunge or pool is dangerous for spreading disease. The inclined shower bath can be regulated for men of various heights and is the best form of hygienic cleansing bath. There are 99 shower baths for the men and two separate bath rooms for boys employed as slate pickers, etc. on the outside. There are also baths for officials and visitors in separate rooms. There is an emergency hospital on the ground floor. The lower floor is devoted entirely to the needs of the men working above ground, its equipment being identical with the two floors immediately above.

The amusement hall, shown in Fig. 4, is 106 by 62 feet and was built for the sole purpose of furnishing clean decent entertainment as well as instruction for the people of Marianna in the evening. The interior wall surfaces are painted in pleasing colors instead of being plastered. There is a theater equipped for vaudeville and moving-picture shows, with an elevated stage and dressing rooms, and seating capacity of about 275. There is also a billiard room. On the same floor, the first, is a drug store and soda fountain, while in the basement are eight standard bowling alleys, a restaurant, barber shop, and lavatories. The third floor is largely given over to a roller skating rink and dance hall, but there are also reading and lecture rooms, in the latter of which it is proposed to give instruction in mining.

The Pittsburg-Buffalo Company evidently believes that a happy workman above ground makes a contented one below ground. At least it would seem so in arranging the amusement hall. It is a pity the lectures cannot be made compulsive, since these men working in a naturally hazardous occupation and in virgin territory, more than usually gaseous, cannot be too much alive to the exigencies surrounding their own craft.

COAL AND OTHER EXPORTS

Coal and coke experts from the United States in 1910 aggregated $45,000,000 in value, and in addition to this more than $20,000,000 worth was supplied to vessels engaged in the foreign trade, making a total of $65,000,000 worth of coal passing out of the United States in the calendar year 1910. In 1900 the total value of coal and coke exported (aside from that supplied to vessels in the foreign trade) was about $23,000,000; 20 years ago, about $7,000,000; and 30 years ago, $2,000,000. Thus the value of coal exported to foreign countries in 1910 is practically double that of 10 years ago, 6 times as much as that 20 years ago, and 23 times as much as that 30 years ago. The quantity exported has grown from a little over a half-million tons in 1880, and about 2,000,000 in 1890, to approximately 8,000,000 tons in 1900 and 14,000,000 in 1910, aside from the 6,000,000 tons supplied to vessels engaged in the foreign trade.—*Department of Commerce and Labor.*

GEOLOGY OF HERRIN QUADRANGLE

*By T. E. Savage**

The Herrin coal district is a rectangle in shape, approximately 250 square miles in extent, situated in the southern portion of the state, at the southwest corner of the Illinois coal field. It lies roughly between the towns of Carbondale and Marion on the south, and Duquoin and Benton on the north; and includes portions of four counties, as follows: About 65 square miles in the northwest part of Williamson, 78 square miles in southwest Franklin, 22 square miles in southeast Perry, and 84 square miles in the northeast portion of Jackson.

Location and Importance of the Area. Correlation of the Seams. Analyses

The region has been mapped topographically by the State Geological Survey and the United States Geological Survey,* in cooperation. The district receives its name from the town of Herrin, which is a rapidly developing coal center. The Herrin quadrangle joins the West Frankfort on the west, and the coal field is a westward continuation of the Johnston City field, in Williamson County. There are operated within this area 32 coal mines, the output of which for the year ending July 1, 1908, was nearly 5,000,000 tons. Notwithstanding this large production, the development of the coal resources of this region has scarcely passed beyond the initial stage.

With the exception of about 40 square miles in the south and southwest portions, the area is underlain by two seams of coal, respectively, about 9 and 4 feet in thickness, within easy working distance below the surface. The quality of the coal in both of these seams is good, and the mining conditions in both are extremely favorable. A good market for the output is afforded by the presence of several lines of railroad within the quadrangle.

The range of surface relief within the quadrangle is about 230 feet, although the altitude over more than four-fifths of the area is included between 380 and 460 feet above the sea. The lowest point is about 3 miles southwest of De Soto, where the Big Muddy River leaves the quadrangle. The highest points are reached in the hills 2 miles northeast of Mulkeytown, which rise slightly above 540 feet.

The surface drainage of the area is entirely accomplished by Big Muddy River and its branches.

The rocks of this district consist of a mantle of loose surficial materials, overlying more consolidated beds of hard rock.

Within the quadrangle the surficial materials have an average thickness of about 40 feet. These deposits are deep over the valleys of the early Pleistocene streams whose ancient channels were broad and considerably deeper than the present valleys, as is shown where the Big Muddy and Little Muddy rivers carved channels in the strata, 75 to 90 feet below the present river beds:

Over the uplands the surficial materials consist of fine-grained silt, 18 inches to 8 or 10 feet in thickness, underlain by pebbly clay or till to a varying depth of from 8 to 25 feet. Along the larger water courses where these mantle materials are thickest, they are composed largely of fluvial, or fine, glacio-fluvial materials. A bed of quicksand, 6 to 25 feet in thickness, is often found near the base of these deposits. This sand runs easily, and has proven a serious obstacle in sinking coal shafts at a number of points in the vicinity of the larger streams. Above the quicksand the materials consist of sand and clay, often mingled in varying proportions, and frequently containing beds of till and thin bands of gravel.

The indurated rocks underlying the loose surface rocks consist of alternating beds of sandstone and shale, with occasional layers of limestone and seams of coal, and belong to the Upper Carboniferous coal measures.

In the early reports on the geology of Illinois the successive coal seams in the state were assigned numbers, beginning with No. 1 at the bottom. More recent work has demonstrated that the numbers formerly applied to the various coal seams in different parts of the state do not always indicate their true correlation. The following change in the use of the numbers is to be noted: The thick, blue-band coal, which is the principal seam worked in this area, will be designated coal No. 6 instead of No. 7, as in Worthen's reports on Williamson and Franklin counties and other counties to the east. This seam is also the equivalent of the Duquoin Coal of the Perry County report, and corresponds with coal No. 6 in the Belleville field. The 4-foot seam, occurring about 35 feet below the base of No. 6, will be referred to as coal No. 5. Another seam, about 250 feet below No. 5, will be designated coal No. 2. These respective coal seams are persistent and easily recognized horizons; the divisions of the Pennsylvania series in this region are made with reference to them, as shown below.

UPPER CARBONIFEROUS OR PENNSYLVANIAN SERIES

The McLeansboro formation embraces all of the "Pennsylvanian" beds occurring above coal No. 6 in this area.

The Petersburg formation comprises the strata between the base of coal No. 5 and the top of coal No. 6.

The La Salle formation includes the strata lying between the base of coal No. 5 and the base of coal No. 2.

The Pottsville formation consists of sandstones, thin shales, and thin coal beds lying between the base of coal No. 2 and the top of the Mississippian series. This is considered the equivalent of the Pottsville formation of the Appalachian region.

Pottsville Formation.—The strata of this lower formation of the Pennsylvanian series are known within the quadrangle from the logs of two or three borings which pass entirely through the Pennsylvanian deposits, into underlying Mississippian beds; and from the records of the few other drillings which penetrate the strata below coal No. 2 to a varying depth of from 100 to 400 feet. Further south, the full section of the beds of this formation outcrops within a dozen miles of the southern border of the quadrangle. In passing north from Cobden to Carbondale, along the Illinois Central Railroad, the outcrops of successively higher beds of hard sandstone appear as a series of conspicuous ridges. From the crests of these ridges the layers are seen to dip northward at a low angle, so that strata of successively younger age form the ridges that are encountered to the northward. The aggregate thickness of the strata of this formation in the region south of Carbondale is estimated at 750 feet. Within the quadrangle the greatest thickness recorded in the drill records shows 676 feet of Pennsylvanian strata between coal No. 2 and the bottom of the Pennsylvanian series. In the boring at St. Johns, a thickness of less than 400 feet is recorded for these beds. The formation is thickest at the south border of the basin, and the thickness decreases quite rapidly toward the north. The rocks of the formation consist for the most part of sandstones. Beds of more or less impure shale occur at a number of horizons; while occasional bands of limestone and thin seams of coal are also recorded. The thickest and most persistent coal seam in this formation occurs 40 to 70 feet below coal No. 2, and has a thickness of 6 to 18 inches.

In the La Salle formation coal bed No. 2 forms the base, while the fireclay below coal bed No. 5 constitutes the uppermost member. The average thickness of the strata embraced between these two beds is about 224 feet.

The No. 2 coal seam consists of two benches, respectively, about 22 and 24 inches in thickness, separated by about 14½ feet of shale. Since this is the important coal at Murphysboro, where the parting is thin, it may have the same character in parts of the area here described. About 55 feet above coal bed No. 2 there occurs a rather persistent coal band 6 to 28 inches thick. This coal is thinner northward and thickens toward the south. It is exposed at the surface in the east bank of Crab Orchard Creek. At a place where the coal has been mined

*Geologist Illinois State Geological Survey.

locally by drifting into the hill, the following succession of layers was seen:

Section Along Crab Orchard Creek

		Feet
5.	Yellowish-brown sandstone with numerous small brown spots	4½
4.	Layer of argillaceous limestone	1½
3.	Black, fissile shale	2¾
2.	Coal	2
1.	Gray fireclay	1½

Eight rods north of this exposure the sandstone member at the top appears to be 12 feet thick. One-fourth mile up the creek from this point there may be seen a thickness of 10 feet of the sandstone, overlain by 6 feet of gray, sandy shale.

Fig. 2. Anticlinal in Coal Measures

Three-fourths of a mile further south, at the east end of the wagon bridge over Crab Orchard Creek, the following section was measured:

Section at Bridge Over Crab Orchard Creek

		Feet
8.	Argillaceous limestone	1
7.	Black, fissile shale	3
6.	Coal	2¼
5.	Fireclay	2½
4.	Gray shale	5½
3.	Gray, sandy shale	7
2.	Yellowish-gray sandstone	8
1.	Fine-grained, shaly sandstone	10

The members 5 to 8, inclusive, in this section are considered the equivalent, respectively, of the members 1 to 4 of the section preceding. Corresponding beds outcrop about 1 mile southeast of the last exposure, near the middle of the same township, where the coal has been stripped for local use, on land belonging to Mr. Ben Lewis, and following layers were seen:

Section on the Lewis Land

		Feet
4.	Sandstone	16
3.	Impure limestone	1
2.	Black shale	4
1.	Coal	2

A thickness of 14 feet of sandstone, corresponding with No. 4 above, outcrops in a ravine about ½ mile north of the last locality, where it is succeeded by about 5 feet of shale.

The succession represented in the foregoing sections is thought to correspond with the beds associated with the coal occurring about 55 feet above coal No. 2 and 150 feet below coal No. 5. The strata intervening between these coals are in some records reported as consisting largely of shale, in others mostly of sandstone, and in still others of shale and sandstone in about equal proportions.

About 135 feet above coal No. 2 (80 feet above the coal seam last described) there occurs another fairly persistent seam, 2 feet in thickness. The strata occurring between this coal and the outcropping seam next lower consist largely of shale, although some of the records report as much as 38 feet of sandstone and sandy shale. Between the horizon of this 2-foot coal seam and the base of coal No. 5 is an interval of about 70 feet. In this interval, shales greatly predominate. In a few of the logs 8 to 10 feet of sandstone and one or two bands of limestone are recorded.

Petersburg Formation.—The average thickness of this formation, which includes the strata intervening between the base of coal No. 5 and the top of coal No. 6, is about 50 feet. Coal No. 5 is found in the quadrangle wherever borings have penetrated to the proper horizon. It is remarkably uniform in thickness, averaging 4½ feet in 40 records. The thickness rarely varies more than 6 inches from the average figures. Overlying coal No. 5, is a bed of black, fissile shale containing numerous concretions, or "niggerheads," in the lower part.

Section of Part of Petersburg Formation

		Feet
5.	Gray shale, yellowish where weathered	4
4.	Very fossiliferous, soft, gray, calcareous shale	1¾
3.	Layer of hard, bluish-gray, argillaceous limestone	1
2.	Black, fissile shale with fossils containing numerous concretions 8 to 30 inches in diameter	6¾
1.	Coal No. 5	4

The thin limestone band, No. 3 of the foregoing section, is usually present at a distance of from 4 to 8 feet above coal bed No. 5. Another limestone, 3 to 14 feet in thickness, generally occurs from 1 to 9 feet below the base of coal bed No. 6. None of the other Pennsylvanian formations in this area contains such a large proportion of limestone. Besides these limestones, and the fireclay below the No. 6 coal, the materials of this formation consist almost wholly of shale. This is more or less sandy in the middle portion, and dark, with bituminous matter, at the base.

In 130 records the thickness of the No. 6 coal bed, and the intercalated blue band, averages about 9 feet and 5 inches.

McLeansboro Formation.—All of the strata lying above coal bed No. 6 in this region are assigned to the McLeansboro formation. They are more variable than the beds comprising the preceding formations. The greatest depth of the coal beneath the surface, and so the greatest thickness of the formation within the area, is near the north line of the northeast quarter of the quadrangle, where some of the borings go down 560 feet before reaching the No. 6 seam.

The No. 6 coal is succeeded by a bed of gray shale or shaly sandstone 15 to 110 feet thick. The average thickness, in 120 test holes, is 64 feet. Above this horizon is a limestone band 3 to 12 feet in thickness. About 40 feet above this limestone, and 104 feet above coal No. 6, there is generally present a 2-foot seam of coal which, for a thin bed, is remarkably persistent over the area. Still another coal band, 6 to 12 inches thick, occurs about 150 feet above coal No. 6. In the northeast portion of the quadrangle a still higher coal seam is often present about 300 feet above the No. 6 coal. The materials intervening between these several coal horizons consist very largely of shale.

cost of mining, and the wise selection of the location for mine shafts. The dip and attitude of the coal seams, as well as the character of the associated strata, very materially affect the expense of drainage and the cost of haulage.

The structure of the strata in the Herrin quadrangle has been determined from the study of about 200 records of test borings, coal shafts, and water wells, using for a base the elevation of the No. 6 coal seam. The position of this seam is easily recognized in the records, and it is found in nearly every test boring made within the area north of its line of outcrop. The altitude above sea level of the No. 6 coal seam in the various borings and shafts was determined as follows: The elevation of the top of the several test holes and coal shafts was generally found by hand leveling from the nearest bench mark. When no bench mark was found near the boring, the surface elevation was determined by aneroid reading which was checked with the nearest bench mark. From the surface elevation of each hole was subtracted the depth to the No. 6 coal at the respective points, as given in the logs.

The coal seams, and the intervals between them, vary somewhat in thickness, yet the strata lie essentially parallel. The layers are not generally horizontal, but dip in different directions, and at various angles, in different portions of the quadrangle. The general dip and the altitude of the No. 6

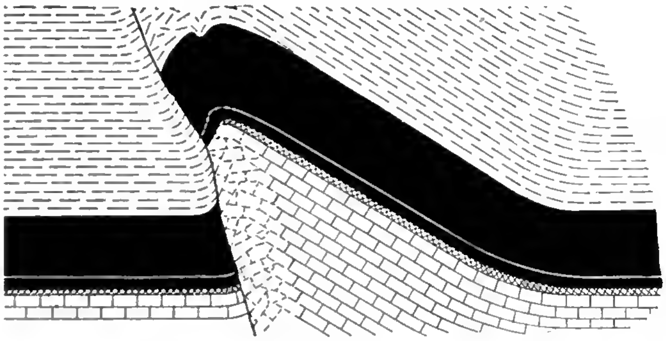

Fig. 4. Sketch Showing Thrust Fault in a Mine

coal at different points is shown on the accompanying map (Fig. 1) by the use of contour lines. The locations of the borings and shafts, the records of which furnished the most of the data used in the construction of the map, are also shown. From the legend the drill holes, mine shafts, and outcrops may be discriminated.

Between adjacent points at which the No. 6 seam was found to lie at different altitudes, the dip is assumed to be uniform. Hence on this structure map, a line connecting all of the known points at which the No. 6 coal seam occurs at an elevation of 400 feet above sea level constitutes the 400-foot contour line. In the same manner all of the points at which this coal was found to lie 375 feet above the sea, are connected by the 375-foot contour line, and so on. A dip of 25 feet is indicated between any two adjacent contour lines.

The assumption of a uniform dip for the coal seam between points where it is found to occur at different elevations is a source of slight error in a map constructed in this manner. A few faults, having a throw of 8 to 21 or 22 feet, and also local irregularities in the dip, and low folds or anticlines were found in some of the coal mines of the quadrangle, and seen in a few surface exposures. Fig. 2 shows a low arch exposed in the north bank of a stream, and Fig. 4 is a sketch showing a thrust-fault seen in Mine "B" of the Chicago-Carterville Coal Co.

The probability of error in the map is greater where the test holes, of which records were obtained, are a considerable distance apart, as in the vicinity of Little Muddy River and in the northeast portion of the quadrangle. Over such areas, where the data are not sufficient to give reasonable certainty of the structure, the contour lines are broken. However, it is practically certain that the errors from the above-mentioned causes do not exceed a few feet along any contour line; and that the general attitude of the No. 6 coal seam, and thus the general structure of the Pennsylvanian strata in this area, is essentially as shown on the map.

From this map it will be seen that in the south part of the quadrangle the No. 6 coal dips strongly toward the north, while near the west border, between Duquoin and De Soto, there is a rapid descent toward the east. Notwithstanding this dominant northward and eastward slope of the strata, local changes of direction and degree of dip are not rare. Near the northwest corner of the quadrangle is an area in which the eastward dip of the coal exceeds 200 feet to the mile. Over other areas the inclination is less than 25 feet per mile. The average dip per mile probably does not exceed 40 feet.

The direction of dip of the strata is assumed to be at right angles to the contour lines. The steepness of the slope is indicated by the distance between adjacent lines. A difference in elevation of 25 feet is shown by adjacent lines, so that the closer together the lines appear, the steeper is the dip, and the wider the distance between the lines, the more gentle is the slope of the strata in that region.

EXTENT OF THE NO. 5 AND NO. 6 COAL SEAMS

There is little doubt that the No. 6 coal underlies practically the entire surface of the quadrangle, with the exception of about 45 square miles in the southern and southwestern portions.

Practically all of the coal produced in this area is taken from the No. 6 seam. It is uniformly thick, ranging from $7\frac{1}{2}$ to 15 feet. The average thickness recorded in 130 borings is about 9 feet and 5 inches, including the blue band or dirt band. The blue band is almost universally present at a height of 18 to 30 inches above the floor. It generally consists of bone or shaly coal, or of gray shale. Its thickness is usually from $\frac{1}{2}$ to $2\frac{1}{2}$ inches. In 25 measurements of the coal seam the average thickness of the blue band was $1\frac{1}{3}$ inches. In the mines along the west border of the quadrangle this horizon is occupied by 5 to 15 inches of gray shale and bone.

A smooth parting of "mother coal" is usually present 16 to 30 inches (averaging 22 inches) below the top of the seam. Small lenses and thin streaks of bone and pyrite are occasionally found. These vary from $\frac{1}{4}$ to 1 inch in thickness, and occur most frequently between the blue band and the upper coal parting. The bony and shaly coal, and the pyrite fragments are picked from the coal by hand, where the best practice prevails.

Above the coal there is a bed of impure, gray shale, 15 to 110 feet thick, shown in Fig. 3, which in the lower part commonly contains a great number of plant impressions. In 120 borings studied, an average of 64 feet of shale intervened between the top of the coal and the overlying limestone horizon. This shale does not stand well when the coal is removed, and so the 16- to 30-inch bench of coal, above the charcoal parting, is usually left for a roof until the rooms are mined out, after which it is sometimes taken down. Timbers are generally set 3 to 5 feet apart in the rooms, and cross-bars are often placed 3 to 6 or 8 feet apart in the main and cross-entries. The fireclay beneath the coal is hard and, as a rule, thin, ranging from 4 to 50 inches. It is generally underlain by limestone and seldom causes trouble by squeezing. Rock rolls locally occur in the top of the seam, the larger ones extending down into the coal for a distance of 2 or 3 feet.

The coal is bright black in color. It is, as a rule, banded and on close inspection appears laminated with alternating bright and dull lines. Thin, more or less persistent partings and lenses, of "mother coal," $\frac{1}{2}$ to 2 inches thick, are found in the upper part of the seam. A distinct cleat is generally present, but it is not so strong as to prevent the cutting of the coal in any direction desired. The composition and fuel value of this coal may be seen from the table of analyses.

The excellent quality of the coal from the No. 5 seam is recognized in this region. Locally, it has a reputation of being superior to coal No. 6. Although it lies about 45 feet deeper, and averages somewhat less than half the thickness of the higher seam, yet its thickness is sufficient to be easily workable and the seam is sure to become of considerable commercial importance. The thickness of coal bed No. 5 is unusually uniform in all of the exposures and records examined, averaging about 4 feet 4 inches at 40 different points. There is no blue band or dirt band in this seam, and the coal appears to be more free from pyrite lenses, bone, and other impurities, than the No. 6 seam. The mining conditions are good. The fireclay below the coal is hard, and does not creep readily. Above the seam is a bed of hard, black shale that usually stands well as a roof with little or no timbering. Concretions or "niggerheads" are commonly present in considerable numbers in the lower part of the roof shale.

Farther east, in Saline County, the No. 5 coal is worked in preference to the upper seam, on account of its higher fuel value and the better mining conditions. The distribution of coal No. 5 is practically coextensive with that of No. 6 in the Herrin quadrangle, and the seam could be mined in connection with the higher coal without the expense of constructing separate shafts.

Mines and Mining Methods

Some of the mines in this area have been worked for many years, and the smaller ones still employ primitive mining methods. The larger and newer mines are generally provided with modern equipments and conveniences. Pick mining is not usually practiced, but the coal is shot from the solid, and hauled by mules on wooden cars of from 1 to 3 tons capacity. No effort is made to prevent the shattering of the coal in the process of mining. About one-third of the mines are furnished with mining machines for undercutting the coal. Compressed air is commonly used for working the drills, and electricity is, in places, supplied for lighting the mines. Electric motors, or tail-ropes, are used for the main haulage in a number of the larger mines. The deeper mines are usually dry, but the more shallow ones are sometimes troubled with water which seeps in from above. In most cases neither the necessary pumping nor sprinkling entails very great expense.

The mine shafts are generally 9 by 16 or 18 feet, in two compartments. The coal is hoisted by steam engines working a 6- to 8-foot drum. Conical drums are installed in a few mines. The cages are single decked and automatic, dumping the coal on the screens, which convey it to cars on Nos. 2, 3, or 4 tracks. Box-car loaders are employed at a number of the mines. The coal is generally screened and marketed in a number of sizes. At the larger mines washers are established, and 50 to 70 per cent. of the output is washed.

A modification of the room-and-pillar system of mining is in general practice. In rare cases the panel system is employed. In the greater number of the mines few of the pillars are pulled, and in some places where the shale drops easily the roof coal is not taken out. The amount of coal left in the ground varies from 33⅓ to 50 per cent. or more. This exceedingly large waste, in a seam averaging 9 feet in thickness, amounts to a loss of from 5,300 to 7,800 tons per acre, or more than 4,000,000 tons per square mile. In other words, under the present method of mining the No. 6 seam, the amount of coal left in the ground on every square mile is nearly equal to the total number of tons produced in this area in 1908. This very large amount of coal is permanently lost, for it is left in such a condition that it cannot be recovered later. With the price of coal land at $150 per acre, the cost of coal per ton to the company is so trifling—about 1 cent per ton—that the operators find it more economical to leave the pillars and less accessible coal in the ground, and take out only that which can be mined the cheapest. The superintendent of one of the large mines of this area is authority for the statement that more than 95 per cent. of the coal could be recovered if the mines were laid out and developed in a systematic manner with this end in view. Instead of that, in the face of excessive competition, the general practice is to get out the greatest possible amount of coal for the least possible expense, regardless of the waste in the process. A wise policy of conservation will look to the prevention of this enormous and unnecessary waste, even at a slight increase in the expense of production and of cost to the consumer.

COAL DISCOVERED IN TERRITORY OF MAGELLAN

This office is in possession of information, which seems reliable, of the discovery of a superior quality of good coal in the Brunswick Peninsula, to the south of the San Juan River, and on Dawson Island, near Lomas Bay. Samples have been analyzed by a competent party and pronounced equal to the best Cardiff coal. The analysis follows:

After water driven off percentages: Carbon, 76.47; hydrogen, 7.91; oxygen, 8.73; nitrogen, 1.93; sulphur, .97; ashes, 3.99. The specific gravity at 60° F. is 1.1342. A further analysis shows: Volatile matter, 24.85; coke (containing ashes), 73.51 per cent.; water, 1.64.

Supplementing my former dispatches concerning the existence of petroleum deposits in the Punta Arenas district, it may be added that the Chilean National Government recently sent a distinguished mining engineer to make an examination of the territory. After a thorough examination he declared that all the surface indications, judging by his past experience, show extensive petroleum beds. Petroleum has also been discovered on Cambridge Island in the Straits of Magellan, and an application for a concession to work these fields has been made by the discoverers.

All that is now definitely known is that there are surface indications of the existence of petroleum covering a large territory and vouched for by competent authority. Concessions have already been obtained for a part of the territory, and the parties having these concessions are now seeking to interest capitalists to aid them in exploiting the field.—*United States Consular Report.*

POSSIBILITIES OF A NEW LIABILITY LAW*

*By Sim Reynolds**

Mr. President and Gentlemen:—In an indirect way the subject of federal and state compensation to injured workmen has been brought to your attention before, and, doubtless will be again, for the subject is one that will not down. It will continue to agitate men's minds until there is a more humane method of treating our industrial wounded, and caring for those left dependent when the breadwinner is killed. We have in various forms in practically the entire country Employers' Liability. How unsatisfactory this is, statistics chosen at random will suffice to show.

The Question of What Shall We Do With Our Industrial Wounded?

Under the present method of paying liability less than 40 cents of every dollar paid by the employers in the United States reaches the men, women, and children for whose care and comfort it should be given. This of itself is unbusinesslike and inhuman, but what is worse, nearly one-half of the 40 cents is taken before it even gets a chance to get into the pockets of the injured workmen or their families. This, obviously, is the result of an indirect method of disbursement in practice generally—the method of paying compensation through the courts.

The bad effect of such a system can best be grasped when one finds 304 fatal accidents in one county, leaving more than 200 families dependent, and 88 of them receiving not one cent of compensation for the death of their breadwinner. Practically the entire three hundred were contributing to the support of others besides themselves. Ninety-two families received funeral expenses only. Thus 180 of the 304 cases cited, or 59 per cent. of these families were left to bear the entire income loss. Of the families remaining, only 62, or 20 per cent., secured in compensation more than $500 for the death of a provider—a sum which would approximate one year's income of the lowest-paid worker killed.

It is often pointed out that the burden must eventually be borne by the community. But wait. Out of 526 men killed in Pittsburg the city was called upon to bury six, and only seven families made any direct demand upon charity, and in these the items of relief were small. Out of 132 fatal cases, 59 of the widows left went to work, cleaning offices, taking boarders, washing, etc. Out of the 132 families, 22 children were taken out of school before they were 16, immediately after the accidents.

These are some of the things that follow industrial accidents, and, although it robs charity of much credit, it proves that as a rule the family of the American worker is not without a sense of pride and independence in taking up the burden of existence.

A well-framed and well-enforced law regulating this matter is of importance to every mining man. The future holds no reasonable hope, despite our best efforts, that the mining of coal will cease to be attended with death and injury; and it behooves us, by beneficent legislation, to alleviate the human misery inevitably resulting when accidents occur.

In nearly all industrial nations, with the exception of our own, this has in various ways been done; and in certain isolated cases—particularly by one of our own state's largest employers—the initiative has preceded the inevitable ultimate framing of such a statute. Public opinion favors a fairer liability law—one that shall deal squarely with employers, not less than employes. Our present method works quite as unjustly on the operators as it does on the men, the only difference is we, as a rule, are better able to stand it.

Many corporations—some of them in mining business and some out of it—have, however, found the injustice of our present compensation law intolerable. Such large concerns as the Cleveland-Cliffs Iron Co., the United States Coal and Coke Co., and many others, have formed plans of their own, and today are carrying them out independently of the laws provided for such cases. While such individual effort is worthy of emulation so long as present conditions exist, yet it cannot in the nature of things be the best thing possible. It speaks loudly for the need of a common law to govern all alike engaged in industrial pursuits, a law governing liability that shall make it unnecessary for one or two corporations to make their own laws in order to have one worth while.

Thorough investigations on the part of those gentlemen responsible for these self-protective measures have found a condition unparalleled in any large industrial country. They found a very pressing need of revision and cautiously but surely revised and amended to suit their own particular needs. They found that the fees exacted by casualty companies were out of reasonable proportions with the amount that reached their injured men and the widows and children of those killed. So they placed their liability to their employes on a business basis, and have the satisfaction of knowing that, while their own method may not be the best that could be drafted and enforced, yet it does result in each dollar going into the stricken homes of their working men. So far, that is very good considering the chaos and injustice it has displaced.

Unfortunately many corporations, while having the best of intentions toward their injured miners and the wives and children of those who are killed, are not in a financial position to essay the philanthropy, and perhaps are not strong enough to compel a species of insurance with an employed personnel that is here today and gone tomorrow, or at best is more or less antagonistic to any insurance fee being deducted from pay envelopes for that which may never occur to them.

The employer grieves at the harrowing spectacle of abject dependence and poverty too often presented in individual homes following the family's deprivation of its usual income. Unless a general provision is made, to give monetary relief in even the most deserving case would set a precedent the employer—being totally without reimbursement from any point—might find beyond his means to follow. This would create a difficulty the end of which none could foresee; and if the employer takes advantage of the tentative offers of certain casualty companies, and covers the possibility of accident by insurance, he generally finds the result unfavorable from every point of view. The money he would have to give to the poor family deprived of its breadwinner—the money he paid hard cash to secure, as he thought, for that very laudable purpose, he finds is used chiefly in the maintenance of a small army of expert ligitants; and the reasons these expert gentlemen can dig up from the simplest kind of testimony why the injured man or his family should not receive compensation is simply astonishing, and astonishes the employer as much as it mortifies the man seeking redress through the courts.

The one improbable chance of indemnity that the injured has is to prove the employer responsible, and even in that case the operator need not prove himself innocent; the injured man instead must prove him guilty.

Here is where the legal representative of the casualty company gets the lion's share of the argument; and in the face of this long-established phase of English common law, now obsolete in England, the employer who has paid money ostensibly for the benefit of his employes stands helpless. Until there is enacted a specific statute eliminating this idea of "contributory negligence" forever from the zone of legal equity, it will be used for this baneful purpose.

Not long ago a mule driver received internal injuries. He was sent to the hospital, and the case was placed by the coal company with the insurance corporation carrying said company's responsibility in such cases. Some time later a relative of the injured man sought the mere justice of at least hospital expenses, realizing that the accident was due largely to carelessness on the part of the injured man. He was referred to

* Delivered before the West Virginia Coal Mining Institute, Wheeling, W. Va., December, 1910.

the main office by the superintendent of the mine, knowing almost to a certainty that his errand would be fruitless. The men composing that mining corporation are far from being the human juggernauts that poor broken miner and his relatives would naturally believe. I know personally that nothing would have pleased them better than an opportunity to make fair compensation to their injured employe, to relieve him of physical anguish and financial burden at the time above all others when he was unable to bear the latter. Yet they could do nothing more than they had already done—carry insurance with the only available companies existing under our present laws. Shortly after the fruitless visit of the injured man's relative came an astute legal light from a nearby city seeking some phase of negligence which would place the whole burden on other shoulders than those of the insurance company he represented. Quite naturally the very purpose of these casualty associations is opposed to compensation. With them it is a business, just as mining coal is a business with you and me; and their chief aim is to secure the most in premiums at the least outlay. Otherwise they could not exist.

The fault is not theirs; but lies in the antiquated methods of law which leaves us only these round plugs to fit into square holes. Nor does the evil stop there; because, under the present system, the fact alone that the employers, or many of them, have the insurance company standing between them and claims for damages by injured workmen does not breed a desire for precaution that would exist in case a liability law were in effect. Unconsciously, the present system allows high pressure, and makes violation of necessary rules almost excusable.

To the average employer this illuminative idea, which, to quote an eminent English jurist, "originated with Lord Abenger, and to which the devil gave aid and increase," is not only obnoxious, but confounding. It is opposed to his sense of equity. That a worthy man, injured while on duty in an industrial pursuit, should be compensated regardless of the fact that his employer has used due care or regardless of the fact that his employe or his fellow workman has been careless and negligent, and have directly or indirectly contributed toward the accident, admits of little argument in the mind of most mining officials; in fact, it has been generally conceded by the majority of men who have had occasion to speak on the subject. Rather, to the logical mind the fact that he has been seriously injured, and through no fault of his own is disqualified to further continue the struggle for a living and the maintenance of his dependents, is not the least of reasons why the workman should receive compensation at the hands of those able and qualified to give it.

The number of employers who flatly deny the need and justice of direct compensation is so small as to be hardly worthy of notice. The fact that this strenuously struggling nation has its legal and industrial affairs in an unsettled state, is about the only logical reason why a workmen's compensation act has not been made an integral part of our national or state law.

From what certain sources shall a fund for this purpose be drawn? Even those countries in which the idea of compensation has long been a permanent feature differ in method, while being unanimous in principle.

That of Germany—which was the first to universally compensate for death or injury in industry—has some features which appeal to an American; but it has also some which would be hardly applicable here. There, accident insurance is compulsory. Funds are raised by trade associations formed specifically for that purpose. These compensation associations cover all dangerous occupations, and disburse to the workman, or the dependents of a workman totally incapacitated, an amount equaling two-thirds of his wages—two-thirds of which compensation is given out of a fund accruing from an assessment made on wages of employes, and one-third from funds of the employers. If the disability continues beyond 13 weeks the compensation comes entirely out of the employers' pockets. In case of death, compensation is provided for funeral expenses, and a pension for the widow until her death or remarriage, and for every child under 15 years of age. The total compensation in any case is not to exceed 60 per cent. of the deceased workman's yearly earnings.

In the event of a widow's remarriage she is given 60 per cent. of a year's earnings in a lump sum, which settles her account against the association. To carry this cost, trade associations form insurance associations for defined districts. All trades in each district in which compensation is a factor enter and are parties to this agreement, but pay only according to the risk involved. A board of directors computes the amount to be allowed, from whose decree an appeal may be made first to a court of arbitration, formed of equal numbers of employes and employers, lastly to the Imperial insurance office whose decision is final.

The result of this method has been highly satisfactory to the German people. In the year 1906 263,000,000 marks were distributed through the sick fund, and 145,000,000 marks for sickness and compensation. In addition, it is said nearly all the great industrial establishments add to their compulsory compensation by voluntary contributions.

The Germans—an intensely practical people—reached workmen's compensation through the same logical deductions by which we, as an industrial people, must eventually reach it. They had abundant evidence in every village, town, and city where industry on a large scale is carried on that when the workman's family is deprived of its sole means of subsistance the result is not only misery, poverty, and starvation in whole or in part to those who are dependent, but, under old methods, that the result is undeniably inimical to the best interests of the community. They reached the simple conclusion that so long as dangerous labor must be performed by human hands and human bodies, accidents would happen. Further, that an accident would not be an accident if it could be foreseen, prevented, predicted, or avoided; that accidents are the inevitable result of the trade. Therefore, since they stood always liable to occur, and, having occurred, wrought a pernicious result that money only can permanently relieve, the way to a satisfactory solution lay in providing that money by insurance, just as any other possible loss is provided for. The Germans consider an accident as such, regardless of the fact that some fool added his contributory mite to the incapacity of a fellow workman. This should not, and does not, remove the human element from the case; nor does it of itself satisfy the poor family's needs.

England, which gave us this present illogical method of defeating justice, long ago saw the fallacy of it, and removed it absolutely from her statutes. There, the employer is liable for all accidents. In case of injury to a servant the master pays his employe 50 per cent. of his weekly earnings, provided that does not come to more than 1 pound per week. The method for those under age is slightly different, but the result to the employer is similar. Compensation in case of death is 3 years' wages, or £150, whichever is larger, but in no case to exceed £300; compensation is paid to the injured workman or to the deceased workman's dependents in a weekly pro rata.

Compensation in England is made a burden on industry. Fully 13,000,000 people are now working under its provisions, and are in line for its benefits in case accident incapacitates them. A member of the British Parliament, in speaking to certain Americans, found a difference of opinion regarding the English method of placing the cost of compensation totally on the employer. He said, in its justification, that the great majority of thinking men in Great Britain believe the method right. It makes the matter a universal one of additional insurance. Under the new British Liability Law no employer in any part is favored at the expense of another, as was the case in the old law. People engaged in other than manual labor and policemen only are excluded from its benefits. Thus, every corporation and every individual employer, whether he numbers his servants by ten or ten thousand, must take this possible loss

into account at the start, just as he does regarding his boilers, his buildings, his flywheels, his plate glass. He simply extends the insurance to take in the human life used in his business for the same purpose as his boilers or his flywheels—to create profit. The regular wages are paid for the labor performed, and do not—as with us generally—also cover the personal risk. Every industry is made to bear its own cost of insurance.

This is the situation in Great Britain and in every country where compensation is in force—with the exception of Germany, Austria-Hungary, and Luxemburg. The employing interests sustain the whole structure. In the four countries named, however, employes bear part of the expense. In all countries definite compensation is fixed by law, and in all countries except Sweden it is based on the previous earning capacity of the injured workman. In Sweden a flat sum is paid regardless of previous earnings.

While the methods differ, yet the central idea remains the same. In Germany and Austria, the workman is sensibly made aware of his participancy in carrying this protection. Such a scheme might work out here, if the better one of placing a small tax on coal production were not grasped as the means to the same end. If not, the resultant burden placed wholly on the employing interests of our state could not prove much worse than the uncertain one we carry today.

If certain constitutional difficulties could be overcome, to the end that the matter of liability could be made a federal instead of an individual state matter alone, the way out of the difficulty seems plain.

It would seem that the most practical and logical way would be in the form of a slight tax on each ton of coal produced in the United States. The difference to the consumer would be scarcely noticeable; the difference to the welfare of our miners and our miner's families would be beyond computation. I speak only of this matter as it concerns our trade. If congressional provisions can be secured to cover our industry, of course, they will of necessity be more or less universal and the result be beneficial to all industries. Many signs point to a general awakening everywhere throughout this country in the respect of the public's duty to its injured toilers. Men, and women too, in constantly increasing numbers are beginning to see in a wounded soldier of industry a fellow human equally deserving of public bounty as the man who falls while bearing arms. Both are essential to the peace, the greatness, and the ultimate welfare of any nation; and the fact that the miner, the mill worker, or the man who sets in place the steel columns for our huge and towering buildings loses his arm, his limb, or his life without the attendant heroics and the brazen blare of the battlefield does not, in the minds of sober-thinking people, detract one iota from the worthiness of his action or the just deserving of reward. General Edward O'Toole says: "I may add that the public shows in many ways that it is not only willing but eager to pay a few additional cents per ton for its steel or its coal, if thereby the business of producing these necessaries may be conducted in a safer and more humane manner."

We have all felt at times the anguish of impotency in face of a great need that was too obvious, too glaring, to be hidden, and too pitifully insistent to be casually ignored. A few of us—fortunately a few—have seen this crying vital need amplified by tens and hundreds following a mine explosion. Then, being impotent, we have tried to forget; but before long it has happened again, and the same dismal scene, unrelieved by the gleam of human sunshine that efficient compensation would lend to the picture, has been gone all over again. Again and again we have been an unwilling participant in that moral and physical tension which is thrust by these accidents on the employing as well as the employed, on the official as well as the subordinate. That mining man does not live nor work, I hope, in West Virginia who, at such times, has not hoped and prayed for the possibilities of hunger to be positively removed from these stricken homes. More, perhaps, than other men, we share the common opinion which seems to sanction the step that would remove this question from the abstruse to the concrete, and set it in practice throughout the states. We have plenty of wholesome precedent to guide us if we need it, out of which we may readily take the best and leave the worst.

Yet even more glaring are the faults of our present system which should be scrupulously avoided. Briefly they are:

1. Unwise legislation, on which large sums are spent to no permanent benefit.

2. We should particularly avoid anything approximating our present roundabout system in which it is positively known that millions of dollars are annually paid for compensation, and yet not near 30 per cent. reaches the injured or their relatives. Our new liability should be nothing if not direct. There should be no necessity of lawyers in this matter; compensation should not be secured through lawsuits.

3. Another glaring feature of our present method we should take heed to remove is, that liability secured through the courts—no matter how small or large it may be—is anywhere from 4 months to 4 years in reaching the recipient. Also it breeds misunderstanding and distrust and enmity where there should be friendliness and cooperation to reach the same end. Such compensation as a newer and better liability law would allow the workman should be paid immediately—at that time when it is most needed. And the removal of all need of threshing the matter of compensation in the courts would not—as some opponents have said—breed carelessness in operation. The fact that a new liability law would take the injured employe's incapacity as sufficient evidence to award him directly his just dues would hardly instill in the wage earner a desire to deliberately get hurt or killed on purpose to get the award. I can't imagine a man saying to himself before starting to load coal under dangerous stone: "Well, here goes. If I do get my back broken my wife will get $3,000 to take care of the kiddies." A workman's carelessness is not deliberate, but spontaneous and impulsive, even though it is habitual with some men. The miner would under our present "high pressure" rules get behind in the race if he didn't take a chance now and then. But the trouble is there are no "loser's ends" in this race. If the fear of death doesn't insure caution in the workman the fear of poverty for his family will hardly do it.

The highest compensation settled on as fair award for injuries in any of the countries considered, comes far below the average earnings of the workman to whom it is paid, hence it would neither be comfortable nor profitable to be careless and thereby get in line for liability funds. Therefore we should above all institute directness in applying any new method. In what particular manner we shall get at it must be left for calm deliberate study.

In addition to the several notable companies which have voluntarily formed compensation funds several states have placed themselves on record as favoring the principle. One of the most progressive and yet uncomplicated systems looking to this end went into effect on the first day of October last in the state of Montana. The legislature there has placed a tax of one cent per ton on all coal mined in the state, to be paid by the operators, and one per cent. of the gross monthly earnings of each employe constitutes the general fund. This is invested by the state auditor. Three thousand dollars are paid to the beneficiaries of each man killed. In case of permanent disability the miner receives $1 per day.

In the state of New York members of a committee appointed to thoroughly study the question placed themselves on record as favoring compensation in at least all dangerous occupations. The report and suggestions of this committee are too elaborate to be detailed here, but, summed up, reach about the same end in a more roundabout way. What action has been taken on this report I have not at this moment means of determining; but the result will undoubtedly be a compensation law for the

state of New York. Nebraska, Maryland, and Wisconsin are among the other states which have officially considered the problem of "What Shall We Do With Our Industrial Wounded?"—all of which adds, if proof were needed, to the contention voiced previously before this Institute, that the United States are awakening to their responsibility in this respect as never before.

What I advocate, is the greatest possible utility from the liability burden we already carry—a huge load of some $23,000,000 annually. This is the tax our present antiquated, inefficient liability law imposes on the employing interests of the United States. To what end? It is computed, from reliable statistics, that less than 30 per cent. of all that huge sum of money reaches the workman for whom we pay it. Why? Because we, too, suffer from the middleman. Even that 30 per cent. must, under our present method of compensation only through a lawsuit, be divided with legal gentlemen who drag the case out to its farthest end. On every dollar we pay in liability fees the families needing it get 25 or 30 cents. Worse still, even that is, on an average, 3 to 4 years reaching them. In the meantime 9 of every 10 families dependent on compensation have for that length of time been public charges, or children who should have been in school and weak women who should have been at home have been compelled to do their poor best to provide food.

Contrast our method with that of Great Britain, where the percentage of lawsuits in this premise is one in a hundred cases, and where, out of each dollar paid by the employer for relief of his injured workmen, practically the entire 100 cents reaches those who need it, and whom he desired to get it. They, have simply rid themselves of an out-of-date, costly, unfair system of liability. In contrast with us, peace between employer and employe remains unbroken—when an accident happens both know what the result is going to be. Here, an accident sets the employer on the defensive against a jury which may prove unfair to him or unfair to his servant. Both go fighting through the courts, where costs and appeals and delays eat up valuable business days and equally valuable dividends. Either that, or a liability company does the fighting for the employer, and a shyster lawyer for the workman, with the spoils falling to the undeserving either way.

Let us fancy, for instance, all the employers in a certain definite district in the coal fields of West Virginia forming a liability association, with a board of directors in control. Let each one annul its liability contracts with outside casualty corporations and place the premiums previously paid into a common fund. Let the board of directors formulate rules and regulations, and designate the amount that shall be paid for injury, or what for death of an employe. Let the companies sharing in the contract add, pro rata with their number of employes, to the amount deficient in any year, and share in the surplus of any remainder. If expenses should be a little more, there would be the satisfaction of knowing that it had gone to the right spot. The whole economic loss would be evenly distributed—and, as a natural result, careless and inefficient employes would be weeded out. The very act of cooperation in this premise would set all the companies concerned on the alert to prevent accidents, and would inevitably, if slowly, result in a beneficent condition as to working conditions, and, doubtless, a diminution of the grievous mortality list. This plan, as others detailed briefly here, has been tried and proved good. One large company which took it upon itself alone said it not only saved money, but did away with legal vexations and curtailed labor troubles. Doubtless, in assuming this plan the board would employ a committee of inspection to work independent of the state, and to be answerable only to the association, to suggest improvements looking to safety at this place and at that, with the aim in view of compelling each member to do his share in effort to decrease liability losses. Thus would the small employer stand on a par with the greater one. By uniting for this purpose—however they hacked at one another's throats in the matter of prices for coal—the weak would become strong. The plan would enable the plant putting out only a few cars a day to share in a liability method available only to such firms as the United States Steel Corporation or those of smaller magnitude. Otherwise the employer of small plants must continue to take his choice of the two evils now open to him: fight any possible cases through the courts on his own responsibility and with his own money, or hide behind a liability company. Within the possibilities of a federal liability law there is nothing whatsoever detrimental to my employer or to yours, gentlemen. I am not urging the placing of additions where the burdens are already as much as can be borne. Rather, I would relieve the moral and financial tension. Does it not occur to you that herein lies a probable solution to a problem that has baffled every man who has to deal with wilful, disobedient, undisciplined employes? Who shall say that a general application of financial responsibility for accidents of whatsoever nature may not compel employers to be less lenient to criminally negligent miners? May it not also instill into the official mining man, and the employer himself, a more wholesome regard for the law as written? Here there occurs to me the only lamentable feature of all the provisions I have read on this subject. I see nowhere that an employe is made responsible. Why not remove the fellow servant contributory clause, and still leave in the penalty for wilful, criminal disobedience or carelessness on the part of the injured man himself? Pitiful indeed, I grant, it would be to see the wife and children deprived of sustenance because of proved criminal carelessness on the part of the husband and father; but might not a greater good accrue because of the widespread lesson? Or would the method of placing the man injured through breaking industrial law where he would not share in the compensation benefits be of avail, at the same time give to the wife and children all that the law allowed? These considerations must, of course, ultimately be dealt with. We can conjecture, but as to the certainty of their working I do not know; but the thought occurred that there should be some way of meting to the criminally negligent employe the just penalties of his injury—if positively proved—as well as its rewards, just as financially the penalty would be shared by the employer. Or would the fact of the workman being deprived of a greater income be penalty sufficient? In some cases I feel safe in saying yes; in others, no. No man—if you will pardon the apparent egotism—is better able to judge the miner than one who, from 11 years of age, has been a miner.

The subject is very wide and in many respects complicated—therefore deserves most careful thought.

SAFETY LAMPS ON BATTLESHIPS

The practical utility of the American Beard-Deputy safety lamp, equipped with the Beard-Mackie sight indicator for the detection and estimation of gas has recently received indorsement at the hands of the Bureau of Steam Engineering of the United States Navy. This Bureau, in connection with the serious explosions that have occurred from time to time on shipboard and elsewhere, in coal bunkers and storage bins, and in the operations of the large fuel-oil storage tanks now required in the navy, after careful consideration, placed a large order for the above type of safety lamp with the American Safety Lamp and Mine Supply Co., of Scranton, Pa.

The indicator requires no skill or technical knowledge in its use. It needs no highly inflammable or volatile liquid to be burned in the lamp when testing for gas. Extremely fine adjustment of the lamp flame when making a test for gas is unnecessary as the indicator shows promptly and plainly the exact condition of the air either with respect to gas or dust. There is no guessing. As little as ½ per cent. of firedamp is clearly shown by the bright incandescence of a single percentage wire, while larger percentages are indicated clearly by the glowing of one additional wire for each ½ per cent. of increase in gas.

SELF-DUMPING CAR HAULS

Written for Mines and Minerals

One of the mine manager's endeavors is to adopt only those improvements that will improve working conditions and decrease cost. This praiseworthy object does not meet the approval of those owners who are unable to understand that the first high cost of an improvement may prove the greatest in ultimate economy.

Different Arrangements Used to Dump Coal and to Handle Mine Cars at the Tipple

Take for example the horn tipple, shown in Fig. 1, which at one time was considered the most excellent device for dumping where the coal came in cars to the tipple floor. The dump was easily and cheaply constructed, and worked easily when built so as to take advantage of the load passing its center of gravity and becoming unstable.

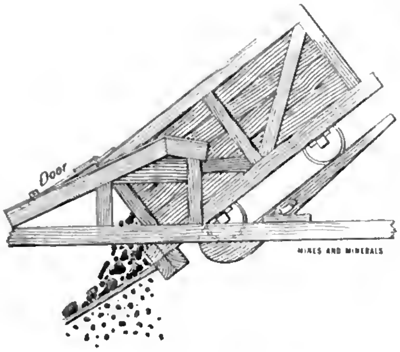

Fig. 1

The most objectionable feature in connection with this horn tipple, was that in case the dumpsman failed to use care the car would hit the horns so hard something would be strained or broken.

Suppose a car weighing 1,500 pounds containing 3,000 pounds of coal, moving at the rate of 5 feet per second is suddenly brought to a stop, its momentum would be 22,500 pounds, and this would be transmitted to the dumper horns, back to the boxes to which the dumper was fastened, to the tipple floor. The reaction due to the impact would reflect on the car boxes, to tear them loose, while the coal would rack the car body.

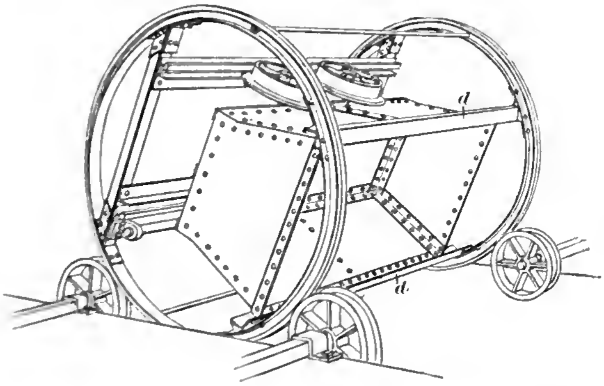

Fig. 2

In a short time when this dump is used some part of the dump and cars will need repairs, or possibly be the indirect cause of more serious matters such as wrecks.

To overcome the objections to the horn end dumper the English mine managers long ago adopted a form of circular dumper similar to that shown in Fig. 2. This to some extent has been adopted in this country, where a cross-over and back switch is used, or where there is an opportunity to approach the chute from the side and dump into it at right angles.

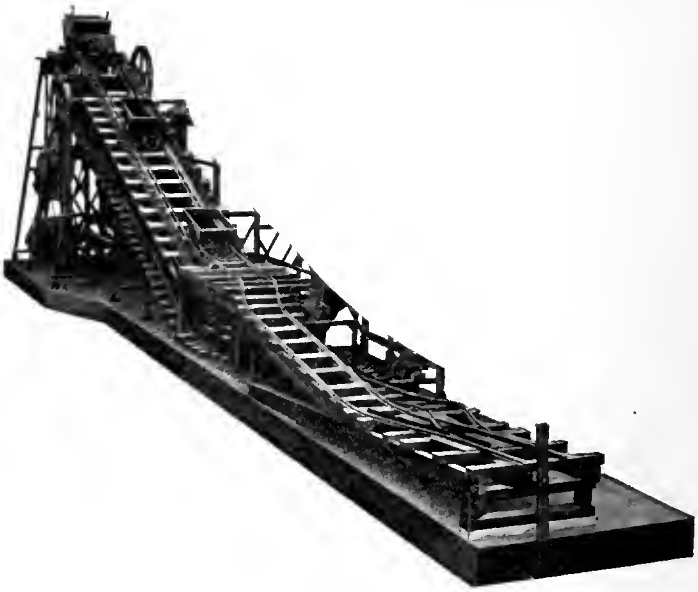

Fig. 4

One feature which adds materially to the value of the circular dumper is that no swinging door is needed on the car, which certainly decreases the cost of car up-keep; prevents loss of coal in transportation, and possible wrecks; keeps the roadways cleaner and does away with the man or boy whose duty is to attend to car doors and latches. The rotary dumper does not rack the cars or work the car boxes loose, besides it can be manipulated so as to pour the coal out into the chute and not send it with a rush that prevents it being properly screened, at least over bars. There is some objection to having fast ends on mine cars, they being harder to load, particularly where the cars are large and the coal bed low; under other conditions this does not militate against them, and in any case they should be used on inclines. Circular dumpers are readily controlled and are sufficiently fast for all practical purposes.

Many changes have been made in the horn or end dump with a view to preventing the shock, to regulate the tilting and dumping, and to prevent the shock when the car has been dumped and returned to its normal position; in every case, however, manual labor has been required to pull the empty car from the dump out of the way so the next loaded car could run on. The Reading Iron and Railway Co. introduced an end rocker dump at their Hammond breaker near Girardville, Pa., which gradually brought the approaching car to rest, and after being discharged the dump in returning to its normal position gave the empty car sufficient momentum to run it out of the way of the next loaded car.

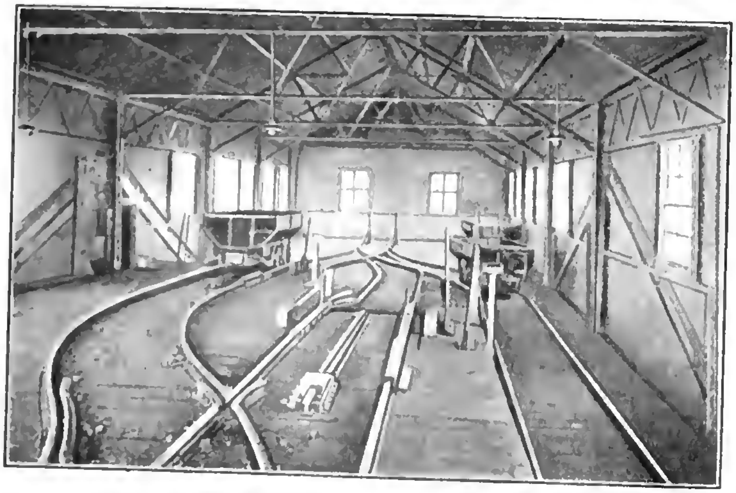

Fig. 3. Interior of Tipple House

In the United States, cross-over dumps are given preference at bituminons coal mines and also at anthracite mines where coal can

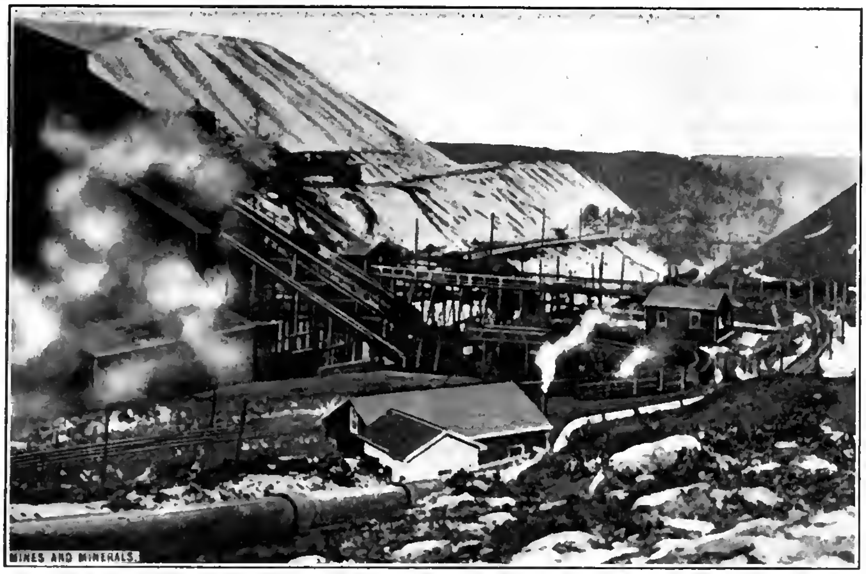

Fig. 5. Burnside Colliery, Shamokin, Pa.

be dumped to advantage at the surface. Cross-over dumpers are arranged so that they can be tilted by hand, or by means of air or steam. The use of this dumper requires that the tipple floor be made long as in Fig. 3 to provide for a kick-back to return the cars automatically to the empty track. At bituminous mines there is no particular objection to this length unless it be the cost; but at anthracite mines the extra room at the top of the breaker could not be obtained, except possibly where the breaker was built on a side hill and the coal came on to the dumping floor on a level.

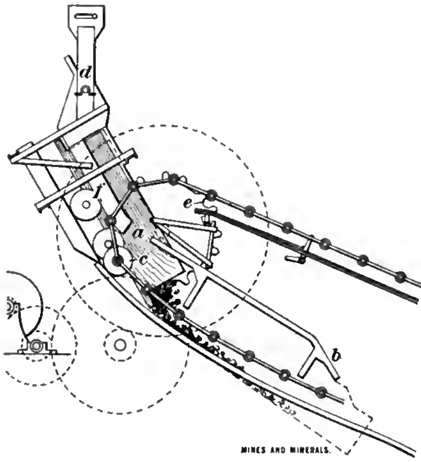

Fig. 6

Where the coal comes to the bottom of the breaker at grade it is becoming the custom in the anthracite fields to use a cross-over dump at the surface and raise the coal up to the top of the breaker by means of an inclined conveyer or scraper line, while in the bituminous fields it is customary to use a chain haul and raise the car to the tipple floor and then unload by means of the cross-over dumper. This requires the use of a bottom man, a dumpsman and helper and an empty-car pusher. It occurred to F. C. Green, a mining engineer in Cleveland, that he could reduce the length of the tipple; the expense of the installation of a cross-over; and the number of men required for the dumping, by making use of the conveyer system, and also obtain the advantages of that system, which are less breakage, cleaner coal, and less vibration to the structure. The result of his endeavors is shown by the model, Fig. 4, that was exhibited at the Wheeling meeting of the West Virginia Mining Institute, and in Fig. 5, which is illustrative of the installation at the Burnside colliery of the Philadelphia & Reading Railroad near Shamokin. The Green self-dumping car haul is constructed on the principle of the endless double-chain conveyer, with a spreader or cross-bar, in which the cars act as conveyer buckets, the loaded cars traveling up the lower runway and the empty cars traveling down the upper runway. In Fig. 8 is shown an arrangement at the foot of the incline where an automatic car feeder and car spotter delivers the loaded cars at definite intervals to the car haul. The car haul consists of a double endless chain, that travels between sprocket wheels on car wheels with axles that act as spreader bars, as pushers, and as retarders of the mine cars when on the plane. Tracks for the mine cars are inside the tracks for cross-bar wheels. When a car is delivered to the haul, the cross-bar moves up to the back car wheels and lifting them from the track assumes the responsibility of parts of the load and pushes all the load up the incline; as the car nears the discharging point the car door *a*, Fig. 6, is opened automatically by the latches *b* and the car being at the normal pitch of the slope, 23 degrees, the coal commences to run out. The full discharge is not effected at once but gradually while the car is in transit, during which time the pitch varies from 23 degrees to 60 degrees; this spreads the coal gradually over the grate bars thereby cleaning it of fine material thoroughly.

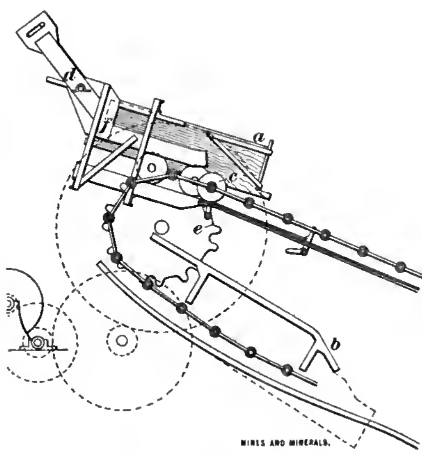

Fig. 7

The cross-bar *c* continuing to travel pushes the car on to the swing-lift transfer *d*, and as the bar must follow the sprocket wheel *e*, it carries the rear end of the car with it over the sprocket and on to the upper or return empty track. This operation is shown in Fig. 8.

The car is received by the swing-lift transfer and retained on the lift by the cross-bar. As the cross-bar starts around the head driving sprockets *e*, the cross-bar wheels engage the horns *f* on the

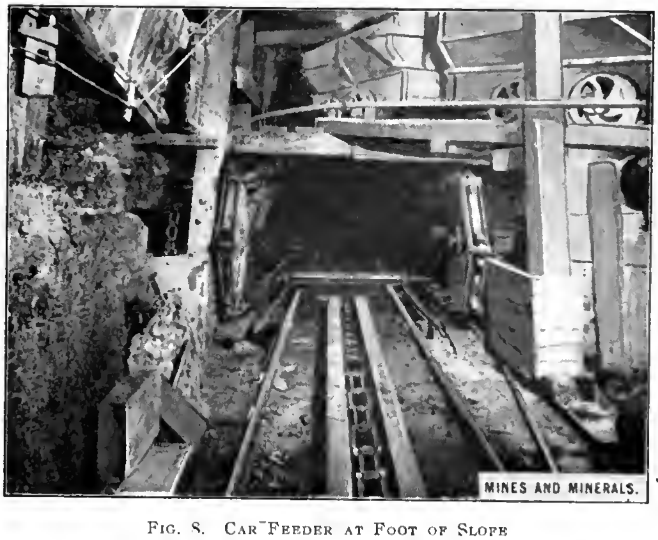

Fig. 8. Car Feeder at Foot of Slope

swing lift. The continued travel of the cross-bar around the sprockets causes the free end of the car to lift and register with the upper runway. The lift is latched in register with the upper runway until the car following the cross-bar is clear of the swing lift, when the cross-bar trips the latch, allowing the lift to swing down and register with the lower runway. The empty car continues to follow the cross-bar down the upper runway of the haul, supported as previously described, until it reaches the bottom of the upper runway.

The writer is indebted to E. J. Neville, Manager of the C. O. Bartlett-Snow Co., who manufacture this dump, for the information concerning it.

FIRST-AID FOR INJURED SPINES

Written for Mines and Minerals, by Thomas C. Harvey

As all injuries to the spine are of a serious nature, it follows that they demand most careful consideration, and especially so where the accident has occurred in the mines or other places remote from immediate medical attention.

Fig. 1

Having been a student of first-aid work for a number of years, and not finding in the various textbooks on first aid anything more definite on the subject than instructions to "keep the patient quiet and send for a physician" (or words to that effect), I feel there should be something more suggested as practicable to aid a person in this serious condition.

Such acidents occur almost without exception at the working face, which is sometimes 1 or 2 miles from the opening to which the injured workman must be carried. It is then that the question arises, how shall the man be handled without further injury and increased pain and suffering.

Since I have been connected with the mine-rescue work of the United States Bureau of Mines, I have been asked a number of times, "what is the best thing to do in case of injury to the spine?" and I have tried to answer the question in a practical way by illustration.

The first-aid man knows that in all injuries one of the essential points is to make the patient as comfortable as possible, binding him up with splints and bandages to attain that end, and it should be particularly true in a case of an injury to the spine, because one has to deal with the most vital nerve center of the body, where the least jar may mean long suffering and eventually death. I may mention that I am taking a case where the spinal ligaments or cord have not been severed.

I therefore submit a dressing which I believe will be a great help to the first-aid man in his humane work and will put his patient in as comfortable a position as possible until he is placed in professional hands.

The splints recommended for use in this particular case are in the form of a double cross and may be called a cradle splint. It consists of four pieces of board preferably 1 inch thick, 3½ inches wide, and two pieces 16 to 18 inches long, or long enough to support the shoulder and hips, as shown in Fig. 1 Also two pieces 4 feet 6 inches to 5 feet in length, as the case may be, or long enough to reach from the top of the shoulder down to the heel. The two long pieces are to be held in place by the short pieces as shown in the illustration. The long splints should be placed about 3 inches apart and directly on the back part of the leg and running up over the muscles of the back. The splints can be nailed together or held in position by bandages, as shown in the illustration.

Fig. 2

Having secured the material and made the splints, the first-aid man will proceed to pad the surface that is to be applied to the back with anything that is at hand, such as hay, cotton waste, cotton batting, or strips of clothing held in position on the splints by strips of brattice cloth, mine cotton, insulating tape or small battery wire, or anything that is at hand that will answer the purpose.

The method of applying the splint is a very important and necessarily careful operation. The first-aid man, with the assistance of three or four other workmen, will turn the patient on his side, being very careful to turn him with one motion, as shown in Fig. 2, so as not to twist the spine, placing the splints on the back, turning him back again flat on the ground before bandaging. He is now placed in the cradle, and the operator should proceed to bandage him to the splint as shown in Fig. 3, starting at the cross-pieces at the shoulder, securely fastening the shoulder to the splint, then fastening the hip joints in like manner. The bandaging should continue down to the knees and ankles, as shown in the illustration. By using inch material a very rigid splint is produced, and then again it will not be necessary to move the patient until he is securely bound, because there is an open space of an inch or more through which to pass bandages under him while he is lying on the ground.

Fig. 3

The patient is now ready for transporting to the surface, that is, after due precaution has been taken to reduce the shock as much as possible, which is severe in this case. He should be moved with the greatest of care and by a first-aid team practiced in the work; and if a person is handled in this manner, I feel confident he will be handed over to the physician in a comfortable condition and with a good chance of complete recovery, which he would not have had with the old method of handling a man who had suffered such injury.

I may add that this particular splint has met with approval wherever shown and that it can be made and kept on hand for an emergency, convenient to the working faces and under the charge of the first-aid men, so that in case it should ever be needed, the time of making it can be used to the benefit of the patient.

Consul Charles Adams Holder, Rouen, France, says: "Not only does France need coal but the United States should furnish it." The total coal production of the world for 1908 was 952,000,000 tons, approximately, made up as follows: United States, 317,323,836 tons; United Kingdom, 261,506,379 tons; Germany, 146,232,646 tons; France, 36,281,098 tons; all other countries, 136,656,041 tons. This is exclusive of lignite, of which the world's production was 100,824,000 tons.—*United States Consular Report.*

ANSWERS TO EXAMINATION QUESTIONS

Answered for Mines and Minerals, by J. T. Beard

Note.—The following questions, selected from different examinations, are here numbered consecutively. The examination from which the question is taken and the number of the question are found at the end of each.

Selected Questions of the Iowa Mine Foremen's Examinations, Held at Des Moines, October 12, and December 6, 7, 1910

Ques. 1.—What is the meaning of "coefficient of friction"? †Q. 1.

Ans.—This expression, as used in mine ventilation, relates to the frictional resistance per square foot of rubbing surface, offered by an airway to the passage of air-current having a velocity of 1 foot per minute. It is often called the unit of resistance. Its commonly accepted value in America is .00000002. (The total resistance for any airway is found by multiplying the number of square feet of rubbing surface by this coefficient, and that product by the square of the velocity of the current expressed in feet per minute. The final product is the resistance in pounds.)

Ques. 2.—A circular airway has a diameter of 9.026 feet what must be the velocity in order to pass 21,120 cubic feet of air per minute? †Q. 2.

Ans.—The sectional area of the airway is $.7854 \times 9.026^2 = 63.985$, say 64 square feet. The velocity required to pass the given quantity of air through this airway is then $21,120 \div 64 = 330$ feet per minute.

Ques. 3.—An entry runs N 46° 54′ E, and the rooms off this entry bear S 61° 21′ E; what is the angle these rooms make with the entry? †Q. 3.

Ans.— $180° - (46° 54' + 61° 21') = 71° 45'$.

Ques. 4.—Tell how to find the latitude and departure of any course. *Q. 3.

Ans.—Multiply the horizontal length of the course by the cosine of the angle of its bearing to obtain the latitude of the course; or multiply the same by the sine of the bearing to obtain the departure.

Ques. 5.—What is the angle included between two lines whose bearings are, respectively, N 10° W and S 88° E? *Q. 6.

Ans.—The included angle is $10° + 180° - 88° = 102°$.

Ques. 6.—If the reading of a plain compass is N 43° W, what would be the true reading after correcting for a declination of the needle of 7° E? *Q. 7.

Ans.—A declination of 7° E means that the north end of the needle points 7 degrees to the east of the true north. In a plain compass, which has no arc for setting off the declination, the reading gives the angle that the line of sight makes with the direction of the needle, which in this case is evidently too great by 7 degrees. The true reading would be therefore $43° - 7° = 36°$, and the true bearing of the line of sight is N 36° W; because the true meridian lies between the line of sight and the magnetic meridian in which the needle sets.

Ques. 7.—What is the disadvantage of using a long needle for mine work? *Q. 8.

Ans.—Some prefer a short needle for use in mines, because it works more quickly and is not as liable to become bent by hard usage; also, the compass is smaller and more easily carried about the mine. The lack of these qualities may be termed the disadvantages arising from the use of a long needle. The latter, on the other hand, though setting more slowly is more reliable and can be read with greater accuracy than the former.

Ques. 8.—How would you lay a good haulage road in the main entry to secure good results and long duration? †Q. 5.

Ans.—To provide a permanent main haulage road in a mine all the chief points mentioned in reply to Ques. 11, page 280, Mines and Minerals, December, 1910, should be considered. The entry should be carefully surveyed and platted. On a profile of the entry establish a grade that shall be as nearly uniform and favor the movement of the loaded cars as far as practicable. Begin the work by straightening the entry and lightening or reducing the curves wherever practicable to do so, and grading the entry to conform to the established grade. Provide ample drainage ditches at the side of the road. Use good ties and iron of suitable size for the proposed traffic. Having laid the ties and spiked and bolted the iron, straighten and ballast the track. See that all low places where the road crosses a depression are kept well drained.

Ques. 9.—How would you proceed to guard the health and safety of the miners and the security of a mine placed in your charge? †Q. 6.

Ans.—It is important, first, to become thoroughly familiar with the conditions existing in and about the mine, and the character of the labor employed, with respect to nationality, intelligence, and general capability. After studying these conditions make and enforce such regulations as will tend to remove, as far as possible, all dangers or liability of accident found to exist. Insist on the strict enforcement of the mining laws. Hold each assistant foreman, fire boss, engineer, pump runner, cager, timberman, fireman, or other person charged with certain duties, to a strict accounting for the faithful performance of such duties. Keep constantly on hand a plentiful supply of timber and all needed material, and arrange to have this material delivered promptly in the mine when required. Watch carefully the ventilation to see that the proper quantity of air is circulated and so distributed to all portions of the working face that no dangerous accumulations of gas can occur. Encourage all men employed in and about the mines to read and study mining books and inform themselves on all matters relating to the dangers of mining.

Ques. 10.—What method is the safest to adopt in the use of dynamite in shaft sinking and which will least endanger life and limb? †Q. 8.

Ans.—Electric firing is the safest method and should always be employed in sinking a shaft. The lead wires at the top of the shaft should remain disconnected from the battery while the men are in the shaft, and should never be connected up by any one but the shot firer, who should be the last man to leave the shaft. Where electric drills are employed the power should be shut off from the drills at the surface before the holes are charged or any connection made for blasting, in order to avoid the possibility of the dynamite being set off by an accidental short circuiting of the current used to supply power to the drills.

Ques. 11.—What is the total pressure required to overcome the friction or resistance and produce a velocity of 400 feet per minute in an airway 6 ft. × 8 ft. and 3,200 feet long? †Q. 9.

Ans.—The rubbing surface in this airway is $3,200 \times 2(6+8) = 89,600$ square feet. The total ventilation pressure, then, for a velocity of 400 feet per minute $p\,a = k\,s\,v^2 = .00000002 \times 89,600 \times 400^2 = 286.72$ pounds.

Ques. 12.—In the last question, what is the pressure per square foot? †Q. 10.

Ans.—The sectional area of the airway is $6 \times 8 = 48$ square feet. The pressure per square foot is, then, $p = 286.72 \div 48 = 5.97+$ pounds.

Ques. 13.—What do you understand by the expression the natural ventilation of a mine? †Q. 13.

Ans.—By natural ventilation is meant such circulation of air as results from natural causes without the use of any artificial means.

Ques. 14.—Under what conditions and circumstances may natural ventilation occur? †Q. 14.

Ans.—Whenever two shafts or slopes, connected underground and open to the atmosphere, are filled with air of different density, there result two air columns of different weights and therefore unbalanced. The heavier column sinks and that presses the lighter one upward, thus producing a movement of the air in the passages connecting these two openings. The air

* Mine Foremen's Examination, October 12, 1910.
† Mine Foremen's Examination, December 6, 7, 1910.

flows from the colder or denser column to the warmer or lighter column.

Ques. 15.—Why should the circulation of air in mines be maintained continuously, and not during the day only? †Q. 15.

Ans.—Because the gases that accumulate during the hours when ventilation ceases in the mine find lodgment in abandoned places; the heavier carbon dioxide sinking to the swamps and filling dip workings with a foul atmosphere that is exceedingly difficult to remove, while the lighter marsh gas rises and forms exceedingly dangerous firedamp mixtures in all pitch headings and chambers, and in roof cavities, and on the falls. It will often require hours for the removal of these gases and the delay of work from this cause will generally outweigh any slight saving that would arise from closing down the ventilator for a portion of the night.

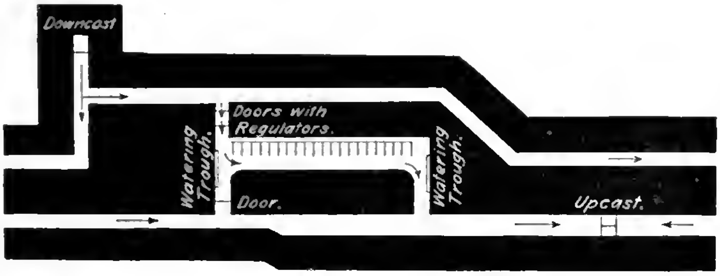

Fig. 1

Ques. 16.—What is furnace ventilation and how is it accomplished? †Q. 16.

Ans.—Furnace ventilation is produced by the use of a furnace built in the passageway, near the bottom of the shaft, which is then called the furnace shaft. The heat of the furnace serves to rarify the air passing over and around it and ascending the shaft. It is this heating of the air in the furnace shaft that makes this shaft always the upcast and produces the circulation of air through the mine, because the hot air in the furnace shaft is lighter than the cooler outside air descending the downcast shaft or slope or entering the drift mouth.

Ques. 17.—Are dangers possible with furnaces, and how may such dangers be avoided? †Q. 17.

Ans.—In the use of a mine furnace there is the danger of the flame or the heat of the furnace setting fire to the shaft timbers or the coal pillars nearby. A furnace should not be used in a mine in which gas is liable to be generated. There is danger of the gas in the return current being ignited at the furnace or in the shaft. To avoid the possible ignition of the shaft timbers, a mine furnace should be set from 10 to 15 yards back from the foot of the shaft, according to the size of the furnace and the depth of the shaft; and the shaft should be walled with masonry for a sufficient distance up from the bottom to avoid all danger. To prevent the ignition of the pillar coal a brick arch should be built in the passage extending from a few feet in front of the furnace to shaft walling. The roof strata should be supported by iron rails or beams spanning the airway and an air space left at each side and above the brickwork. Firebrick should be used for the most of this work. To avoid the ignition of gas, two methods have been employed: (1) The return current is diluted with a sufficient addition of fresh air from the intake to render the gas non-explosive before it reaches the furnace. (2) The return current containing gas is made to enter the shaft by a dumb drift at a point from 30 to 50 yards above the bottom of the shaft; the furnace in this case is fed by a separate scale of fresh air from the intake.

Ques. 18.—If a certain fan produces 65,000 cubic feet of air, at a certain mine, running at 40 revolutions per minute, what volume of air would it produce at a speed of 55 revolutions per minute? †Q. 18.

Ans.—It is generally assumed that the volume of air produced by a fan, under the same conditions, is proportional to the speed of the fan, making the quantity ratio equal to the speed ratio of the fan; or, in this case

$$\frac{x}{65,000}=\frac{55}{40}=\frac{11}{8}\text{; and } x=65,000\times\frac{11}{8}=89,375 \text{ cu. ft. per min.}$$

In practice, however, the results are more nearly,

$$x=65,000\sqrt[5]{\left(\frac{11}{8}\right)^4}=83,860 \text{ cu. ft. per min.}$$

Ques. 19.—If 170,000 cubic feet of air is passing through a fan drift per minute, under a water gauge of 2.1 inches, what is the horsepower on the air? †Q. 19.

Ans.—The power on the air is

$$H=\frac{170,000\times 2.1\times 5.2}{33,000}=56.25+ \text{ H.P.}$$

Ques. 20.—Explain the meaning of the expression "motive column" in ventilation. How is the motive column in any circulation of air expressed, and how is its value ascertained? †Q. 20.

Ans.—The word motive column, as used in ventilation, denotes an imaginary column of air of given density, 1 square foot in cross-section and of such height that its weight is equal to a given pressure expressed in pounds per square foot. Motive column is expressed in feet. The motive column corresponding to any given pressure expressed in pounds per square foot is found by dividing the given pressure by the weight of 1 cubic foot of air at the given temperature and pressure. If the pressure is given as inches of water gauge, it must first be multiplied by 5.2 to reduce it to pounds per square foot and then proceed as before. For example, assuming a temperature of 60° F. and a barometric pressure of 30 inches, find the motive column corresponding to a water gauge of 2.5 inches. The pressure corresponding to this water gauge is $2.5\times 5.2=13$ pounds per square foot. The weight of 1 cubic foot of air at the assumed temperature and pressure is $\frac{1.3273\times 30}{460+60}=.0766$ pounds. The corresponding motive column is then $13\div.0766=170$ feet, nearly.

Ques. 21.—What is the total pressure required to overcome the frictional resistance of an airway 7 ft. × 5 ft. and 6,000 feet long when the air-current is traveling with a velocity of 300 feet per minute? *Q. 5.

Ans.— 259.2 pounds. See Ques. 11.

Ques. 22.—If the ventilation is insufficient and you cannot increase your power, how will it be possible to increase the volume of air in circulation? *Q. 10.

Ans.—It may be possible to split the air at one or more points in the mine without reducing the velocity of the air-current below what is required for good ventilation. This will increase the quantity of air circulated without requiring additional power. The same effect is accomplished also by cleaning up airways, straightening air-courses, and wherever practicable shortening the distance the air-current must travel.

Ques. 23.—How would you construct and ventilate an underground stable, and where would you locate such stable in a new mine? *Q. 14.

Ans.—A mine stable should be excavated in the solid coal. It should be from 16 to 20 feet wide and 7 or 8 feet high in the clear, and as long as will meet the requirements of the mine. All the doors, partitions, roof supports, and fittings of the stable should be of incombustible material. There should be provided a water trough and an ample supply of good water piped to the stable. The floor should be hard and well drained. The stable should be ventilated by a scale of air direct from the intake current, sufficient to maintain a pure atmosphere without making it too cold. The air that passes through the stable should be conducted at once into the main return by which it will be carried out of the mine without further con-

taminating the mine air. In planning a new mine, the stable should be located in the shaft pillar, between the two shafts, so as to provide good ventilation and be easily accessible from either shaft in case of need, and convenient for the handling of the daily supplies and refuse. A good arrangement in a shaft mine is shown in Fig. 1; another arrangement is shown in Fig. 2, which, with some modification, would be applicable to a slope mine, the stable being located at the foot of the slope.

QUES. 24.—In a gangway 8 ft. × 8 ft. the water gauge shows a reading of ¾ inch when the velocity of the air-current is 280 feet per minute; what is the estimated rubbing surface? *Q. 16.

ANS.—A water gauge of ¾ inch indicates a pressure of $\frac{3}{4}\times 5.2 = 3.9$ pounds per square inch; and the total ventilating pressure is then $pa = 3.9\ (8\times 8) = 249.6$ pounds. The rubbing surface may therefore be estimated as approximately

$$s = \frac{pa}{kv^2} = \frac{249.6}{.00000002\times 280^2} = 159{,}183, \text{ say } 160{,}000 \text{ sq. ft.}$$

QUES. 25.—What is gained by splitting air-currents in mines? *Q. 17.

ANS.—A larger quantity of air is circulated per unit of horsepower; purer air is supplied to the working face; the ventilation of the mine is under better control, as the air can be

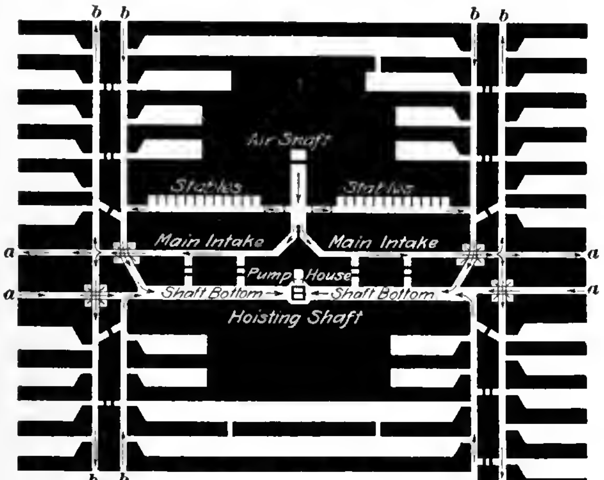

FIG. 2

distributed so as to meet the needs in different parts of the workings; trouble with gas or the circulation of air in one section does not affect other sections of the mine; and finally, it is possible, then, to concentrate the entire circulation upon any single section of the mine, temporarily, by closing down other unaffected sections till the trouble is overcome.

QUES. 26.—Explain the action of a pulsometer pump. *Q. 18.

ANS.—Steam under a pressure capable of forcing water to the desired height is admitted by an automatic valve, alternately, to two separate water chambers fed through valves by the same suction pipe. The pressure of the steam forces the water through discharge valves and up the delivery pipe to where it is discharged. At the moment when the water level in the chamber reaches the discharge valve the water and steam mix violently and the steam filling the chamber is instantly condensed, causing a vacuum; the steam valve is shifted by the excess of pressure in the other chamber. Steam is thus admitted to that chamber and performs the same work there, forcing the water from that chamber into and up the delivery pipe. At the same time, the atmospheric pressure forces water up the suction pipe and into the chamber where the vacuum was formed by the condensation of the steam. This action is automatic and continuous, alternating between the two chambers.

QUES. 27.—The plunger of a double-acting pump has a diameter of 12 inches and a stroke of 18 inches. If the pump makes 50 strokes per minute how many gallons of water will be discharged per hour, the efficiency of the water end of the pump being 80 per cent.? *Q. 4.

ANS.—The sectional area of a 12-inch plunger is $(.7854\times 12^2)\div 144 = .7854$ square feet. At a speed of 50 strokes a minute the plunger travels $50\times 18\div 12 = 75$ feet per minute, and the plunger displacement is $75\times .7854 = 58.9$ cubic feet each minute. Assuming an efficiency of 80 per cent. for the water end, this will handle $60\times .80\left(\frac{58.9\times 1{,}728}{231}\right) = 21{,}150$ gallons per hour.

QUES. 28.—Is the double notch better than the single notch for ordinary entry timbers? Give reasons. *Q. 9.

ANS.—For ordinary entry timbering the single-notch method is generally preferred, because it is simple, more easily made, and does not weaken the collar where it bears on the leg, as is apt to be the case where the double-notch method is employed. The single notch is better adapted to timbering where the roof pressure is the greater; but for a heavy side pressure, the double notch is often used to advantage.

TEST OF DOUBLE-INLET SIROCCO FAN

The following test was conducted at the Alice mine of the Monongahela River Consolidated Coal and Coke Co., November 6, 1910, under the supervision of Mr. S. A. Scott, General Manager of Mines M. R. C. C. and C. Co. Anemometer readings were taken by Mr. F. W. Cunningham, State Mine Inspector, 21st District, and Mr. Wm. G. Louder, Mine Inspector, M. R. C. C. & C. Co. Velocity readings were checked with Pitot tubes by Mr. T. Chester and Mr. F. Thorp, of the American Blower Co., also checked with "Hydro" recording velocity and volume gauge by Mr. H. Bacharach, M. E. Pressure readings were made with water gauge, checked with gasoline gauge and "Hydro" recording gauge by Mr. G. F. Osler, chief engineer M. R. C. C. and C. Co., and Mr. T. W. Fitch, Jr., of American Blower Co. Power and speed readings were taken by Mr. C. S. Davies, superintendent of electrical equipment M. R. C. C. and C. Co., and Mr. U. U. Carr, mechanical engineer of the same company. The following table shows results:

Fan Wheel 8′ 6″ diameter × 5′ 8″, driven by Morse Chain Transmission from 200 H. P. Western Electric Co.'s Motor. Fan exhausting during Test.

	Test 1	Test 2	Test 3
Time of test	1:30 to 1:45	2:55 to 3:10	3:26 to 3:41
Revolutions of fan per minute	220	248	275

Theoretical water gauge	4.46″		
Manometric ratio	124%		

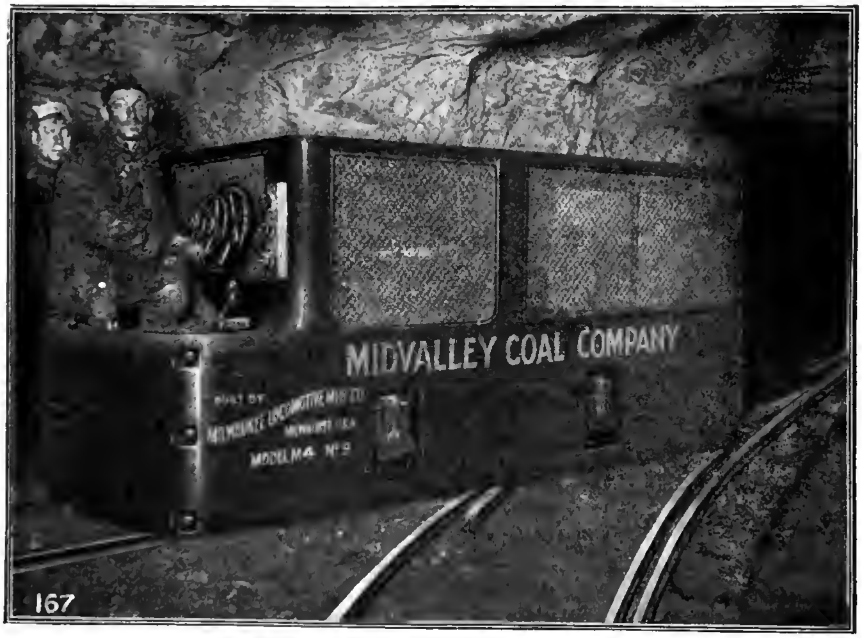
George H. Hollingsworth, F. G. S., says in page 406, of the Practical Engineer Pocketbook: "Such results as 75 per cent. of the indicated horsepower being realized in work done upon the air are manifestly impracticable." The Sirocco fan seems to have a habit of upsetting theories in fan efficiencies.

GASOLINE LOCOMOTIVE FOR MINE USE

Written for Mines and Minerals

Results of Experience at Mines of the Midvalley Coal Co., With a Milwaukee Gasoline Locomotive

In January, 1907, Editor H. H. Stoek, inserted the following in Mines and Minerals: "A large number of inquiries have been received for the address of an American manufacturer of gasoline mine locomotives. If manufacturers will communicate with the editor they will be placed in touch with inquiries from time to time." In August, 1910, there was an article on the gasoline mine locomotives used in Austrian and German mines which was very productive of inquiries concerning the manufacturer and where they were in use in this country. While the article was being written a locomotive was on the way to the Midvalley Coal Co., Wilburton, Columbia County, Pa., that was built by the Milwaukee Locomotive Mfg. Co. In the October, 1910, issue of Mines and Minerals mention was made of the first gasoline mine locomotive in the United States replacing five mules and a steam locomotive. At that time, while the Milwaukee gasoline locomotive was working satisfactorily, the Midvalley mine management considered the matter in the light of an experiment and therefore were reluctant to furnish more than general information.



Milwaukee Gasoline Mine Locomotive

Since that time a second locomotive has been installed and a third one ordered, thus showing conclusively that this company is satisfied with the results. Several beds of coal are worked at Wilburton necessitating the maintenance of a haulage system for each bed as well as each level. Every coal miner knows that the haulage system at a colliery must be flexible to comply with the demands of the colliery, also that so much depends on local conditions that scarcely at any two collieries is it possible to haul coal at the same cost figures with the same kind of motive power, yet in a general way comparisons are made which approximate theory, and are of use when estimating on the installation of new haulage plants. Probably the most accurate comparisons between haulage systems are those made at a mine where one system has been substituted for another. The management of the Midvalley Coal Co. kindly furnished data, which showed a saving of 32.2 per cent. on coal hauled by substituting the gasoline locomotive for mules.

To the writer this comparison seemed too conservative, because the locomotive was in a position where its full capacity could not be demonstrated, in fact was idle a large part of the time, making only 24 miles per day when it is capable of doing more than twice as much. The management estimates that the new locomotive ordered will save practically 50 per cent. over the present system of haulage as it is to be placed on a level where it will be supplied with sufficient work to keep it moving, and do the work of 15 mules.

By comparing the cost of haulage with the gasoline locomotive at Midvalley and the average cost of electric locomotive haulage as furnished in the Coal and Metal Miners' Pocketbook, it was found that there was a lessened cost of 27.9 per cent. in favor of gasoline. The Midvalley Coal Co.'s locomotive shown in Fig. 1 uses naphtha for fuel, it being less dangerous and better to handle than gasoline. The consumption of naphtha is about 15 gallons per day ($1.50 per day), where if gasoline were used the consumption would be about 12 gallons for the same work while the cost would be 30 cents more.

Judging from the odor produced by automobiles it would be supposed that locomotives of this description would foul the mine atmosphere. To prevent this disagreeable feature, a series of parallel pipes perforated underneath are fitted in a steel tank and then submerged in a chemical solution of chloride of calcium. The exhaust from the engine passes into these pipes, then through the perforations into the solution where all flame is extinguished and the gases of combustion cooled to about 100° F.

The mine inspector after careful examination was unable to detect any odor in the mine atmosphere that could be attributed to the locomotive. The Midvalley locomotive, rated as a 9-ton locomotive, has about the following dimensions: Length, 150 inches; width, 59 inches; height, 60 inches; wheel base, 48 inches; and diameter of driving wheels, 24 inches. The following table gives the detail of the average work performed daily by the first locomotive in 6 months, during which period approximately 2 hours out of a 9-hour day were devoted to switching, a feature which fails to show on the cost sheet:

Work Performed by Midvalley Locomotive

Average tonnage of loaded cars per day	550 tons
Average tonnage of empty cars per day	250 tons
Average mileage of loaded cars per day	12 miles
Average mileage of empty cars per day	12 miles
Weight of one loaded car	5½ tons
Weight of one empty car	2½ tons
Average number of cars per train	8 cars

Cost of Operation

Wages of operator and helper per day	$3.35
Cost of fuel per day	1.50
Cost of lubricating oils per day	.12
Consumption of fuel in gallons daily	15

Maintenance

Cost of maintenance of locomotive for six months, including repairs and labor	$65.14

The Imperial Royal Mine Chief Schardinger, of Austria, issued orders on January 5, 1907, concerning the use and working of traction explosion motors in mines in Austria. In Article II, Section 2, of this order the following will be found:

"In mines subject to firedamp such locomotives may, as a rule, be permitted for hauling only in mines in which the air-current does not contain mine gas in excess of .5 per cent. and which has not already passed through other parts of the mine. Exceptions are permissible in the latter case when the

supply of a perfectly fresh air-current would involve disproportionate costs; further, the quantity of air supplied by the air-current in question corresponds to the requirements of Sec. 9 (Abs. der h.) (a Verordnung Z. 3142/02) without consideration of the deviations permitted in Sec. 9 (Abs. 2, bez. Sec. 15, Abs. 3); and finally, if the employment of the machine hauling in the mine diggings which are aired by the air-current conducted from the local workings seems justified by the amount of hauling.

"The mine levels traversed by the locomotive must be examined in every level by the district overseer with the safety lamp, and in the event of the presence of mine gas, the locomotive traffic must be stopped. Once a week the mine gas contents of the air-current in the levels traversed by the locomotive must be established by the Pieler lamp or by analysis. In such case the result of the examination must be noted in the mine book (Befahrungsbuch).

"In mines subject to firedamp the mine levels traversed by the locomotive must be kept so moist by means of sprinkling water conduits, that dangerous coal-dust deposits in the same are constantly prevented; revocable exceptions to this may be allowed by the district mining office in so far and for as long as the mines in question are naturally moist."

ELECTRIC SHOCK IN MINES

Written for Mines and Minerals, by Syden F. Walker

(Continued from March)

Footwear and Shocks. Relative Safety of Armored and Unarmored Conductors

An important matter bearing upon the question of shock, is the footwear. A striking instance of this occurred at a colliery in Scotland, in connection with the haulage rope of an electrically driven coal-cutting machine. A man wearing leather boots trod upon the haulage rope and was killed. Another man wearing clogs trod upon it, and only received a slight shock. The important point to be noted here is, that the clogs offered a very much higher electrical resistance to the passage of the current through them than the leather boots. Leather soles, besides being thin, and sometimes of very poor material, are very much more porous than wood. At any rate there is a better chance of a larger quantity of moisture being held in the pores of a leather sole, than in that of a wooden clog. In some tests that were made some years ago, by a British Government official, of the electrical resistance offered by the human body to electrical currents, it was found that changing the boots, and changing the socks, made a very great difference. A paper was read before the British Institution of Electrical Engineers on the subject, by the official in question, and he illustrated the lecture by showing measurements of his own electrical resistance, recorded upon an instrument provided for the purpose, when he had different foot wear. When wearing socks that had been in use the whole day, and were therefore fairly impregnated with perspiration, and wearing the boots he had also worn the whole day, and were therefore also fairly moist, a comparatively large current passed through his body. When he changed his boots, the electrical resistance offered by his body increased, and the current passing through him decreased proportionately. Changing the socks to dry ones still further increased the resistance. With men working in mines, this has a very important bearing upon the question of shock. It often happens that men have to repair roads which are very wet. Also the temperature is often so high that they work with very little clothing upon them, and some of the most serious accidents that have taken place, have been due to these two causes. In one case, which occurred some years ago, some men were repairing a dip, down which a fairly continual stream of water was flowing. The water was not sufficient to stop their working, but it kept their boots in a moist state. They were also working without coats, and with very little upon their bodies. There was a cable on the side of the road, supported by insulators attached to the props carrying current to a dip pump farther toward the face. The repairs necessitated the removal of a steel H girder. In removing the girder, its sharp edge cut through the insulation of the cable, which was not armored, the girder becoming alive. The man who was handling the girder received a shock, which brought him to the ground, and a second man catching hold of the body of the first man, also received a shock. The first man was killed. Somewhat similar cases of this kind have been fairly frequent throughout British coal mines, even up till quite recently.

The question of armored versus unarmored cable has been very fully and occasionally somewhat hotly discussed. In the writer's opinion, amoring as a rule is not wise, but he would have, in place of armor, a thick covering of the insulating material, and a further thick protecting covering of some substance such as jute, the jute being rendered as fully waterproof as possible. The argument in favor of armor is, if a fall of roof occurs, the armor may probably prevent a breakage, and in a great many cases it may prevent the skinning of the insulating envelope of the cable. This is quite correct, but the reasoning is based upon the badly insulated cables that were so much used in the early days of electric light and power in mines, owing to the efforts that were made to keep the cost down, and that are now even sometimes employed, owing to the mistaken policy of the purchasing agent. The mine manager sends in a requisition for a certain quantity of cable of a certain section, and he requires it to be insulated in a certain way. The clerk who sends out for tenders, either allows himself to be persuaded by a plausible traveler, that the very much cheaper form of cable than the colliery manager has requisitioned will answer, or he takes it upon himself to save, as he thinks, his firm a certain sum, by buying a cable whose insulation is much thinner, and to which there is very little protection. Such a cable succumbs to every trifling accident. A horse may bite through the cable insulation and be killed, the sharp edge of a piece of stone falling from the roof will skin a place on the cable, which is probably not noticed, and may lead to some one receiving a fatal shock. A bell wire may accidently be rubbed against the cable, or a haulage rope, a haulage pulley, the steel edge of a mine wagon, etc. In all cases the thin insulating envelope is quickly cut through, and either the cable is left bare, and a source of danger by itself, or as more frequently happens, the conductor makes connection with the metallic body, the wire or the rope, or the pulley that has rubbed through it, and these objects become part of the electrical service of the mine, that is, become "alive" as it is termed, and transmit their killing properties to every metal body with which they come in contact. This is the source of a very large number of the accidents that have been recorded. Mine managers, finding that they have difficulty in obtaining thickly insulated, and thickly protected cables, naturally order armored cables, since the armor does give some protection. The purchasing agent is rarely able to take upon himself the altering of an order from armored to unarmored, and, consequently, armored cable has more and more come into use in mines. In the writer's view, armoring a cable introduces considerable danger. There is always the possibility that a fall of roof will drive the armor through the insulating envelope on to the conductor. The armor then becomes "alive," and transmits its killing properties to every metal with which it comes in contact. Further, it is more dangerous when it becomes "alive" in this way, because of its supposed innocence; no trouble is usually taken to prevent the armor of a cable from touching other metals, and, consequently, if the armor is "alive," they become "alive," and a whole series of connections may be made to different metallic bodies about the mine, any one of which when touched may give a fatal shock. The reply to the advocates of armor is, that if

the armor is "earthed or grounded," and it becomes "alive," the fuse or circuit breaker at the switchboard will cut off the conductor, and therefore the armor will remain harmless. Unfortunately this only introduces a new source of danger. "Grounding" is a very difficult matter in coal mines, and assuming for the moment that efficient "earth" is obtained, and that the armor is efficiently connected to "earth," if a fall occurs, and the armor and conductor are both severed, unless the armor as well as the conductor is fully jointed, that is to say, the joint in the armor is made to offer very little resistance indeed, the armor beyond the joint, if it becomes "alive," as it may easily do, is a source of danger. This will be seen in the following case. Suppose the conductor to be jointed, the joint covered, but the armor not jointed, or only imperfectly so; every one about the mine supposes that the armor is perfectly harmless; but suppose a fall occurs at some point beyond the joint, again driving the armor through the insulation, and making it "alive," any one now touching the armor will receive a shock that may be fatal.

In the writer's view, the only method which thoroughly provides efficient protection, where armoring is employed, is the concentric system of distribution, in which one of the cables forms the outer conductor, and its continuity is absolutely necessary to the continuance of the electrical service. The concentric system, which has been efficiently worked out by an eminent firm of Scotch electrical engineers, has been principally applied to continuous currents, though it has recently also been applied to three-phase services. Its working with continuous currents is very simple. One conductor forms the center of a cable, and is insulated in the usual way, its insulating envelope being protected by layers of jute or some similar substance. Outside of the layers of jute the second conductor is laid, concentric with the first, and the outer conductor is not insulated, but left free to make contact with everything it touches. Further, it is rendered of at least equal conducting power to the inner conductor. In the system mentioned, a lead tube assists to protect the insulating envelope of the inner conductor, and in some cases the outer conductor is also armored, but the armor and the conductor form one conducting mass. With this cable, if a fall occurs, and the cable is severed, it is absolutely necessary for both the inner and the outer conductors to be jointed so efficiently, that neither joint offers an appreciably increased resistance to the passage of the working current above that of the cable as it was before the fall. It may be mentioned incidentally that the resistance of any "earth" path is of very great importance in the question of shock, and in the matter of carrying the return current in such a manner that fuses or circuit breakers will operate. It will be seen that the working of the concentric system ensures that the outer conductor, and the armor, or whatever may be employed to protect it, shall always be continuous, and therefore that protection is always provided, so far as an "earthed" armor can provide it.

The concentric system has been adapted to three-phase service by one of the three cables being employed as outer conductor, much in the same manner as the rails of some of the electrical railways using three-phase currents are. The protection afforded by making one of the three cables an uninsulated outer, with three-phase working, is not so perfect as that offered by the uninsulated outer of continuous current cables, but it is far better than the protection afforded by the usual armor of the ordinary three-phase cable. The common arrangement of three-phase cables, as employed in the United Kingdom, is that the three conductors are separately insulated, the insulating envelope of each being slightly protected by yarns. The three insulated cables are then laid up into a sort of rope, around a heart of jute or similar substance. A filling of jute is added to make the rope into a cylinder, and the whole is insulated outside of all, armor usually being laid on outside of the insulating envelope. One of the peculiarities of the three-phase system is that a single cable must not be armored This applies equally to single- or two-phase systems, but neither of these are now in use, in British collieries at any rate. If a single cable carrying alternating currents is armored, the armor makes a very heavy charge upon the currents passing through the conductor, owing to the useless currents which are generated in it, and to the changes of magnetism which are also created in its molecules. A favorite form of three-phase cable for mining work in British collieries consists of three paper-insulated conductors, laid up together as explained above, the whole being drawn into one lead tube, and armoring laid on outside of the tube. It is not permissible to use separate paper-covered cables carrying alternating currents, for the same reason that separate cables may not be armored. The ordinary three-phase armored cable, the armor being "earthed," is subject to the same objections as the continuous-current armored cable. It is usually safe, so long as the armor is "earthed," and if the neutral point of the system is "earthed," but in case of the cable being severed by a fall, unless the armor is jointed as fully as the cables, a very difficult matter indeed, seeing that three joints have to be made inside the armor, besides the joint of the armor itself, and that the joints have to be made under very difficult conditions in a mine, the armor may become "alive" beyond the break, and any one touching it may receive a fatal shock, or it may transmit its killing properties to other metallic bodies about the mine, as described in connection with continuous currents

FIRST-AID CONTEST IN WASHINGTON

Written for Mines and Minerals

Dr. M. J. Shields, surgeon of the field branch of the National Red Cross Society, and the "Father of First-Aid" work in the coal mines of the United States, was at Roslyn on February 6

First-Aid Team, Northwestern Improvement Co., Cle Elum, Wash.

and 7 to take part in the first annual first-aid contest of the teams of the Northwestern Improvement Co., which company operates in the Roslyn coal field.

On the evening of the 6th, Doctor Shields gave an instructive lecture on first-aid work with demonstrations of methods of handling persons overcome with gas, smoke, or electric shocks, and in adjusting splints, bandages, and tourniquets, both with volunteer subjects from the audience and by lantern-slide pictures.

This was the doctor's first trip to the coal mines of Washington, and he expressed his surprise and delight at the progress of first-aid work already made by the Northwestern Improvement Co. and their employes in the Roslyn field.

On the afternoon of the 7th, picked teams from each end of the field contested against each other for a silver cup offered by the Northwestern Improvement Co. as a permanent trophy to be contested for annually. The team representing the Roslyn and No. 3 mine was comprised of A. G. Lindsey, captain, L. Lloyd, John Heathcock, Jas. Farrington, Wm. Smith, Geo. Morris, Adam Stewart, John Graham, Robt. Bell, Tony and Nick Stanfel, Martin Coleman, and Wm. Ward, while John Heathcock, Jr., Frank Norta and Isaiah Greenhalgh were the subjects operated on in the various events. The lower end of the field, including the Cle Elum, No. 5 and No. 7 mines, was represented by John Hutchinson, captain, Dave Taylor, John Parker, Dan Murphy, Thos. Daglish, Jas. Pascoe, Ben Russell, Dan Shields, Thos. Summerill, E. McGilley, Chas. Chabert, Wm. Reay, Fred Smith, and Chas. Lee, with Wm. Smallwood and Thos. Choice as subjects.

Dr. E. W. Stimpson, chief surgeon of the Roslyn-Cle Elum Beneficial Association, who trained the men and deserves full credit for their splendid showing, acted as field manager and announced the events. Doctor Shields and D. C. Botting, the state mine inspector, acted as judges, and J. W. Anderson and J. B. Warriner, company mine inspector, acted as time keepers.

The contesting was spirited and close, and the skill of the teams provoked round after round of applause from the spectators. None but an expert could have detected any difference between the work of the contestants, and Doctor Shields was moved to admit that it was the closest contest he had ever had to judge. The cup was finally awarded to the Roslyn team by the narrow margin of 2½ points, due to their greater speed in the third event, which they completed in the remarkable time of 3 minutes and 53 seconds. They will, therefore, hold the silver cup for 1 year, and will each receive individual bronze medals setting forth facts of their victory.

First-aid work is taught at the company's Red Lodge mines in Montana, and General Manager Claghorn is arranging to have an interstate contest in the near future.

OBITUARY

GEORGE SHARP RAMSAY

George Sharp Ramsay died at St. Mary's, Pa., February 21. He was in apparent good health in the morning and it is supposed that an attack of acute indigestion affected the heart action to such an extent as to cause his demise. Mr. Ramsay was born in Dunfermline, Scotland, in 1857; came to America with his parents in 1863 and after attending public schools went to work in the mines. His wide experience made him one of the best informed coal-mining men in this country. During his career he held positions in West Virginia, Colorado, Wyoming, and British Columbia, and for 15 years prior to his death was the chief in the line of the development of the Shawmut Mining Co.'s properties.

George S. Ramsay was a man of sterling worth, his life was clean in and out of business, he was scrupulously honest with his fellow men in all things, and he had high estimates of those things that tended to an incorruptible and noble character. He was a type of man whom everybody admired, and his pleasing personality, his sympathetic impulses and high sense of honor won for him the confidence and esteem of the general public as well as establishing a friendship among his associates that will not soon be forgotten. George S. Ramsay was one of God's true noblemen and it is to be regretted that the life work to which he was so eminently fitted should be concluded before its intended achievements had opportunity of maturity. In the circles to which Mr. Ramsay devoted his best energies, he was regarded as a man of sound judgment, and in his particular line he was perhaps the best informed and most capable official of the present day.

George S. Ramsay

CHARLES T. DENNISON

Dr. Charles T. Dennison, President of the Board of Trustees of the California State Mining Bureau, died in San Francisco, February 24, aged 70 years.

MAJOR HEBER S. THOMPSON

Major Heber S. Thompson, age 71 years, for many years chief engineer for the vast coal lands and other properties of the Girard Estate in Schuylkill and adjoining counties, died March 9, at Pottsville, Pa., of general debility. He was a First Defender during the Civil War and rose from a private in the Forty-Eighth Regiment, P. V. I., to command of a battalion in the regiment.

"LO THE POOR PROSPECTOR"

FIRST the buffalo, then the "wild" Indian, and finally the "poor prospector" has been gathered unto his fathers. But the "poor prospector," like "an infant industry" when any change in the tariff is broached, refuses to stay dead and bobs up serenely at the first attempt to improve upon our antiquated, and some darkly hint iniquitous, system of administering the public domain. How those words "public domain" roll from the tongue of the spell binder and from that of him who is out of office, and what tears can be evoked by a touching reference to the "poor prospector." The public domain is fast being absorbed and the poor prospector now travels in a Pullman, and what will the land grabber do for something as an appeal to the emotions when both are history.

A MODEL COAL MINE ACT

RECENTLY the editorial staff of MINES AND MINERALS felt compelled in the interest of fairness to those directly concerned to criticize a proposed mine law. They now take pleasure in commenting on a mine law recently passed in British Columbia. Owing to "State Rights," a particularly important phase of mine legislation has been sadly neglected in the United States, that is the part in which the general public are concerned.

If a bill is partial to the miner it is objectionable to the operator; if it is partial to the operator it is objectionable to the miner; if it favors both operator and miner it may be objectionable to the general public, who are the ones most interested. In order to draft a just and satisfactory mine law all parties concerned must be consulted and their suggestions combined as far as practicable.

The Honorable Premier Richard McBride, also Minister of Mines for the Province of British Columbia, recognizing the importance of fulfilling the three conditions imposed, withdrew the bill of 1910 for 1 year, in order to make the act as perfect as practicable. In the interim he sent his deputy with the Chief Inspector of Mines to the various coal-mining districts to confer with both operators and miners and obtain suggestions for changes or additions to the bill of 1910. The outcome was the 1911 bill, which, with three or four minor amendments, was passed as presented by the Premier.

Wm. Blakemore, a mining engineer, writes editorially in *The Week* congratulating the Premier, as Minister of Mines, on the able and exhaustive speech with which he introduced the measure, saying, among other things: "It is not a little surprising that a man of so many activities and responsibilities should have been able to acquaint himself to such a remarkable extent with the technicalities of mining and the details of the bill."

J. H. Hawthornthwaite, leader of the Socialists of the Province, although of the opposition, congratulated

the government on the spirit shown in weighing the suggestions offered from the opposition side for the improvement of this bill, and accepting such of these as were deemed to possess merit. "The bill passed was," he believed, "as strong and good a piece of practical and necessary legislation as it was possible to devise, and one of the best bills of its character in the world. Upon it the House and the entire country were entitled to congratulation. Having passed this law, it now only remains for the government to see that it is effectually carried out, which, after all, is the main thing."

Here we find the people, the operators, and the miners satisfied, a condition which no politically fostered mine legislation can bring about.

GEOLOGISTS AND NATURE FAKIRS

SHORTLY after the death of Herbert Spencer a critic observed that he had wasted his energies, money, and time in trying to impress his ideas on origin and the hereafter on people who were perfectly satisfied that they were born and had to die.

An atheist took the critic to task, and among other acrimonious remarks, said the man was not capable of criticizing so great a philosopher.

The reply was: "Spencer theorized on some matters concerning which he knew absolutely nothing, and as I am equally learned in them I certainly am able to criticize him as a 'nature fakir.'"

We wonder if when Colonel Roosevelt used the expression "nature fakir" he had in mind the practical geologist with a pet theory on ore deposits, as well as the zoologist, for it is this uncertainty, coupled with a paragraph in Doctor Peters' "Copper Smelting," that has discouraged us from furnishing some engineering society with our "Résumé of Ore Deposits."

Doctor Peters' remark was to the effect "that the practical man had infinitely more theories than the theoretical man, but the trouble was they were all wrong."

When about to become a theoretical geologist and avoid the stigma placed on the practical geologist, our supposed friend, W. R. Ingalls, informs us through an editorial that the practical geologist is not justified in taking up the time of a mining society in riding some inane hobby, or words to that effect. So again we are in a quandry how to class ourself. Since the champion geological scrapper became a "nester" there have been few public encounters; therefore, the patriarchs delight to discourse on the good old sport which originated when Cain slew Abel with a rock.

The first geological set-to in the United States took place at Poker Flats, Cal., and was reported by Bret Harte as follows: "A piece of old red sandstone hit him in the abdomen and curled him on the floor, where subsequent proceedings interested him no more."

The second memorable geological sporting event occurred shortly after the San Francisco earthquake, and if memory is not at fault, was between Tobasco Tom and Dosalane sub Rang. While the function culminated in a riot of words, the feldsparing was by far the best witnessed. There seems to have been no available place since Tobasco won the championship where a geological event could be held, except at the clubs of the mining societies, and these are about ready to limit such sports, on the grounds that while they are entertaining to some, it is immaterial to the majority whether the fracas is brought about by the Elijah thermal or Dives meteoric method of deposition. This restriction does not signify, we are informed, that papers of this kind will not be received and printed, for undoubtedly the councils know as well as others that there is much to learn about ore deposits before the subject becomes a science. It does signify, however, that where society meetings are held at long intervals, practical papers that will be helpful in producing results are to be given preference.

We desire to emphasize that these comments have no reference to geological papers that remain inside the realm of dubiety, but merely to those papers which are composed of ideas evolved during sedulous thought, and which one can neither disprove nor contra prove, not having been around at the time. There have been presented to institutes many practical geological papers that record observations and impart information on the district described in a way that allows deductions to be made and applied to other districts. The authors of such papers should receive favorable comment and thanks from all engineers. However, we still hesitate to advance our Résumé of Ore Deposits.

THE COKEDALE, COLO., MINE EXPLOSION

ACCORDING to the evidence adduced at the coroner's inquest, the explosion at the mine of the Carbon Coal and Coke Co., at Cokedale, Colo., about 9 o'clock on the night of February 9, appears to have been due to the ignition of an undetermined quantity, certainly as much as 25 pounds, of 40-per-cent. dynamite in charge of the shot firers working. Owing to the rapidity with which shot firing was going on all over the mine and the consequent amount of dust produced thereby, as well as to the open and connected character of the workings and to the large volume of air in circulation, there appears to have been a great quantity of dust of strong coking quality in suspension in the air. This was ignited by the inflammation of the dynamite and the resultant dust explosion swept practically throughout the entire workings bounded by the First and Eighth West B entries and the Third and Fifth South entries.

Investigation has shown that the systems of mining, ventilation, watering and shot firing in use, while stamped with the approval of the best practice here and abroad, each contained an unsuspected "weak"

feature, and these weaknesses being in evidence or in force all at the same instant brought about the accident in question.

Owing to lack of space and to the fact that certain radical changes are being made at the mine as a result of the experience gained at this accident, the extended discussion of the subject will be left for a later issue.

A NEW BOOK CATALOG

FOR the convenience of our readers who may want the most up to date and reliable books on Mining, Mineralogy, Metallurgy, Prospecting, and Assaying; and on Mechanics, Electricity, Chemistry, etc. as related to mining and metallurgy, we have prepared for the Technical Supply Co., of Scranton, Pa., a comprehensive and convenient catalog of "*books worth while*," which will be sent free on request to any reader on application to either Mines and Minerals or the Technical Supply Co.

The prices quoted in the catalog are strictly publisher's prices and any books ordered from the Technical Supply Co., will be sent postpaid. Orders received by Mines and Minerals will be promptly filled by the Technical Supply Co.

BOOK REVIEW

Colliery Guardian Co., 30 Furnival Street, Holborn London, E. C., have printed abstracts on American Coal Dust Experiments conducted at the Pittsburg Experimental Station, and on the Austrian Coal Dust Experiments conducted at Rossitz Experimental Station. The prices of these abstracts are each 1s.

Practical Mineralogy Simplified, by Jesse P. Rowe, Ph. D. This book is intended for mining students, miners, and prospectors. It is divided into ten chapters and has tables for the determination of minerals. The writer realizes the number of splendid textbooks on Mineralogy that are now published, but from his long experience with mining students, miners, and prospectors not familiar with scientific methods, and with other college students in this kind of work, he realizes that there is ample room for a simple scientific work on the ores and minerals. There is no question but that a work of this kind will appeal to those who wish to obtain the practical part of Mineralogy. A little explanation of each mineral goes a long way with the prospectors who must use their eyes and make ordinary physical and elementary chemical tests. The book contains 155 pages, in addition to the mineral tables. In this work Professor Rowe limits the number of minerals to the more common of any class and does not deal with the extremely rare complicated minerals. It is believed that this method of presenting mineral information will appeal to a large number of those interested in metal mining. The price of this book is $1.25 net. It is published by John Wiley & Sons, New York City.

We are in receipt of Bulletin 2, 1911, West Virginia Geological Survey, Levels and Coal Analyses, by I. C. White. Part I is devoted entirely to levels, Part II to coal and coke analyses of the Pottsville series, Kanawha series, the Allegheny series, the Conemaugh series, the Monongahela series, and the Dunkard series. In addition there are statistics of coal production, coal areas of the several counties, and the classification of coals. Address I. C. White, Morgantown, W. Va.

Geology of the Iron River District of Michigan, by R. C. Allen, Director Michigan Geological and Biological Survey, Lansing, Mich. From a geological standpoint this is an exceedingly interesting book on the geology of the iron formation of Michigan.

Features of Producer Gas Power Plant Development in Europe, by R. H. Fernald, Bulletin No. 4, Bureau of Mines, Washington, D. C. This bulletin will be found exceedingly useful to those who are interested in the use of gas for power plants. It is stated that suction gas producers fed with anthracite or coke are in general use at the small power plants in Great Britain and on the continent. At the large producer gas power plants in Europe, bituminous coal is generally used both at those which save by-products and at those which do not. At a plant in Wales an installation of the by-product type comprises two pressure producers, each of 1,250 horsepower. At this plant an inferior coal is used containing 23 per cent. ash, 27 per cent. volatile matter, and 2 to 3 per cent. sulphur. Owing to the fact that the wholesale price of the sulphate of ammonia in the principal markets is from $55 to $60 a ton, the recovery of ammonia as a by-product in the manufacture of producer gas is a very tempting project abroad. Mr. Fernald states that one of the most interesting by-product installations in Europe is a 16,000-horsepower Mond gas plant at Dudley Port, South Staffordshire, England. He says that the leading manufacturers of gas producers are all working on suction plants for bituminous coal, but that each manufacturer places special restriction on the kinds of fuel that may be used.

The general situation in Europe regarding the use of low-grade bituminous coal is not much unlike the situation here. For the most part the better-grade coals are being used and the poorer grades are being left in the mines. The lignite or brown-coal briquets made in Germany form an excellent producer gas fuel and are in common use in the small suction plants, generally of the double zone type, that are put out by the various manufacturers. This brown coal closely corresponds to some varieties of the American lignite. The first peat producer gas plant stands in the center of a peat bog near Skabersjo, Sweden. Another peat-burning plant that is attracting the attention of engineers interested in producer gas development is at Visby, Gothland, Sweden.

Annual Report of the Board of Regents of the Smithsonian Institution for 1909, Charles D. Walcott, Secretary, Smithsonian Institution, Washington, D. C. The general appendix to the report contains high-class articles and brief accounts of scientific discovery in particular directions, and memoirs of a general character that are of interest and value to the numerous correspondents of the institution. There is an article on The Future of Mathematics, by Henri Poincare; What Constitutes Superiority in an Air Ship, by Paul Renard; Researches in Radiotelegraphy, by Prof. J. A. Fleming; Recent Progress in Physics, by Prof. J. J. Thomson; Production of Low Temperatures and Refrigeration, by L. Marchis; The Nitrogen Question From the Military Standpoint, by Charles E. Munroe; Solar Radiation Researches, by Jules C. Janssen; The Return of Halley's Comet, by W. W. Campbell; The Upper Air, by E. Gold and W. A. Harwood; The Distribution of the Elements in Igneous Rocks, by Henry S. Washington; The Mechanism of Volcanic Action, by H. J. Johnston-Lavis; Some Results of the British Antarctic Expedition, by E. H. Shackleton; Antiquity of Man in Europe, by George Grant MacCurdy; The Republic of Panama and Its People with Special Reference to the Indians, by Eleanor Yorke Bell; Ceramic Decoration, Its Evolution and Its Applications, by Louis Franchet; Some Notes on Roman Architecture, by F. T. Baggallay; The Relation of Science to Human Life, by Prof. Adam Sedgwick; Intellectual Work Among the Blind, by Pierre Villey; The Relation of Mosquitoes, Flies, Ticks, Fleas, and Other Arthropods to

Pathology, by G. Marotel; Natural Resistance to Infectious Disease and Its Reinforcement, by Simon Flexner; Conservation of Natural Resources, by James Douglas, in addition to several geographical articles.

BOOKS RECEIVED

United States Geological Survey Publications, Washington, D. C.: The Production of Anthracite Coal in 1909, by Edward W. Parker. United States Geological Atlas, Johnstown Folio, Pa., by W. C. Phalen, United States Geological Survey, Washington, D. C. This also furnishes an extra good idea of the coal fields in that vicinity, giving sections and geology. The price of this Atlas is 25 cents.

Map of Wood, Ritchie, and Pleasants Counties Oil and Gas Fields of West Virginia, including structural contours, West Virginia Geological Survey, Morgantown, W. Va.

Permissible Explosives, Miners Circular No. 2, by Clarence Hall, Bureau of Mines, Washington, D. C.

Oil Resources of California, by M. L. Requa, University of California, Berkeley, Cal.

The Prevention of Coal Dust Explosions by Zone Systems, by E. O. Simcock. Excerpt from the Transactions of the Institution of Mining Engineers, Newcastle-Upon-Tyne, England.

Some Relations Between the Composition of a Mineral and Its Physical Properties, by Prof. G. H. Cox and E. P. Murray, Vol. 3, No. 1, University of Missouri, School of Mines and Metallurgy, Rolla, Mo.

An Act to Consolidate and Amend the Coal Mines Regulation Act and Amending Acts, Province of British Columbia, Honorable Minister of Mines, Victoria, B. C., Canada.

Preliminary Review and Estimate of Mineral Production of Mines, William Fleet Robertson, Provincial Mineralogist, Victoria, B. C.

The California State Mining Bureau has issued a map of Whittier-Olenda Oil Fields, Louis E. Aubury, San Francisco, Cal.

Preliminary Report of the Oil and Gas Developments in Tennessee, by M. J. Munn. Address George H. Ashley, Nashville, Tenn.

The Farmers Handbook of Explosives, E. I. Dupont de Nemours Powder Co., Wilmington. Del.

PERSONALS

Mr. Wren, of the Canadian Pacific Railway, is receiving praise for furnishing a special train for the rescue party at the time of the Bellevue explosion.

Henry M. Lancaster, E. M., has removed his office from Wallace, Idaho, to 715–716 Hutton Building, Spokane, Wash., where he will continue the practice of his profession as mining and consulting engineer.

Sidney Norman has severed his connection with the Los Angeles *Mining Review*, having disposed of his interests in the paper to Mr. George H. Scott, formerly connected with Munsey and McClure magazines.

Ralph E. Davies, recently connected with the Montana School of Mines, has been appointed director of the Wisconsin State Mining School. Mr. Davies has had much practical experience in copper mining and is a proficient instructor.

W. R. Bauder has been appointed assistant general superintendent of the Breitung-Kaufman mining interests on the Marquette, Menominee, and Michipicoten iron ranges.

Frank Koester, sometime connected with the American Smelting and Refining Co., has opened an office at 115 Broadway, New York, as consulting engineer.

George E. Sylvester, of Rockwood, Tenn., has been appointed chief mine inspector of that state. He succeeds R. A. Shiflett, who has so ably performed the duties of that office, which in Tennessee includes all kinds of mines.

Warren R. Roberts, class of 1888, delivered a lecture at the University of Illinois on "The Engineering Features of Coal Mining and Handling."

James Epperson (Rep.), who for 16 years past has successfully filled the office of chief mine inspector in Indiana, will be succeeded March 11 by one of his able assistants, Frank I. Pearce (Dem.), of Brazil, Ind. This is an aftermath of the clean sweep the Democrats made last November in Indiana, when they elected all the state officers and an overwhelming majority in the state legislature.

Edgar M. Tuttle, E. M., of the Department of Mining and Metallurgy, New Mexico School of Mines, has changed his eastern address from 30 E. Logan St., Germantown, Philadelphia, to 1024 E. 9th St., Brooklyn, N. Y. He will unless he receives a commission in the meantime be at his Brooklyn home about May 1.

ENGINEERING SOCIETIES

The sixty-third meeting of the American Society of Mechanical Engineers will be held in Pittsburg, Pa., from May 30 to June 2, inclusive. The society has not met in that city since 1884. An executive committee consisting of E. M. Herr, chairman, George Mesta, J. M. Tate, Jr., Chester B. Albree, D. F. Crawford, Morris Knowles, and Elmer K. Hiles, secretary, will have charge of the Pittsburg meetings. It is expected that from 300 to 400 members and ladies will be in attendance.

It is proposed to celebrate the fiftieth anniversary of the Massachusetts Institute of Technology on April 10 and 11. At the same time there will be held a Congress of Technology, during which a large number of technology graduates will present papers dealing with various phases of the country's industrial problems as they exist today and promise to shape in the future. The papers, separately, will discuss the conditions and prospects in specific industries, and will therefore be of exceptional interest to the great number of men practically engaged in them. No similar discussion of the industries has been attempted on such a scale, and the record promises to be of unique suggestive value to the manufacturers of the country. The meetings will be open to the public.

The National Gas and Gasoline Engine Trades Association hold their convention June 20 to 23, inclusive, at Detroit, Mich., Albert Stritmatter, secretary, Cincinnati, Ohio.

The ninth annual meeting of the Western Branch of the Canadian Mining Institute was held in the Provincial Court House, Nanaimo, on February 17. Mr. W. F. Robertson, provincial mineralogist, of Victoria, B. C., was made chairman, and E. Jacobs, Victoria, B. C., secretary. E. B. McKay addressed the meeting, giving some interesting reminiscences of early days in Nanaimo. He stated that he first came to the district in 1875, bringing with him the first diamond boring machine, in order to prove the coal below what is known as the pitch in the old Douglass, and it was found at a depth of 240 feet. The paper by Charles Graham, superintendent of the Middlesboro colliery in Nicola, on "First Aid and Its Relations to Coal Mining," was read by Secretary Jacobs. C. F. J. Galloway, of Vancouver, read a paper on "The Beginning of Coal Mining in British Columbia." The first coal mined in British Columbia was in Rupert, in 1835. These workings were abandoned, however, for the Nanaimo workings in 1850. Mr. F. Napier Dennison, F. R. N. S., of the meteorological office, Victoria, delivered an address entitled, "Earthquakes, Strains, and Stresses in Relation to Coal-Mine Explosions." Mr. Jacobs read a report relative to the death of Fred Alderson, the Hosmer miner, who lost his life in attempting to rescue another. A vote of thanks was tendered the director of the United States Geological Survey for sending Mr. E. W. Parker to attend the meeting of the institute. It is proposed to hold the next branch council meeting at Trail, B. C., in May of 1912.

SELLING ZINC ORE ON CONTRACT

Written for Mines and Minerals, by Lucius L. Wittich

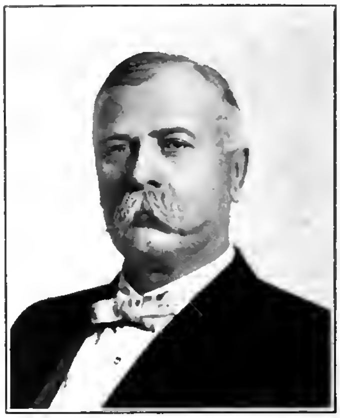
Method by which Prices for Zinc Ore are Based upon Price of Spelter and Analyses of Ores

Of almost 20 smelting companies buying zinc ore in the Missouri–Kansas–Oklahoma district, two, the American Zinc, Lead, and Smelting Co., and the Grasselli Chemical Co., are making purchases on a contract system, based on the average price of spelter at East St. Louis; this innovation having been introduced through the efforts of the Zinc Ore Producers' Association, an organization of mine operators of which C. E. Matthews, of Webb City, Mo., is president.

It is the first time in the history of this district, which has been a producer of zinc ores for almost 50 years, that a heavy tonnage of ore has been sold at a price determined to the fraction of a cent by the price of spelter. Of approximately 6,000 tons of zinc ore produced weekly in this district, almost 1,000 tons are now being disposed of on the contract basis, the sheet-ground producers of the North Webb City, Mo., field being conspicuous as the first to sign contracts on the new system. Fig. 1 shows a group of Webb City sheet-ground producers, the daylight workings of the Bradford–Kansas City Mining Co. being noted at the right of the picture.

Whether the contract system will result in the ore producer receiving a greater or less figure for his output than if he sold in the open market to the highest bidder is a question that is resulting in a storm of discussion, the majority of high-grade ore producers maintaining that the open market has its advantages, while the prevalent sentiment of low-grade ore producers is that the contract system will give the operator the best of the market. Comparative figures of prices paid, in the open market, and by contract, since the new system has been introduced, would indicate that both methods have their merits; but it is the contention of the Producers' Association, almost to a man, that cooperation of all producers will, in the end, result in better conditions and will create more harmonious relationship between smelter and ore producer.

After months of preliminary negotiations between the Zinc Ore Producers' Association and the various zinc-smelting companies buying ore in this district, which produces more than 50 per cent. of the zinc ore of the United States, which is converted into primary spelter, the first sales of ore on a contract basis were made in the week ending January 14, this year, and were based on the average price of spelter, East St. Louis, for the previous week. This spelter average was $5.37½. The contract specifies that zinc concentrates (except sludges) carrying 60 units of metallic zinc, shall bring $37 per ton (2,000 pounds, dry weight), when the previous week's spelter average shall have been $5 per 100 pounds, East St. Louis. The unit variation for metallic contents above or below 60 per cent. is to be $1 for each unit. That is, zinc blende containing 64 per cent. metallic zinc would command a premium of $4 per ton.



C. E. Matthews, President of Zinc Producers' Association

The price variation is to be 8.5 cents on or from the ore price per ton when spelter shall go up or down 1 cent per 100 pounds. The contract basis price for the first week of the experimental selling therefore was $37 per ton plus $3.19 (37.5 cents multiplied by 8.5 cents) which made the basis $40.19. The open market price for that week ranged from $40 to $44 a ton, basis of 60 per cent., which would appear, at first glance to indicate that those selling in open market received a better figure. However, several circumstances combined at that time to boost the open market bids, which, under other conditions might have been absent. For instance, the demand for ore was unusually strong at a period when spelter was weakened. At

Fig. 1 Sheet Ground Zinc Mines, Webb City, Mo.

another time, excluding the possibility of a manipulated spelter market of course, the metal would be high at a time when ore might not necessarily be in strong demand. Results under such conditions might give the producer selling on contract a big margin of gain.

Another feature of the contract welcomed by the producer of ores carrying 2 or more per cent. of iron is the clause which reads:

"Iron allowance: 2 per cent., no penalty; above 2 per cent., to and including 5 per cent., $1 per ton per unit penalty; above 5 per cent., 50 cents per unit penalty."

Under the present system of open market selling, only 1 per cent. iron is allowed without penalizing; for each additional per cent. $1 is deducted. So this clause in reality adds $1 a ton to the contract price; hence the bulk of ore that sold for $40.19 basis was of a class that would have been penalized at least $1, or more, in the open market.

Still another clause that appeals to the ore producer is this: "The producer shall have the right to withhold from delivery any ores and concentrates covered by this agreement, at any time during the continuance hereof when the base price under this agreement is below the sum of $40 per ton, but the producer shall notify, in writing, and not later than Tuesday of the week of production of which he desires to withhold, the agent of the smelter of his intention to so withhold such production; and provided further, that such production shall not be withheld from delivery for a longer period than 4 successive weeks."

Another clause specifies that the operator shall not be compelled to operate his mines steadily and that he may discontinue operations temporarily or permanently without affecting the terms of the contract.

In the week ending January 14, the first epoch of contract selling, the average price of all zinc blende sold was $41.49 per ton, which was higher than the contract basis price. The next week, ending January 21, saw the contract price jump to $40.49 a ton, reckoned on a spelter average of $5.41 for the previous week. The average price, all lots, was $41.06, a decrease, while the contract price had ascended. The basis price in the open market also was weaker, ranging from $38 to $43. For the week ending January 28, the contract price per ton was $40.23 on a spelter average of $5.38, but in this week the open market offerings slumped heavily, the basis ranging from $36 to $42.50 per ton, while the average price of all zinc blende sold was $38.78 a ton, considerably less, and for the first time, than the contract basis.

Producers of exceptionally choice zinc blende find a ready market for their output, the Matthiessen & Hegeler Co., operating five furnaces and more than 4,000 retorts, at LaSalle, Ill., and the Illinois Zinc Co., operating seven furnaces and almost 5,000 retorts at Peru, Ill., being willing to raise prevailing market quotations by several dollars per ton. The high basis prices paid by these companies in the open market are not criterions of the basis price paid by other companies, and because of this condition, the prevailing basis of all ores sold will be considerably lower than the top prices reported week by week. And because the producers of this grade of ore find such a ready market at prices in excess of that paid for second quality ore, they are opposed to the contract system, and justifiedly.

But to the mass of small producers, and to those whose ores are not in great demand in the open market, the contract system apparently offers relief, gives assurance of constant demand, and places a value on the producer's ore which will enable the producer to find bankers more willing to advance money on the output than they have been in the past. The contract system abolishes the competitive bidding, relieves the producer of the anxiety concerning his possible ability to sell his ore at a profitable figure, and gives him the privilege to withhold from the market his ore for a period of 4 weeks.

The contract system is not the result of months of mere discussion; it is the fruit of a carefully laid campaign during which the Producers' Association has sent agents to the plants of virtually every zinc-smelting company in the United States. Data on spelter production have been secured; every detail of the metal industry as well as the mining department has been given careful study, and upon the information so secured the scale was determined. Comparisons of what contract prices "might have been," had the contract system prevailed in years gone by, show a margin in favor of the open market system of selling; but this fact must not be forgotten: Had the contract been in force in the past, had the zinc ore producers of this district enjoyed control of the situation, would it not be reasonable to presume that the average price of spelter would have been sufficiently higher to have shown a margin in favor of the contract prices?

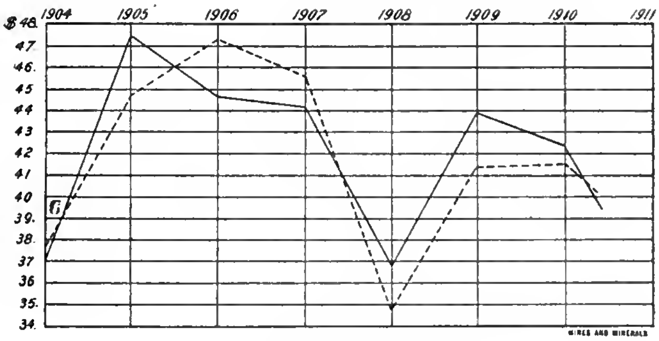


Fig. 2. Zinc Ore Prices

Relative to the smelter's margin, the Zinc Ore Producers' Association gives out the statement that $14.80 on 5-cent metal is reasonable and just; although this figure appears rather high to a great many zinc-ore producers of this district who have not forgotten the recent battle at Washington for a protective tariff on zinc ore, and on that occasion the supposition gained currency that the smelter asked for only an $8 margin.

Had the producers of the Joplin district been selling their ore on contract for the past 7 years, and had the same smelter prices prevailed that did prevail, the district would have received an average of $41.87 a ton for all ore sold instead of $42.42, the actual average basis, and this would have meant a loss to the district producers of hundreds of thousands of dollars. Fig. 2 shows a diagrammatic scale of actual and hypothetical prices, the solid line indicating actual basis offerings, while the dotted line shows the hypothetical basis, figured on the contract system, giving an idea of how the producers, at the existing spelter prices, would have profited in certain years by the contract system and would have lost in other years. The average for the whole period, however, is a strong argument in favor of the existing method of ore buying.

Table 1 shows the average price of spelter, East St. Louis, and actual basis price of 60-per-cent. zinc ores from and including 1904 to 1910; the value of metal in a ton, calculated on a recovery of 85 per cent. from 60-per-cent. zinc ores; the actual working margin of the smelters, and the calculated ore prices and smelter's margin had the contract been in force,

Table 1

Year	Average Price Spelter, St. Louis	Value 1,020 Pounds Spelter	(Old Scale) Ore Price 60 Per Cent. Zinc	(NewScale) Ore Price 60 Per Cent. Zinc	(Old Scale) Smelters Working Margin	(NewScale) Smelters Working Margin
1904....	$4.97	$50.69	$37.40	$37.75	$13.29	$12.94
1905....	5.79	59.06	47.40	44.72	11.66	14.34
1906....	6.10	62.22	44.82	47.35	17.40	14.87
1907....	5.90	60.18	44.36	45.65	15.82	14.53
1908....	4.62	47.12	36.63	34.77	10.48	12.35
1909....	5.39	54.98	43.98	41.32	11.00	13.66
1910....	5.42	55.07	42.35	41.57	12.72	13.50
Average 7 years		55.61	42.42	41.87	13.19	13.89

The proportions between spelter and ore base price under the old system figures out 7.76 to 1, while under the new system or scale the proportion is 7.65 to 1. That is, when spelter is quoted at a certain figure per 100 pounds, the price of ore, per ton, has been 7.76 times as great. While the contract price is slightly lower than the other, the contract scale is more than compensated by the difference in penalties exacted. The allowance of another per cent. of iron without penalty, the lowering of the penalty to 50 cents per unit after the fifth unit, the premium of $1 for less than ½ of 1 per cent. of lead, make ample provision for the difference in ratio, even had spelter prices been the same. The association maintains that the producers, through curtailment, would have been enabled to have "pegged" the spelter market at a much higher point than the low quotations of the past 7 years. The association maintains, for instance, that in 1904, when spelter averaged $4.97, the average could have been held to $5.25 or better. That a curtailment of zinc ore from this district will have a tendency to stop the slump in spelter has been evidenced this year, the spelter market having been held above $5.25 when there was every indication that it was scheduled to hit the $5 mark before the end of January. The metal now is ascending, and so long as this condition exists the producers selling on contract will enjoy stronger prices for their ore, week by week.

In compiling the new scale, the association and the smelters start at a point where it is claimed both the miner and the smelter are just breaking even. When spelter goes below $5 it is claimed neither smelter nor ore producer will make a profit, except in the case of exceptionally rich mines; but, as the price of spelter ascends, the miner's revenue not only increases proportionately, at the ratio of 8.5 cents for each 1 cent increase in the price of spelter, but the smelter's margin likewise widens. Table 2, shows the calculated price for zinc ore carrying 2 per cent. or under in iron and less than ½ of 1 per cent. lead on a spelter basis varying from $5 to $6.50; also shows working margin to smelter with 88 per cent. metal recovery.

Table 2

Spelter Price Per 100 Pounds	Metal Return and 88 Per Cent. Recovery in Pounds	Spelter Value	Ore Price Under Scale	Working Margin to Smelter
$5.00	1,056	$52.80	$38.00	$14.80
5.50	1,056	58.08	42.25	15.83
6.00	1,056	63.36	46.50	16.86
6.50	1,056	68.64	50.75	17.89

"Under this scale would it not seem reasonable," declares the Producers Association, "that the smelter would rather pay $50.75 for his ore and reap a bigger profit, his margin being $17.89, than to pay $38 for his ore and have a margin of only $14.80?"

From this it would appear that both ore producer and smelter would be benefited; but the objection is raised that $14.80 is a princely margin for the smelter, that in 7 years under the old system the margin was $13.19, and that if the smelter could prosper on this latter margin, and construct new plants in all portions of the country with the view of producing more spelter, why could he not profit on a $14.80 margin, keeping the price of spelter at a figure where the demand must necessarily be heavier than would be the case if the metal price were higher. Just as a merchant would sell more eggs at 10 cents a dozen than at 20 cents a dozen, so would the smelter sell more metal at $5 per 100 pounds than at $6.50—enough more, in fact, some contend, to more than overbalance the added price per 100 pounds. And again, a very pertinent question is propounded by those who are prone to question the practicability of the new scale: "Is there not sufficient scope for manipulation in the spelter market to permit the metal producer to buy at one figure (the reported price week by week) and sell at another price, in advance of the quoted one. That manipulation of the spelter market is not impossible is the common supposition in this district; and this presumption is strengthened by the reported efforts of certain operators to purchase metal at the actual East St. Louis quotations. For example, spelter at East St. Louis, at the close of January was reported to be ranging between $5.25 and $5.30, but to purchase any considerable amount at this figure is said to have been an impossibility. The private contracts of numerous concerns, especially those producing sheet zinc, hinge to a small extent on spelter quotations. It is true that in this district there is much guesswork relative to the secret workings—if such secret workings actually exist—of the powers higher up in the spelter industry; but be this as it may the spelter market quotations upon which the scale will be based each week are of vital interest. The contracts call for settlement upon the average of the preceding week's metal prices, East St. Louis. That the quotations received will be the actual quotations there should be little question—for no insinuation is made that alterations will be made in giving the actual figures. Considering that a heavy tonnage of metal is sold on private contracts at higher figures than the quoted metal prices, as has been explained, it is clearly seen how the ore producer will be selling on a lower quotation than the one upon which the actual sales of spelter are made. The ore producer thus loses and, in nine cases out of ten, would not know when he lost. In this connection it is well to explain that the spelter made from Joplin ores is for the most part more choice than that from other fields, and a larger portion of it is sold as special brands and at a premium over ordinary prime western spelter. For instance, three smelters handling Joplin ores make a "brass special" for which they receive a premium over the prevailing price. Others make a spelter for sheet zinc, the Joplin ores being especially desirable for this purpose. That the producers of the choicer grades of ore shall have incentive for cooperating in the contract system movement, the association is negotiating with the smelters of high-grade ores with the view of securing a more liberal contract which will appeal to others besides the producers of second-grade zinc ores.

SOLUBILITY OF THE RARE GASES IN WATER

The solubility of xenon, krypton, argon, neon, and helium in water was determined at temperatures from 0° to 50° C. The solubility rises with the increase of the atomic weight. At 20° C. the solubilities are He., .0138; Ne., .0147; Ar., .0379; Kr., .0670 and .0788 (the reason for this difference in values is not known), Xe., .1109. The solubility of xenon is greater than that of any other gas, which does not form a compound with the solvent. In the case of all the rare gases, there is a distinct minimum of solubility. The minimum for xenon and argon lies at 40° C.; for krypton between 30° and 40° C.; for helium at 10° C.; and for neon probably at 0° C. A. V. Autropoff. (Proc. Roy. Soc., A. 38, 744.)

SILICON STEEL

This article will well repay careful perusal, as it gives a careful resume of tests to show its superiority over other kinds. Among other things it is stated that high silicon steel was largely used in the construction of the Mauretania and Lusitania, the requirements being, ultimate tensile strength 74,000 to 85,000 pounds per square inch; elongation in 8 inches, 18 per cent. The United States naval requirements are: Minimum tensile strength and elongations of 60,000 pounds and 25 per cent.; and 75,000 pounds and 17 per cent. for medium steel. Manufacturers have found that the requirements for high tensile steel can be met much more readily by high silicon than by high carbon steel. G. A. Bisset, Naval Constructor, U. S. N. (Iron Age, lxxxvi, 8.)

MINING IN THE TINTIC DISTRICT OF UTAH

Written for Mines and Minerals, by Leroy A. Palmer

The Tintic district is one of the oldest mining regions of Utah, and has been one of its most productive. Notwithstanding this fact, some of its greatest mines are scarcely more than names to many well informed on mining subjects.

The Eureka Zone and Some of the Principal Mines—Conditions and Methods of Operating

The district is south of Salt Lake City, in the central portion of the Tintic Mountains, the easternmost of the narrow ranges rising out of the basin of the old lake. This range is about 40 miles long and is practically continued in the Oquirrh Range on the north and the Cañon Range on the south. These mountains are not very high, Tintic Mountain, the highest peak, rising to an altitude of 8,214 feet. The region is very dry, there being but one perennial stream. Such water as is used is obtained from springs and wells and by piping from Cherry Creek, 18 miles distant in Tintic Valley. Naturally, vegetation is sparse, consisting mostly of sage and stunted and gnarled pines. In this district, in a portion about 12 miles long and half as wide, are found the mines that have yielded the richest ores in Utah, and its most stubbornly contested lawsuits.

The first discovery was made by a party of prospectors returning from Western Utah, who located the Sunbeam claim on December 13, 1869, thus making Tintic the fourth mining district in the state, Bingham, Stockton, and Alta having been located at that time. The district was handicapped for years by the fact that it had no railroad, but the richer surface ores were hauled to Salt Lake, and from there shipped to Reno, San Francisco, Baltimore, and even Swansea, Wales. The average was too low for such expensive shipment and many attempts were made from time to time to mill or smelt in the district, and two mills and two smelters were erected in 1871. From that time up to 1895 several mills were erected, but owing to the refractory nature of the ore, amalgamation met with little success and two attempts at leaching were even less successful. These failures were due in part to a scarcity of water, but an attempt to operate a dry concentrator met with only indifferent success. From 1871 to 1908 seven smelters were built in the district but none of them survived more than a short run. The last was a modern plant of 1,200 tons capacity adapted to both lead and copper ores, which closed down just a year from the time it started. This was due largely to the fact that the district supplies ore that is mainly silicious, and favorable freight rates on outside ores which would have made suitable mixtures were not forthcoming. So it may be said that the Tintic district has been a very successful one from the miner's standpoint, but a dismal failure from the point of the metallurgist.

The Union Pacific built into the district from the west in 1883 and this aided materially in its development. In 1891 the Rio Grande Western built in from the east so that for the past 20 years the mines have had two outlets to the outside world.

The ores of the district occur in both the sedimentary and the igneous rocks; and for the first few years production was about equal from each. As the oxidized ores were exhausted in the igneous rocks a number of the mines were abandoned. Later shafts were sunk that encountered good sulphides, and mining in this formation was resumed after an interval of practically 20 years. The mines in the sedimentary formations have had a steady and increasing production and some of them are developed for years ahead.

The Tintic Range is a composite range of different rocks in which the sedimentaries are partly buried by volcanic outpourings and contain intrusions of igneous rocks, all being more or less concealed by surface accumulations, which condition has tended to hamper prospecting.

The sedimentary rocks, which are of the Paleozoic era, consist of limestones and quartzites of a total thickness of 14,000 feet. They are divided into the Tintic quartzite, 7,000 feet so far as exposed, a pure, compact, fine-grained rock of the Cambrian period with occasional beds of fine quartz pebbles; the Mammoth limestone, 4,000 feet, of dolomitic, cherty and shaly lime of the lower Carboniferous age; the Godiva limestone, 3,000 feet of upper Carboniferous blue and gray limestone with sandy beds in the lower portion and carbonaceous beds in the upper; and the Humbug formation, which consists of 250 feet of fossiliferous limestone alternating with arenaceous limestone and calcareous sandstone overlying and conformable with the Godiva limestone. The section presenting these strata is the western limb of a syncline which pitches toward the north. This limb is characterized by steep dips with beds vertical or even overturned, while on the eastern limb the dips rarely exceed 35 degrees.

There are a number of faults, the most of them with throw of only a few feet, but others with throw up to 400 feet, and cutting the limestones near the town of Mammoth is the Spy-Ajax fault with a throw of 1,000 feet. There may have been some displacement along the many fissures in the lime, but it is hard to detect, and, in any case the faulting in this district seems to have been of less importance than the folding.

The volcanic activity probably took place in the Neocene period of the Tertiary era. The igneous rocks, which are both intrusive and extrusive, are, in the order of their eruption, rhyolite, monzonite, and andesite (same age), and basalt. These rocks cover the greater part of the district, andesite being the most characteristic rock of the Tintic Mountains, about 100 square miles being overlaid by it and its tuffs and breccias. The rhyolite is the next most widely distributed, while the basalt and the monzonite occur only in limited areas, chiefly in sheets and dikes, and both of them of a composition closely resembling trachyte.

The rocks give evidence of alteration, both by physical and chemical agencies. In some belts the massive limestones have been reduced to a shale-like rock, which has in turn decomposed to a plastic clay, by sheeting and crushing. Hydrometamorphism has played an even more important part than dynamic action, and superficial alteration has caused extensive

surface deposits, as well as affected the character of the ores above the ground water level. The igneous rocks were not erupted until after the period of folding, so do not show much metamorphism.

There are two classes of fracture systems, those in the sedimentaries and those in the igneous rocks. The fracturing and mineralization of the sedimentaries took place before the period of volcanic activity and consequently before the fracturing and mineralization of the volcanic rocks. The fractures are very numerous and are easily traceable in the quartzites and hard limestones. They are also most numerous in the vicinity of the mineral-bearing zones of which there are three in the district, the Eureka, Mammoth, and Godiva-Sioux. Most of the fractures occur in the northeast-southwest quadrant and the most of these are almost due north and south. The fracture planes are nearly vertical, the dip in general being not less than 70 degrees. Of the east-west fractures the Spy-Ajax fault is the most prominent. Most of the fractures cross but do not fault one another. The faulting fractures are later than mineralization, but, as they do not occur in the igneous rock, were previous to volcanic action. The general direction of the ore bodies is along the north-south fractures.

The ore occurs along the fracture zones in both the sedimentary and the igneous rocks. In the sedimentaries it is confined to the three zones mentioned, and in the igneous rocks to short veins widely separated. The more common minerals are pyrite, sphalerite, galena, enargite, and their oxidized forms carrying gold and silver in a quartz or barite gangue. In the

Fig. 2 Centennial-Eureka Shaft Buildings

igneous rocks the ground water level was found at a depth of 200 to 700 feet, the line being very marked by the complete oxidation of the ore above and the unaltered condition below. In the sedimentary rocks the oxidized zone extends to great depths, in fact only two mines have entered it, the Gemini at 1,670 feet, and the Centennial-Eureka at 2,250 feet. In the igneous rocks the ore occurs only in the walls of fissures; in the sedimentary rocks it fills irregular spaces or chambers along the fissure zones or replaces the country rock. At the northern end of the zones lead and silver ores predominate and at the southern end gold and copper.

A feature of this district is the number of ore bodies that occur filling caves in the limestone. The supposition is that these were originally replacement deposits or deposits in cavities caused by dynamic action. They underwent leaching, which left the ore body in a more or less porous condition and caused contraction. Then occurred some disturbance which caused the loose mass to settle leaving a cave with ore on the bottom and clinging to the sides and roof.

The deposition of the ore was apparently made by ascending heated solutions which contained hydrogen and alkaline and arsenical sulphides, with some forms of silica, barium, lead, copper, silver, and gold. The replacements in the lime were due to chemical reactions and to the checking and cooling of the solution by some already existing cavity, or to contact with surface water containing oxygen or carbonic acid or organic matter. The separation of the minerals and the original complex ore bodies into those containing only one was due to a difference in the stability and solubility of the original minerals.

Taking into consideration the actively operated mines, the Eureka zone may be considered as extending from the Ridge and Valley on the north to the Apex in Mammoth Basin on the south, thus taking in the Gemini, Eureka Hill, Bullion Beck, and Champion, Centennial-Eureka, King William, and others of less importance. The greatest fracturing in this zone is between the Eureka Hill, Bullion-Beck, and Champion shafts. The ore bodies follow the fracture planes, which have a general north-south trend in the southern end, but turn toward the west in the southern end of the Eureka Hill, and between the two shafts mentioned have a course N 35° W from which they turn north of the Bullion Beck and Champion to almost due north. Toward the southern end of the zone the ore bodies are continuous and extend to great depth, but toward the northern end they are not so continuous and are in lens-shaped masses scattered through the zone. The Centennial-Eureka is the largest shipper in the Eureka zone, and in fact in the Tintic district, so will be taken as an example of operation in this portion.

The Centennial-Eureka.—This mine lies southwest of the town of Eureka toward the southern end of the Eureka zone, being the farthest south of the important producers of this belt. The ore is mostly copper with good gold values, the copper occurring as a carbonate or oxide with a very little native, although some small bodies of argentiferous galena are found. The shaft has recently reached the water level and it is supposed that below this point the values will be found as sulphides. The occurrence of the ore follows the general rules mentioned in the notes on geology of the district and is usually found near the intersection of two fissures. The ore bodies have a dip nearly vertical and vary in width up to 18 to 20 sets. The occurrence is more regular than in some of the other mines and the grade of the ore is such that, in general, all is extracted and the stopes do not present the irregular outlines found in some of the mines in the northern end of the zone.

For years the main working entry has been the Centennial-Eureka shaft, a two-compartment and manway vertical shaft that has been carried to a depth of 2,250 feet, but the Holden tunnel, recently completed, which connects with the shaft at a depth of 535 feet, is now used for the transportation of supplies and ore. The shaft is carried down in firm limestone, the two compartments and manway all having a measurement of 4 ft. × 4 ft. in the clear. Timbering is done with 8″×8″ sawed timbers, with 2-inch plank lagging. The tunnel will effect a considerable saving in the handling of ore and supplies, besides being much more convenient for the men. Reaching the shaft at the 535-foot level, it cuts off just so much from the height to which ore and water must be hoisted and permits of delivery of the ore directly to the shipping bins from the mine cars, whereas, in the past this delivery has been by aerial tram. The saving in the delivery of supplies is proportionate, timber, for example, being framed in a shed at the tunnel mouth and sent directly to place in the mine instead of being hauled by a winding wagon road to the shaft house.

There seems to have been no regular system in spacing the upper levels of the mine, which were driven some years ago. The first is 160 feet below the surface and from there to the 1,400-foot level the average distance is 112 feet. At this depth the shaft is a considerable distance from the ore body, so, in order to avoid a great amount of dead work, levels have been driven from the shaft at intervals of 225 feet, with blind working levels between. The levels so driven are designated as the 16, 18, and 20, the latter having a depth of 2,250 feet below the surface. Below this level a sump has been sunk 65 feet.

The drifts, which run through the lime formation, are 5 ft. × 7 ft. with an 18-inch track well laid and maintained. They require little timbering, a few sets, or posts and head-boards being all that is required. Ingersoll-Rand piston drills are used for drifting and most of the stoping is done by Waugh stopers.

Stoping is done by the underhand method. A slice is carried the width of the vein on the drift level and timbered with square sets. The stope is then carried upward and supported by square sets of 8″×8″ timbers. As a rule the lime walls have a steep dip and are firm, so that no lagging is required, but, as will be seen later, some very heavy ground which calls for special timbering is encountered. Most of the stopes are large, allowing the men plenty of room in which to work, so that the ore breaks well and one man can bring down 15 to 18 tons per shift. The broken ore is wheeled to chutes to the next through level on which it is hauled by mules in 20-foot cars to the shaft. The chutes are 14 in. × 14 in., of steel, and have given very satisfactory results, the increased cost being more than returned by the freedom from repairs and the longer life than timber chutes.

Timbering is an interesting feature in this mine and has been conducted with great care so as to preserve the ground and afford absolute safety to the workmen. In ordinary ground square sets are used. These are 8″×8″ sawed timber, spaced 5 feet in the clear with posts cut with a 1-inch tenon and caps butting. Much of the ground is heavy and some special forms of timbering have been used. If the pressure is not too great an ordinary doubled-up set is used, a set of eight by eights being placed inside the regular set. If there is a tendency to heavy side pressure, angle braces are carried from one cap to another so that the pressure is transferred in part to the posts. On the hanging wall every alternate set is carried clear to the wall, at which point the caps are connected to a long stull which covers the two sets and rests against the wall. A strut is carried from the intermediate cap to this stull and perpendicular to it so that the entire pressure of the hanging wall is transferred through the caps to the foot-wall. The foot-wall timbering consists simply of short sets tightly wedged to the wall with such braces as may be necessary. All sets are floored with 2-inch plank and these floors are kept tight while the stope is being worked, the manways being the only open part. As a stope is worked out it is filled with waste that is taken out in development work. If a stope is of such size that the timber shows signs of working before all of the ore is extracted, that portion that is worked out is bulkheaded off and filled while the remainder is being worked. Only such waste as is taken out during development is used for the filling and none is mined especially for the purpose. A sufficient amount is obtained in this way to fill most of the larger stopes. In some portions of the mine, notably on the 1,000-foot level, extreme pressure was encountered, as shown by the crushing of doubled-up sets that had been reinforced by angle braces. Here resort was had to cribbing to keep the stopes open while the ore was being extracted, after which they were filled as quickly as possible. The cribbing is made of eight by eights laid crossways with 8-inch spaces between and the whole filled with waste and waste filling between the sets. These cribs are built as close to the walls as possible and heavily braced to them. In times past some effort has been made to recover the timbers from the stopes, but without success, and the practice has been given up.

From the foregoing it will be seen that the ore is easily mined, although the timbering necessary makes its cost high. While there are not many places where cribs are necessary, it is probable that mining cost, including development and general expense, is in the neighborhood of $3.50 per ton.

The surface equipment is quite complete and is well maintained. The shaft house is of corrugated iron over a steel frame. In the boiler room are four 150-horsepower Stirling water-tube boilers generating steam at 100 pounds. They are equipped with American stokers, belt-driven by a small vertical engine, and draft is supplied by a 4-foot diameter centrifugal blower driven by a Sturtevant piston-valve engine.

The hoisting engine is a 20 in. × 60 in. Fraser & Chalmers duplex first motion, with 12-foot reels which can be operated independently or clutched together and run in balance. The reels wind a ½″×5″ flat rope. The head-frame is 60 feet high, consisting of two 12″×24″ timbers bolted together, with a batter of 1 inch to the foot. These uprights are braced on each side with an 18″×24″ timber tied to each upright by a 12″×24″ strut, thus making a staunch and rigid structure. The sheaves are wrought iron, 8 feet in diameter. The cages are double-decked, attached to the ropes by four clamps, each with four bolts, and are equipped with safety catches which operate automatically if the rope breaks. The compressor is a two-stage Sullivan 13 in. × 26 in. ×44 in. ×20 in. ×32 in. with a capacity of 1,500 cubic feet per minute. The machine and timber shops are under the same roof as the shaft. They are operated by a 12″×24″ Corliss engine.

The use of flat ropes is a general practice in the deep shafts of Utah. The objections that have been made to them are their great first cost and the shorter life caused by the wear of the rope winding on itself and rubbing on the edges. This latter feature can be eliminated to a large extent by carefully lining the reel and the head-sheave, and, if the lead from the shaft to the engine is a long one, providing guides to keep the rope from swaying. The Tintic operators profess themselves well satisfied with the flat ropes, and they are also in general use at the largest Park City mines. One of the latter claims an average life for a ½″×5″ rope of 5 years. The advantages are the saving in space and the fact that when the hoist is begun and the inertia of the load must be overcome, the drum winds on a small diameter, thus giving the engine a large leverage, and as the hoist is being made and the cage gathers momentum, this diameter is increased, allowing an increase of speed. For such a shaft as the Centennial-Eureka each drum would have to be 6½ ft. × 15 ft. to accommodate a round rope of the proper diameter and length. The reels therefore effect a large saving in space as well as allow the use of a much shorter and consequently smaller shaft.

Fig. 3. Timber Connection to Hanging Wall in Centennial-Eureka Shaft

One of the characteristics of the Tintic district is the great depth attained before water is encountered. In the case of the Centennial-Eureka this occurred while extending a drift at a depth of 2,250 feet. The drift, which was being run to the south, encountered a water course, supposed to be the same as that in the Gemini, the two being only 2 feet different in elevation, which gave a flow of 300 gallons per minute.

The mine had no pumping equipment, so a concrete bulkhead was built across the drift and the flow was cut off except for such portion as seeped through the formation into the sump. This amount was only such as could be handled by bailing skips. Bailing was carried on between the regular shifts, a skip being hung in each compartment in place of the cage. These skips are cylindrical with shoes working in the cage

guides. Each is 3 ft. × 10 ft. of ⅛-inch iron, with a large butterfly valve forming the bottom. Below the bottom is a pointed hood so that the skip enters the water easily, this hood being open on two sides so that the valve opens and the skip fills. Each skip has a capacity of 500 gallons and they gave good results in handling the water in the sump while the pumps were being installed.

The shaft is equipped with a No. 9 Cameron sinking pump which raises the water to a concrete sump 6 ft. × 9 ft. × 24 ft., with a capacity of 10,000 gallons, on the 2,250-foot level. Here a large station has been cut out and two 13-stage centrifugal pumps installed. This is, so far as the writer's information goes, the first installation of centrifugal pumps for station work against a high lift in this country. This type of pump was used by the United States Mining Co. in Mexico with such success that it was recommended for this installation. The station has provision for four pumps, two of which are installed. Each has a capacity of 500 gallons per minute. They are built in two sections, one of five and one of eight stages, with a 400-horsepower 4,000-volt General Electric induction motor mounted on the shaft between the two. The five-stage section receives the water through a 10-inch suction pipe, the intake being about 5 feet above the surface of the water when the sump is full. This discharges to the eight-stage section which in turn discharges to the 10-inch water column terminating at the Holden tunnel 1,715 feet above.

Fig. 4. Cribbing in Centennial-Eureka Stope

The concrete bulkhead was shot out when the pumping equipment was in running order and the drift extended. A cross-cut was driven and from this a drift to the sump. These drifts have 4′×6′ cast-iron water doors with dressed edges close-fitting against a cast-iron frame. They swing inward against the flow of water and provide protection against a sudden increase of water flow such as may be expected in a lime formation.

The Holden tunnel starts near the bottom of the gulch below the town of Eureka, and terminates at the 535-foot point in the shaft. It is 2,207 feet long, 9′×8′ in cross-section, with a grade of .40 per cent. It was driven through the hard lime all of the way, so that after the surface formation is passed only 12 sets of timbers are required in the entire length. It is laid with a 36-inch track of 35-pound steel for electric haulage, this track running over a trestle to the ore bins which are beside a spur of the San Pedro Railroad. At the station at the shaft is a 700-ton ore bin with eight air-operated gates, and beneath the track is a coal bin from which the coal can be unloaded to cars and hoisted to the shaft house. All freight will be hauled in through the tunnel, and timbers will be framed at a shop at the mouth.

Power is generated in a brick building with concrete floors near the portal of the tunnel. Coal for the power plant is unloaded to bins beneath the railroad tracks, from which an inclined conveyer carries it to storage bins from which it is hand trammed to the stoker bins. The boiler room has three 225-horsepower Stirling water-tube boilers with American stokers. The feedwater is heated in a Hoppes heater which receives the exhaust of the feed-pumps, two Epping & Carpenter duplex-plunger 7½ in. × 4 in. × 5 in. × 10 in. × 10 in.

Electricity is generated by a 400-kilowatt, 4,000-volt, General Electric three-phase, 60-cycle alternating current generator mounted on the shaft of 19″×37″×24″ cross-compound Ball-Wood engine. There are two General Electric exciters, one 20-kilowatt, 125-volt, chain-driven by a 7″×7″ Sturtevant slide-valve engine and one 17½-kilowatt, 125-volt, direct-connected to a 25 horsepower, 400-volt, induction motor. The power for the haulage system is supplied by a 25-kilowatt, 250-volt, General Electric direct-current generator, direct-connected to a 35-horsepower, 440-volt induction motor. The engine is connected to a Worthington barometric jet condenser with a 10″×18″×12″ vacuum pump. The current is led direct to the mine pumps and to two 30-kilowatt General Electric transformers stepping down from 4,000 to 440-volts, which furnish current to the exciter and motor-generator sets. There are also some smaller transformers stepping down to 120 volts for the lighting systems. As an additional source of power, current can be taken from the Utah County Power Co.'s lines through three 250-kilowatt, 11,000- and 5,500-volt primary and 4,000-volt secondary transformers located in a small brick substation.

The Centennial-Eureka has been described in detail as the largest mine of the district and the one presenting the most interesting operating features. At the northern end of the district where the production is of silver-lead ore the Gemini is the most active. This mine has a two-compartment shaft to the 1,670-foot level, and a winze from there to the 1,970-foot level. The ore is extracted by square setting and the stopes have an irregular shape owing to the fact that the ore is not of uniform grade and only that which will ship is extracted. Water was encountered on the 1,670-foot level, and below this point copper ore running high in silver has been found. Pumping is done by a 12″ × 12″ Aldrich quintuplex pump on the 1,970-foot level and a similar pump on the 1,670-foot level. The surface equipment includes three 200-horsepower Stirling boilers, an 18″×60″ Fraser & Chalmers duplex first-motion hoist with ½″×5″ flat rope and an 18″×36″×20″ Noerdberg duplex compressor. North and east of the Gemini is the Ridge and Valley, which is worked from the 1,670-foot level of the Gemini. The formation is the same as that in the Gemini and, in general, the same method of operation is followed.

Across the cañon from the Gemini, and adjoining it on the south, is the Bullion Beck and Champion, now owned by the United States Mining Co. Butting on the Bullion Beck and Champion is the Eureka Hill, which joins the Centennial-Eureka on the south. The Bullion Beck and Champion is working only a few company men, and the Eureka Hill none at all. A number of leasers are working in both mines. Each mine has a depth of about 1,500 feet, with two-compartment shafts, and 20″×60″ duplex Fraser & Chalmers hoists. It was between these two companies that one of the most stubbornly contested legal suits of the district was fought.

The Eureka zone has produced very liberally, but just what the production has been it would be hard to state. Many of the mines are held by close corporations which have an aversion to giving out figures. Also in the early days of the camp some of the mines were worked as partnerships, and no one knew just what was taken out. The known dividends of the mines on the Eureka zone are as follows, but the actual profits doubtless exceed this considerably: Gemini, $2,000,000; Eureka Hill, $1,500,000; Bullion Beck and Champion, $2,738,400; Centennial-Eureka, $5,317,000.

The Ridge and Valley is supposed to have paid some profits which are not of record. Beyond the Centennial-Eureka are the Apex and King William, which are still in the prospect stage and the only mines on the zone that have not shown a profit.

REVERBERATORY COPPER SMELTING

Written for Mines and Minerals, by E. B. Wilson

Methods of Roasting Ores and Smelting in Reverberatory Furnaces

This first of a series of copper smelting articles is descriptive of roasting and modern reverberatory practice. Welsh copper smelting, while it may be described in a general way, involves 12 or 15 operations before the copper is ready for the market. The successful operation of the Welsh method requires an experience which cannot be described, and as it is not practiced in the United States and is going out of style in Swansea, the reader is referred to Dr. Edward D. Peters' "Metallurgy of Copper" for further particulars. In the Lake Superior copper district, where practically metallic copper is melted, skimmed, and refined, all in reverberatory furnaces, the smelting is comparatively simple, and has changed little since its introduction, except in mechanical features.

The ore, previous to smelting, is cleaned as thoroughly as is consistent with economy, in which condition it carries probably about 35 per cent. of rock impurities that cling to it and are difficult in some instances to remove. The furnaces are not made large, being capable of smelting 625 tons of ore and producing about 400 tons of copper per month, which is a remarkable contrast between the Washoe, Cananea, and Arizona smelting companies' reverberatories, which, running on sulphide ores, smelt to matte from 250- to 350-ton charges in 24 hours.

The hearth of the Lake Superior furnace is 12 ft. × 18 ft., that of the Cananea furnace 100 ft. × 19 ft.

The ore is charged into the furnace through a hopper in the top; the mass copper through the working doors in the side; and large mass too heavy or large to pass through the doors is charged by a derrick when the roof is repaired. The copper commences to melt soon after it is charged, and slag skimming commences as soon as it accumulates in sufficient quantity.

After skimming the melted mass on the hearth it is flapped to oxidize the impurities and send them into the slag. Where flapping was once carried on with paddle-shaped tools thrust into the bath and then raised, it is now generally done by

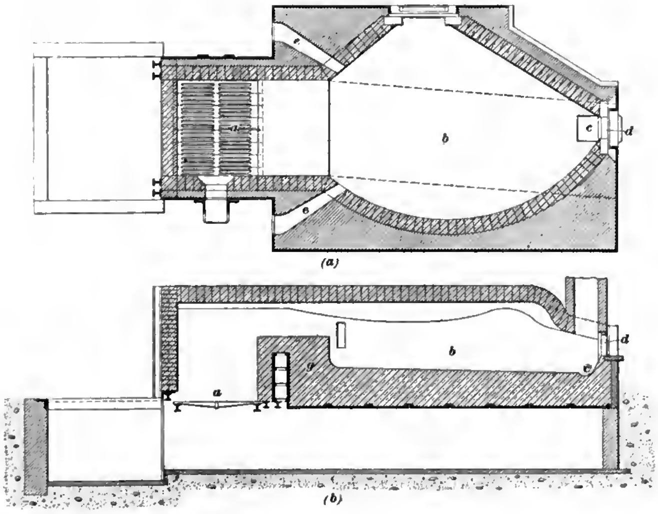

FIG. 1. LAKE SUPERIOR REVERBERATORY FURNACE FOR COPPER

thrusting pipes through which steam is forced under pressure into the bath. In flapping, the rabble or steam pipe should not be thrust deep into the bath, but only a little below the surface, where the lighter impurities are, and even then considerable copper is oxidized and sent into the slag. The slag is removed from time to time during the flapping process, which lasts several hours. Test samples are taken during the operation by means of small ladles and examined to ascertain the progress of the melt. When the impurities are thoroughly oxidized, the test sample on being cooled and broken shows a slight depression in the middle and the fracture has a mottled appearance. The next operation consists in spreading charcoal over the top and then thrusting a green sapling into the bath. This operation, termed "poling," has for its object the stirring of the metal and the reduction of any copper oxides remaining by bringing them in contact with the reducing action of carbon in the charcoal and in the sapling. If this operation

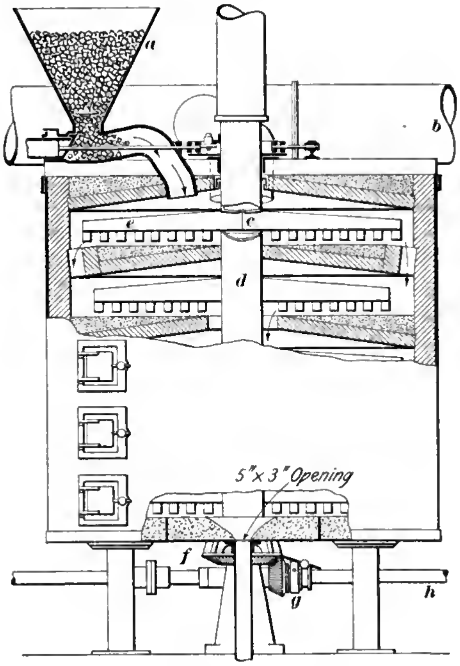

FIG. 2. HERRESHOFF FURNACE

is carried to just the right point a sample of the metal will not have a depressed surface, the fracture will show a fine texture, and the metal a reddish color. The metal is now cast into ingots and after pickling is ready for the market.

Slag from the first skimming of the reverberatories contains from 10 to 20 per cent. copper and is worked over in blast furnaces, while the rich slag from the final flapping and the poling, which contains from 20 to 35 per cent. copper is remelted in the reverberatories.

The furnace operations will be now about as follows:

1. Mineral, black copper from cupola, limestone flux and rich copper slag from *d*.

2. *a*, fusion; *b*, removal of slag; *c*, rabbling; *d*, poling; and *e*, casting and pickling.

3. Slag from operations *b* and *c* is sent to the blast furnace; slag from operation *d* is charged into the reverberatory.

The blast furnace mentioned is designed to recover the copper from the reverberatory slags and is more properly termed a cupola (about 36 in. × 76 in.), because of its size and intermittent working. It is charged with slag from *b* and *c*; two-fifths as much limestone as slag and about one-seventh as much coal as slag and limestone. The product of the cupola is "black copper" containing from 70 to 80 per cent. metal and slag. The black copper is charged into the reverberatories and the slag is wasted after standing some time in a settling pot.

When the rich copper ores of the West were at the surface and mining was carried on in carbonates and oxides, as at Clifton and Bisbee, Ariz., the blast furnaces produced what was termed black copper, a product carrying from 70 to 90 per cent. copper; with depth, however, the ores changed to sulphides, and the furnaces were changed to produce a complex sulphide product termed "matte." To free the sulphides from rock, crushing and wet concentration were introduced, and, because the concentrate was too high in sulphur and iron, and

comparatively low in copper, a combination that made a matte too poor in copper and too rich in iron, part of the ore was roasted, or otherwise part of the matte had to be crushed and oxidized. At first hand-rabbled reverberatory furnaces were used for roasting, then the Bruckner cylinders, the Brown horseshoe furnace, the Holtoff-Wethey, and others, until at last the majority of the copper smelters seem to have settled on the Herreshoff furnaces, or others somewhat similar known as the McDougall and the Klepetko-Evans-McDougall.

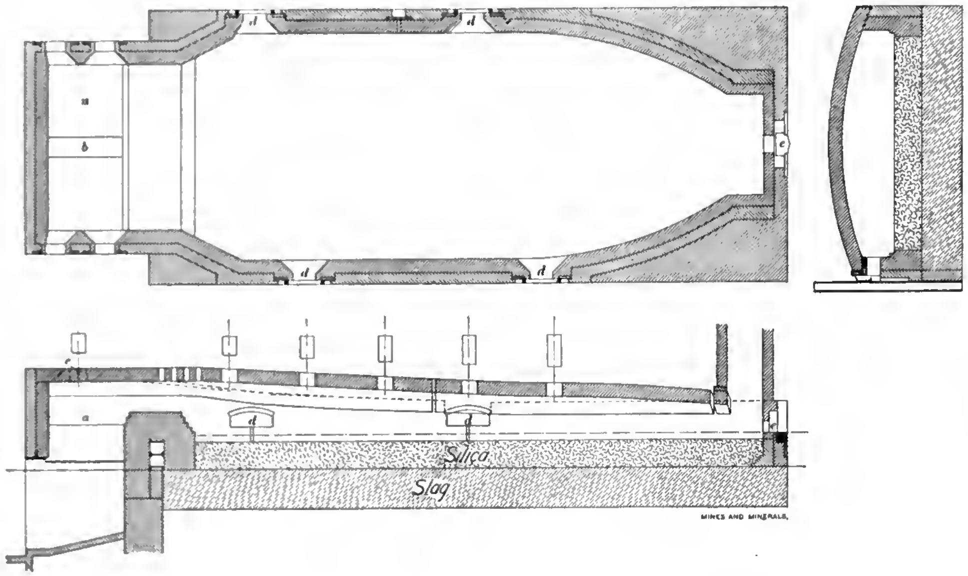

FIG. 3. LARGE REVERBERATORY FURNACE FOR SMELTING MATTE

The favorable acknowledgment that this style of furnace has received from copper metallurgists is owing to the cheapness with which it roasts ore compared with some others. The Herreshoff roaster is shown in Fig. 2. It consists of an iron cylinder mounted on pedestals, lined inside with firebrick. At intervals concave-convex arches are built of firebrick which answer as hearths on the upper side, and as reverberatories on the lower. In the center of the roaster is a hollow shaft through which air circulates, and attached to this shaft are rabble arms carrying teeth pitched so that when the shaft is revolved the teeth on the arms will move the ore to or from the center of the hearths. The shaft is turned by the gears shown underneath the lower hearth. When the furnace is put in operation the ore is admitted to the top hearth near its center, and by means of the revolving arms is worked slowly from the center to the circumference, where it falls to the second hearth.

TABLE 1

Name	Size	Per Cent. Sulphur in Ore	Per Cent. Sulphur in Product	Tons Roasted in 24 Hours	Cost Per Ton
Hand reverberatory	69.5′ × 16′	35	7.5	13.0	\$2.00
Allan-O'Hara	2.94′ × 9′	35	8.0	51.0	.78
Bruckner, 8½ revolutions per hour	8′ × 16′	37	9.5	10.0	1.25
Pearce double-decked	7′ hearths	35	6.5	42.0	.98
Herreshoff 5 hearths	10′ 10″ diam.	35	6.0	6.0	.50
McDougall 6 hearths	15′ 10″ diam.	35	7.0	40.0	.35
Klepetko-Evans-McDougall		35	7.5	37.5	.34

On the second hearth the teeth are pitched to work the ore from the circumference to the center, where it falls to the third hearth, and so on alternately from the center to the circumference and back to the center of the next hearth, until it is finally discharged at the center of the lower hearth. After the sulphur in the ore has been ignited in the lower hearth, no fuel is required, as the heat rising upwards follows the roofs to the exits and thus heats the descending ore, until the sulphur in the latter takes fire and keeps up the heat necessary for the roast.

The rabble arms of the Herreshoff roaster are solid, and owing to their corrosion by the sulphur and sulphur dioxide do not last indefinitely. When one is badly corroded the revolving shaft is stopped so that the arm will be in line with a door, which is then opened so that the arm can be withdrawn and another substituted. In order to reduce the cost of repairs the McDougall roasting furnace was constructed with water-cooled arms, and has now become more popular than the Herreshoff.

Table 1 herewith gives the size, capacity, cost per ton of roasted ore, and the percentages of sulphur in the ore before and after treatment in the roasters named.

Quite a number of reactions have been advanced to show the various chemical changes that occur during the roasting period, based on the fact that pyrite, FeS_2, loses one atom of sulphur when heated in air to a temperature of 516° C., and also on another fact that copper has more affinity for sulphur than any other metal. Starting with a chalcopyrite, $CuFeS_2$, the following reactions are assumed to occur:

1. $CuFeS_2 + \text{heat} = CuS + FeS$
2. $CuS + FeS + 3O = CuS + FeO + SO_2$
   158 160
3. $2CuS + 2FeO + 3O = Cu_2S + Fe_2O_3 + SO_2$
   158 160 48
4. $Cu_2S + Fe_2O_3 + 3O = Cu_2O + SO_2 + Fe_2O_3$

On examining the table it will be seen that the sulphur remaining in the different roaster products varies from 6 to 9.5 per cent. This shows that the roasting was incomplete; and as copper has more affinity for sulphur than iron, the product will contain sufficient copper sulphide to satisfy the sulphur.

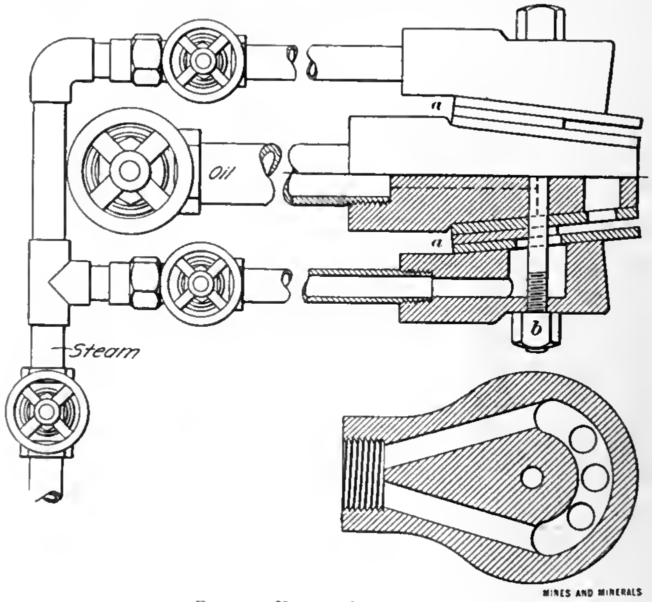

FIG 4. KITTLE OIL BURNER

From the molecular weights given in equation 4 there is 43.17 per cent. of the ore cuprous sulphide, or in every 100 pounds there are 43.17 pounds. Since 20.25 per cent. of Cu_2S is sulphur, there is 34.43 pounds copper in the ore and

8.74 per cent., or pounds, of sulphur; but 6 per cent. sulphur, or 6 pounds, remained in the roasted product, and to satisfy this it will require 8.74 : 6 = 34.43 : 23.64 pounds copper, and the copper remaining to form cuprous oxide is 10.79 pounds. Instead of equation 4 the roaster would furnish the following product per 100 pounds:

5. Fe_2O_3 = 43.71 pounds
Cu_2S = 29.64 pounds
Cu_2O = 15.16 pounds
SO_2 = 11.49 pounds

because there is 13.12 pounds of oxygen in equation 4 to be satisfied. One of the principal laws in chemistry may be stated as follows: "It requires as much heat to separate a mineral as to form it," but so far that quantity of heat has not been determined for chalcopyrite, consequently thermochemical data are wanting for equation 1.

The heat of formation for ferrous sulphide, FeS, is 429 calories; for cupric sulphide, CuS, 159 calories; for cuprous sulphide, Cu_2S, 160 calories; for ferrous oxide, FeO, 1,173 calories; for ferric oxide, Fe_2O_3, 1,746 calories; for cuprous oxide, Cu_2O, 344 calories; and for sulphur dioxide, SO_2, 2,164 calories. All the heat units or calories mentioned have been determined by experimenters.

In the second equation the copper is unchanged, but the ferrous sulphide is broken up and oxidized to FeO and SO_2.

The heat absorbed to separate FeS = 429 calories
The heat evolved to form FeO = 1,173 calories
The heat evolved to form $SO_2 = \frac{32 \times 2{,}164}{56} = 1{,}236$ calories

Net heat evolved 198.0 calories

In the third equation cupric sulphide furnishes an endothermic reaction, and cuprous sulphide an exothermic; at the same time the ferrous oxide is endothermic and the ferric oxide exothermic.

The heat absorbed to separate CuS = 159 calories
The heat absorbed to separate FeO = 1,173 calories
The heat evolved to form Cu_2S = 160 calories
The heat evolved to form Fe_2O_3 = 1,746 calories

Net heat evolved 574 calories

In equation 4 the cuprous sulphide is endothermic and the cuprous oxide and sulphur dioxide exothermic.

The heat absorbed to separate Cu_2S = 160 calories
The heat evolved to form Cu_2O = 344 calories
The heat evolved to form $SO_2 = \frac{32 \times 2{,}164}{126} = 549$ calories

Net heat evolved 733 calories

FIG. 6. TAPPING AND GRANULATING SLAG, ANACONDA FURNACE

FIG. 5. INTERIOR OF ANACONDA REVERBERATORY FURNACE

The calculations have been formed using pound calories; that is, the heat that will raise 1 pound of water 1° C., and have been based entirely on the theoretical supposition that the furnace roasted pure sulphides when in practice. This is merely approximated. Again, the calculations have been based on a dead or oxidizing roast, when the resulting product from the roaster was assumed to contain 29.64 per cent. Cu_2S; 15.16 per cent. Cu_2O, and 11.49 per cent. SO_2, therefore, no matter how pure the minerals may be, the calculations should not be carried beyond the sulphur in the roasted ore. To approach practice, the final calculations are based on the 6 per cent. sulphur in the roasted product; but it is to be remembered that the ore before the final roasting in 4 contained 43.17 per cent. Cu_2S, and after roasting 29.64 per cent. Cu_2S.

The heat absorbed to separate
13.53 per cent. $Cu_2S = 160 \times .1353 = 21.65$ calories
The heat evolved to form Cu_2O ($.1516 \times 344$) = 52.15 calories
The heat evolved to form SO_2 ($.1149 \times 594$) = 63.08 calories

Net heat evolved in last operation 93.58 calories

The deductions from such calculations, while merely approximate, show the metallurgist that for a dead roast he must use the hand-rabbled furnace with the extra expense for fuel and labor attached; that in a mechanical roaster he must use the purest possible concentrate; and that without iron sulphide he must use fuel to generate sufficient heat to roast.

There would be great difficulty in roasting the mixed sulphide product termed matte, if it were not for the iron it contained; and where, as in Chili, the minerals atacamite, $CuCl_2\,3CuO + 3H_2O$, and covellite, CuS_2, are concentrated, pyrite carrying copper is a necessity in order to obtain a suitable matte.

It was assumed for the purpose of heat calculations that the final product from the roasters was reached when the 6 per cent. sulphur was distributed to satisfy the copper; this, however, is unlikely, because the ore cannot be roasted so uniformly as to produce theoretical results, and it is undoubtedly true that there will be iron and copper sulphides, and iron and copper sulphates, as well as oxides of both metals, in the product coming from the roaster. The net heat units evolved in the final calculations where sulphates are formed in such small proportions would not vary much from the 93.58 calories found; on the other hand, if the sulphides were oxidized to sulphates directly and completely, two or three times

as much heat would be given off as in oxidation, and this would create incipient fusion and loup the ore.

At the Yampa smelter*, Bingham, Utah, there are nine McDougall roasters, 18 feet in diameter. The rabbling arms to these roasters make one revolution every 58 seconds, and as there are six decks it requires about 1 hour and 15 minutes to work a charge through. Each roaster has a daily capacity of 47 tons of concentrate from which it eliminates about 83 per cent. of the sulphur. The McDougall dust assays on an average: Copper 2.36 per cent., iron 30.5 per cent., silica 25.8 per cent., sulphur 21.2 per cent., lime 2.6 per cent., alumina 7.4 per cent.

The accretions which form on the sides of the roasters are barred off and trammed to a bin from which they are mixed with the charges going into the blast furnace.

A 20-horsepower direct-curent motor drives the McDougall roasters.

The roasted ore is discharged from the McDougall roasters into cars, having a capacity of 7,300 pounds each, and hauled by a motor to a building adjacent, where there are three reverberatory furnaces two of which are in continuous operation. The furnaces (a drawing of which is shown in Fig. 3), are 17 feet wide, 47, 53, and 59 feet long, each with a rated smelting capacity of from 150 to 175 tons of raw ore per day, but they actually treat much more. The fireboxes *a* are of uniform

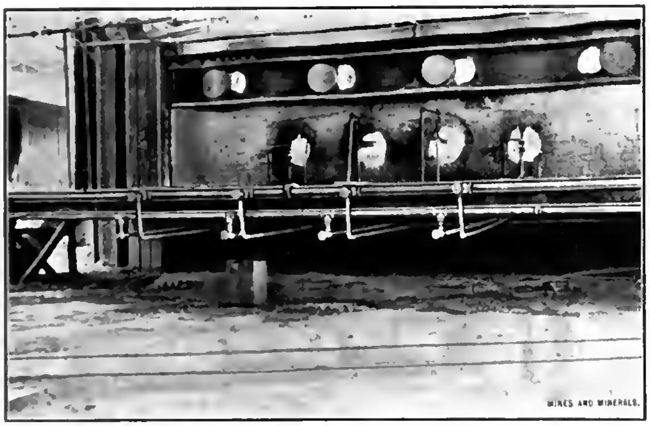

Fig. 7. Oil-Fired Reverberatory Furnace

size, 9 ft. × 12 ft., divided into two compartments by a brick wall *b*, so that each compartment is 5 ft. 6 in. × 9 ft. Each side of the firebox is connected to a 15-inch air line, while the fuel is fed from the roof through three 15-inch openings *c*. Draft for the fireboxes is supplied by a 16-inch centrifugal blower at a pressure of considerably less than 1 inch of water. A 20-horsepower induction motor drives the blower.

The furnaces are of brick, stayed with 4-inch I beams tied across the top and spaced on 16-inch centers, except where two doors *d* 15 in. × 24 in. have been left in each side to allow the furnace men to feel the charge. A 12″ × 15″ door *e* is in the back of each furnace for skimming.

Between each furnace and the stack is a 300-horsepower water-tube boiler utilizing the waste heat from the furnace to generate steam at 110 pounds pressure. These boilers deliver an average of 180 horsepower, effecting thereby an economy equal to 150 tons of coal for each furnace per month. This 180 horsepower represents an efficiency of only 60 per cent., which is small

The construction of the reverberatory furnace of the modern type requires much more skill and material than one of the smaller ones. This is due to their width and enlarged fireboxes, to the systematic methods of charging material and fuel, followed by handling the matte and slag. Furnaces are made as wide as 19 feet, and this feature necessitates great care in constructing the arched roof which in any case is low and flat; and in placing buckstaves as near together as possible that they may resist the expansion which ensues from the flat arch and heated brickwork.

*Leroy Palmer in Mines and Minerals, Vol. 31, page 14.

In Fig. 5 is shown the interior of one of the large furnaces at Anaconda, Mont., which illustrates to those accustomed to smaller reverberatories the absolute need of the increased care that is used to reinforce the sides.

The roof of the reverberatory is made of firebrick, as is the inner wall, which comes in contact with the flame and the hot material. The bridge wall between the firebox and the hearth is of firebrick, and has flues for admitting air for the combustion of gases arising from the coal. Flues for the same purpose are placed above the firebox, the object being to furnish sufficient air to completely burn the volatile hydrocarbons of the fuel and prevent smoke, which cools the furnace walls and the top of the charge. While the waste heat of the furnace is utilized to generate steam, and thus economize in fuel, no particular or serious attempt has been made to preheat the air previous to combustion and further utilize the heat that escapes. In this connection it may be stated that, from experiments made by Dr. E. D. Peters, it was found that one-quarter of the coal consumed by the reverberatory smelters performed useful work, that is, heated the charge, while three-quarters of the coal was required to heat up the walls of the furnace. Owing to the peculiar construction of reverberatory smelting furnaces there is great radiation, and ready chilling takes place when the working doors are opened for any purpose. Any heat, therefore, be it in the air for combustion or in the charge, saves a certain quantity of coal.

The hearth of a modern copper reverberatory furnace is made of quartz sand from 24 to 36 inches deep. The top layers are dried and sintered and are not corroded so long as oxides do not reach them; and in hot-matte covered hearths oxides are not likely to sink as deep as the hearth. Silica will not unite with sulphides, but will with oxides, and since there is not a blast of air passing through the matte to form oxides, no corrosion occurs except at the level of the liquid material in the furnace. The firebox is made of a size to conform to the area of the furnace, the object being to burn as much coal as possible in as short a time at possible. The Anaconda furnace, which is 102 feet long by 19 feet in width, has a firebox 7 feet long and 16 feet wide. This ratio of the hearth to the grate, 16 : 1, all silver men will agree on as being the proper one. In this reverberatory furnace about 285 tons of charge is smelted daily with 57 tons of coal; or 5 pounds of ore are smelted to every 1 pound of coal burned. When this ratio of fuel to ore is compared with blast-furnace smelting where 1 pound of fuel smelts from 8 to 9 pounds of charge, economy in reverberatory smelting seems to be wanting; however, fuel is not the only consideration, and when the details of machinery, kind of ore smelted, and the higher priced fuel are taken into the calculation, the comparative cost will, under usual circumstances, favor the reverberatory. In order that the fuel may burn freely, there must be a free draft to keep the products of combustion moving out of the furnace, and as the heat expands the hot gases enormously, the area of the grate to the area of the stack is an important ratio, which in general may be stated as follows: The smaller the area of the grate is in proportion to the area of the stack the greater will be the draft; but it must be remembered that the larger the area of the grate the more coal can be burned in a given time, and that combustion increases about in the inverse ratio of the area of the grate to the area of the chimney. A good ratio for a large reverberatory would be where the area of the grate was twice as large as the area of the stack, as this ratio would permit the combustion of from .65 to .75 pound of coal per minute on each square foot of grate area. The Anaconda furnace burns about .7 pound of coal per minute per square foot of grate area.

In modern reverberatory practice the matte is never entirely tapped from the furnace for three good reasons: (1) It protects the hearth bottom from oxidized ore; (2) it retains heat and keeps the furnace hot, thereby hastening the melting process; (3) it does away with spreading the ore by hand, as fresh ore dropped upon a bath of matte spreads over the matte without assistance.

The third reason also saves heat, and as the ore is generally heated when charged, considerable economy is reached by this method over the old style method of spreading the charge by means of tools inserted through the working doors in the sides of the furnace.

As the reverberatory process of matte production is one of melting and liquidation rather than one of reduction, the charges are not calculated, neither is flux added, but there must be conditions favorable to quick melting, and these are brought about by the use of fine ore, not lumps, composed of silicious sulphide concentrate, roasted concentrate, and flue dust. This combination will furnish a richer matte, but a more refractory slag containing more copper than the blast furnace products. Several ore charges are allowed to melt down and then the matte is tapped as the converters require it. The slag is allowed to flow off from time to time through a trough, as shown in Fig. 5, into a stream of water which granulates it, but not enough is allowed to flow away at any one time to more than lower the contents of the hearth to a proper level and make room for a fresh charge of ore.

Where 30 years ago reverberatory smelting was an intermittent and tedious operation, at the present time it is practically continuous.

Within the last few years oil has been substituted for coal at Cananea and at the Arizona smelting companies' plants with excellent results. It is said that with this fuel higher silica slags and lumps of ore up to 2½ inches in diameter are used without materially retarding the furnace. At one of the Arizona smelting companies, two oil-burning furnaces smelt from 300 to 350 tons of charge in 24 hours, producing 40 per cent. copper matte from 5 per cent. copper ore and 12 per cent. sulphur. To smelt such ore 1¼ barrels of California oil is used, costing $1.25 per barrel of 42 gallons.

In the January, 1910, Mines and Minerals, there is an article by R. L. Herrick on the use of oil in the large reverberatory furnace at Cananea. Four burners are used, as shown in Fig. 7, placed in the front end of the furnace. Details of these burners are shown in Fig. 4. The oil is atomized by steam coming from the waste-heat boilers, 1 pound of oil requiring .4 pound of steam for the purpose. In reverberatory furnace work the aim is to produce a flame that will roll the length of the furnace, and this is accomplished by the burner shown. Where this furnace treated 100 tons of flue dust and calcines per day with coal, the capacity was increased to 250 tons, with the consumption of .9 barrel oil per ton smelted.

COTTRELL FUME-CONTROLLING DEVICE

The Balaklala Copper Co. has installed the fume-controlling device invented by F. C. Cottrell, of the University of California. In this method the solid particles, which cause the damage to crops, are separated by static electric discharge. The plant will have an electrode area of 100 square feet, and is designed to handle 70,000 cubic feet of smoke per minute. The device consists of a precipitating chamber in which are placed 126 electrodes. These are strips of iron 4 feet long by ¾ inch wide, with saw teeth their entire length. Between the electrodes are placed flat plates of iron about 6 inches wide. An electrical current of 27,000 volts is delivered to the electrodes, and as the smoke circulates between the positive and negative electrodes, the solid particles are precipitated on the adjacent plates.

The experimental plant shows that 90 per cent. of the solid particles carried by the smoke are precipitated by this method. The gases from the main flues are drawn into the precipitating chamber and are driven into the main stack by two fans 186 inches in diameter, whose combined capacity is 500,000 cubic feet per minute. There will be nine permanent units in the plant, seven for constant service, and two for reserve purposes. The total cost will approximate $125,000.

AIR FROM A HYDRAULIC COMPRESSOR

Written for Mines and Minerals

Readers of Mines and Minerals will remember that the lights would not burn in the mines at Cobalt that were supplied with compressed air from the Ragged Chutes hydraulic air compressor. Messrs. F. W. McNair and G. A. Koenig were commissioned to examine the conditions that existed at the Victoria Mine, Ontonagon County, Mich. The results of their determinations were given out in a paper read before Section D of the American Association for Advancement of Science at the Minneapolis meeting, parts of which are quoted.

The fact that water in intimate contact with air not only dissolves it but takes up a greater percentage of its oxygen than of its nitrogen, has long been known. Each successive solution will render the dissolved air richer in oxygen. Since the hydraulic air compressor delivers, not the air dissolved, but what is left, it follows that the air delivered must be poorer in oxygen than normal air.

Determinations of the hydraulic air made by means of a Hempel pipette, charged with thin sticks of phosphorus, showed an oxygen content of 17.7 volumes to the 100 volumes of compressor air, whereas in 100 volumes of normal air there are about 21 volumes of oxygen. The air from the Cobalt compressor gives 17.7 volumes of oxygen to 100 of air, which agrees with the determination at Victoria. This is what may be expected from a single solution. If, out of 100 volumes of normal air, the water extracts 2.15 volumes of nitrogen and 4.47 volumes of oxygen, the ratio of solution will be that given in textbooks, and the resulting percentage of oxygen will be found as by the determination. It would at first seem doubtful that this shortage of 3.3 volumes of oxygen could cause the reported trouble with the lights.

To investigate the action of the Victoria air six candles were chosen. The candles were first lighted and observed on the surface to judge the normal rate of burning, the height and general appearance of the flame, together with the cup at the bottom of the wick. On lighting these same candles underground a marked difference in their burning was recognized. The flame was in every case lower than normal and much more blunt. The tail, partly of semiluminous and partly of sooty carbon, so characteristic of the flame in normal air, was as a rule wholly absent. The cup was only meagerly supplied with melted wax and showed a frozen appearance around the edge. The candle was also easily extinguished by a sudden sidewise movement.

Evidently the deficiency of oxygen in the compressor air is wholly responsible for the difficulty with the candles. The lower oxygen content allows only a slower combustion, heat is supplied more slowly, the temperature remains lower, the wax melts at a slower rate and is liquid over a smaller area.

Regarding the effect of this air on persons working in it, conclusive evidence is not easily obtained; however, it had no effect on the experimenters, although they purposely exerted themselves to ascertain its toxic action. It is interesting to note that this solution of air lowers what might otherwise be the efficiency of the hydraulic compressor. For instance, if all the air at Victoria mines was drawn in and delivered compressed to 114 pounds gauge, the compressor when absorbing 1,961 horsepower would show an efficiency of 82 per cent. If it is assumed, as above, that 6.6 volumes of each 100 drawn in are diverted, the efficiency cannot be above 76.6 per cent.

CORRESPONDENCE

Safety in Mines

Editor Mines and Minerals:

Sir:—The following are just a few hints, with the hope of bringing forth from others some new and better ideas.

In conversation with an old miner recently, the question of accidents and recent disasters were freely discussed, and several points were brought forth concerning the safety of coal mines, some of which may be worth while reading. While these questions have been discussed many times, it may be well to again mention some of them in order to arouse those interested in mining, and bring out some new and better ideas.

When I think of the many catastrophies of the past in coal mines, it makes me wish that I were young again to get into line and try to employ some means that would eliminate at least some of these, for in my opinion many of them, with a little foresight, and with forcible leaders, could be avoided.

From time to time we read opinions from our most able observers as to the dangers of the dust, gas, and inflammable structures, but few seem to advance any forcible ideas that are stringent enough to eliminate their dangers. Until the government officers get the experience, I am afraid these things will go on, because our present system of mine inspecting is not able to handle the question as it should be. Rigid measures, regardless of cost, should be used. Wherever safety appliances and progressive improvement are installed and tried out, you will find the strictest economy, fewer accidents and cheaper coal with better general results. Conditions locally are a large part concerning these matters. Our under-managers have a habit of traveling a beaten path and too often carelessly leave very important points to lieutenants who, from lack of experience, take everything for granted. This is another common result of lack of force. If you were to go through some of the larger mines, you would frequently hear the foreman, or underforeman, inquire of some of the employes as to the conditions of a certain point, or ask a miner about the condition of the roof of the place in which he works, the answer would invariably be that the places inquired about needed repairs and that the needed repairs would be made as soon as the miner could get time to make them. The miner will, in nearly every case, promise to take down the bad roof, or to set a prop under it in order to make it safe, "after I have loaded another car," or that "he will see to it first thing in the morning." These answers are absolutely wrong. The men in charge should have these repairs done without delay. The bad roof should have been safely propped up or taken down as soon as it was reported, and other dangers, which are apt to result in the loss of life, attended to at once. Any one refusing to act promptly in such cases, should be immediately suspended. If the putting off until tomorrow was eliminated, more than one-half of the local accidents would be avoided. You will often hear the remark, from men concerned, when an accident occurs, that it was the victim's own fault. "I told him to make his place safe." That order, telling him to make his place safe, might be all that the law required, but it would have been better if the foreman had seen to it that the order was carried out at once. All such orders should be rigidly enforced.

Yes, all mines should be so planned and the coal so removed that a sufficient pillar will be left for the walling off as soon as any portion of the mine is abandoned. Dust and fires in old workings cause more disastrous explosions than any one thing that I know of. When such places are properly walled off and the stoppings carefully looked after, there is no more trouble from them. Keep the air away from the old works and you will have no trouble with them. Also keep a good current of air playing against the old work stoppings in case of a leak and there will be no cause to worry over them. This, with keeping the mine in a damp condition, will make an extended explosion impossible. The trouble, if there be any, will be local and its spread will be very limited.

I have had several local explosions during my time, caused from a strong feeder of gas, or a door left open carelessly, but it never extended for any distance, and with no results more serious than scorching a few men. But if the mine had been dusty as a result of not wetting the workings, at the time of a local explosion, and opened old workings near by, I dread to think of the results. There is the key, give it a start and there is no telling the end.

I know it is impossible to eliminate all the dangers or explosions, as oftimes the one you place the most confidence in proves to be the most negligent and with dire results. With all these dangers in mind, why not try to figure out something that will give the man under ground more heart? Since he places all confidence in the management, it seems a duty of the men in charge to try something automatically to help him. I would like to see a system of piping tried out. A system so arranged as to escape the force of an explosion as much as possible. These pipes could be taken, or laid from the surface into the mine with branches laid in every entry with laterals and proper connections at the most convenient points, to which a hose could be attached that would reach any point of danger. In case of an explosion, could it not be arranged that an air compressor be installed at each and every mine and connected to the water mains to furnish air to large chambers, installed at different points in the mine, where imprisoned miners could get a supply of compressed air and find refuge until rescued? From this system of piping through which air could be pumped into the mine, some at least of the men could live instead of being suffocated in the air deprived of its oxygen.

Cherry and Leyden and many others have taught us lessons that we should never forget. We should try to enforce some vigorous action to better the present conditions and some measures to overcome the agonies of the afterdamp.

Ogden, Utah — A Miner

Warnings to Colliers

Editor Mines and Minerals:

Sir:—Under the title "Warnings to Colliers," there used to be issued in newspapers circulating in the Midland and Yorkshire coal field of England 45 to 40 years ago, notices signed by William Cooper, F. M. S. (Fellow of the Meteorological Society), calling the attention to coming falls of the barometer, the inception of which had been observed.

In these notices, firemen were warned to be extra vigilant in their inspections of the workings, and to exercise special care in seeing that all brattices and stoppings were tight, and in good order; and sometimes they were enjoined to particularly examine the lips of the gob, which at the time meant crawling into the gob and reaching up the faces of the breaks.

Some of these colliery managers, who were then unfortunately in charge of pits where the ventilation was chronically bad—and this was a numerous class—were liable to judge these warnings as of something special and beyond what could be observed in the pit itself.

The warning which the mine gave always anticipated those in the newspapers, sometimes by many hours.

The writer was, in the fall of 1868, newly in charge of a colliery in North Derbyshire, which gave off firedamp freely, with very bad ventilation, which could only be changed slowly. The motive column, 500 feet, was set up by a fire-basket. There were over 300 men employed underground.

We were sailing very close to the wind of disaster, and were very conscious of it, and a heavy fall of the barometer was always looked forward to with anxiety, and when it came the

addition to the area over which the gas constantly showed was carefully watched and noted.

Locked safety lamps were exclusively used and strict discipline was easily maintained, the overshadowing calamity at the Oakes colliery being still fresh in the memory of both officials and colliers.

The chief night foreman was somewhat of a wag, as well as being a very capable and cautious examiner. So, in addition to making a circumstantial report in the official book when the gas cap showed any sensible lengthening, at the close of the shift, this man would come across the fields to my house and call out from outside, "Look out for Mr. F. M. S." This would occur at 5 o'clock in the morning, and the writer would quickly make his way to the colliery. If the barometric disturbance occurred early in the night, the warning would appear in the newspaper which we would get at 9 A. M. If it occurred after say 11 o'clock, the newspaper would give it the next day; 35 hours after it had been observed already in the pit.

It is a simple conclusion that an incipient fall of the barometer will show itself very readily in the mine, such as is described above, by the expansion of the gas and air in the goaves, fully as soon as it will on any instrument at the surface, and *this* warning comes direct to the collier, whereas observations at the surface, like Mr. Cooper's, must be read, recorded, transmitted to the newspaper office, set up in type, printed, and sent out through the ordinary channels of circulation, entailing a loss of many hours.

At the above-mentioned time there was one colliery where the height of the barometer determined whether it should work or play. This was Shipley Gate colliery, Derbyshire. When the barometer fell below a certain level (which cannot now be remembered), the men were withdrawn, the pit laid idle, and the fan—a large Guibal—increased in speed.

Rope Haulage

Editor Mines and Minerals:

Sir:—We are interested in the letter of Mr. Chester Moon published on page 425 in Mines and Minerals for February, relating to the practicability of operating an endless rope haulage 1½ miles long in conjunction with a 35-degree incline plane to a tipple, and passing around a curve at the foot of the incline.

The rope in any endless-rope haulage must be run under a certain tension, and while it is practicable to run around curves on a level track, there would be an objection to extending the line up the incline plane, owing to the upward lift of the rope, which might cause trouble at the curve by the derailing of the cars, and we think therefore that it would be desirable to use an independent rope for raising the cars up the slope.

The proper sizes of ropes for the haulage and incline plane would depend on the output, and the number of cars hauled or hoisted at each trip, which information is not volunteered in Mr. Moon's letter.

We mail you with this two copies of our book on "The Application of Wire Rope to Surface and Underground Haulage," which may be of assistance in determining the best arrangement for Mr. Moon's purpose.

The Trenton Iron Co.

Steel Supports in Mines

Editor Mines and Minerals:

Sir:—Under the caption "Steel Supports in Coal Mines" in your February issue Mr. R. B. Woodworth has an excellent summary of the use of steel in place of timber for permanent mine workings. A good deal of the material is not new, but it is the most complete review of the subject that I have seen and it will prove of value.

There is one point, however, upon which Mr. Woodworth is notably silent, and that is as to the impossibility of using steel as a mine support in properties where the ore is a sulphide, undergoing oxidation in the upper levels. This condition it seems to me absolutely prohibits the use of steel supports (steel timbers sounds altogether too anomalous), and without knowing the circumstances in detail, one is strongly inclined to think that the failure of the "few adjustable sets" in one of the western copper mines of which Mr. Woodworth speaks, was caused rather by the action of the H_2SO_4 and $CuSO_4$ laden waters than by any structural defect.

That preservative coatings count for little, we have ample evidence in the case of pump columns, where various non-corrosive alloys or else wood-stave pipe have to be used, steel or iron pipe in spite of most careful coating often lasting not more than a week or two. I question very seriously whether any ordinary paint such as is described will serve the purpose; slight movements of the ground, the rubbing of men's clothing covered with grit and dirt, cars getting off the track, hitting with pick and shovel and the like, soon remove the paint in spots and once the acid mine waters begin to attack the iron they will speedily creep along behind the paint layers exactly as rust gets beneath the paint on steel structures at the surface, only much more rapidly.

This problem is a serious one and will undoubtedly be solved in time—possibly by some heat-treatment of the steel—for steel is bound to replace timber. Concrete, either plain or reinforced, is too heavy for most uses and has the serious disadvantage of giving no warning when it is taking heavy pressure. Francis A. Thomson

State College, Pullman, Wash.

Editor Mines and Minerals:

Sir:—I have duly noted Professor Thomson's letter of February 15, with the criticisms which he has to offer on my paper entitled "Steel Supports in Coal Mines." There are three points in this letter calling for consideration:

1. I use the words "roof supports" to indicate beams or channels laid on the coal resting on side walls or supported at one or both ends by wooden props. The words "gangway support" I construe to indicate the three-piece gangway set or a steel roof support with one steel leg, the whole structure in either case being a rigid one, which may be considered as a unit. The designation "steel mine timbers" I have coined to indicate the regular use of steel in mine timbering uses as contradistinguished from wooden mine timbers, or possibly as contradistinguished from concrete mine timbers. At the first blush the term may appear anomalous. It is, however, a very handy trade designation, is coming into quite extended use, and has the merit of exactly designating the particular use to which the material is put.

2. My information as to the failure of the few adjustable sets installed in one of the copper mines of the Far West is precise. I do not care to name the installation, but the reason stated in my paper is correct. The failure was not in any way due to the action of acid-laden waters.

3. I have not made any experiments in the protection of steel against waters laden with copper sulphate. So far as waters laden with free sulphuric acid or ferrous sulphate in solution, which is even worse, are concerned, I have no reason to doubt that proper protection to the steel is afforded indefinitely by the simple means stated. The Professor will find a brief notice of my experiments and conclusions in this direction in Cushman and Gardner's recent work on the "Corrosion and Preservation of Iron and Steel," to which I contributed some half a dozen pages, and he will note that my conclusions in this respect are indorsed by the editors of that work. The theorectical considerations mentioned by the Professor are not corroborated by experience in the actual use of steel mine timbers in this country and abroad. My own recommendations

in the proper preservative treatment of steel have back of them both laboratory experiments and wide experience. I have sufficient confidence in the results of advanced research into the preservation of iron and steel structures to think that even in copper mines it is possible to preserve steel mine timbers intact over any reasonable period of use without fears of any structural weakness due to the action of copper solutions. The use of steel for pump columns is by no means a parallel case.

I am unable to see in what way heat treatment of the steel can protect it, provided the chemical constituents remain unchanged. Certainly the successful introduction of steel for mine timbering purposes is based on the elimination of any factor which would in any way tend to increase its relative cost, and experience in other lines indicates that the problem of underground mine timbering is in no way different from the use of structural steel in buildings and bridges generally. In fact, the large merit of the proposition from the standpoint of the mine owner and operator is the interchangeability of steel with a material with which they are already perfectly familiar, and the consequent simplicity of its use.

R. B. Woodworth

427 Carnegie Building, Pittsburg, Pa.

ORE NOTES

After 6 months spent in development and the placing of new machinery, shipments have been renewed from the Colonel Sellers, of Leadville, which is owned by the Empire Zinc Co. It is reported that the company has taken $350,000 out of the zinc ore on the dump.

Plans for another drainage tunnel in the Cripple Creek district are under consideration. T. R. Countryman, the construction engineer of the Roosevelt tunnel, has been asked to prepare a report. The Roosevelt tunnel will add 730 feet to the workable depth of the Cripple Creek mines, and it will probably be 6 or 8 years before the drainage effected by this tunnel is completed. According to the plans now under consideration, a tunnel 500 feet deeper is to be driven. By taking plenty of time for the work, it is believed that the cost of driving the proposed tunnel can be kept within $500,000.

The Standard mine, near Silverton, B. C., is said to have run into a body of silver-lead ore 41 feet wide. In the same vicinity the Rambler-Cariboo mine ran into the largest and richest ore shoot ever found in that property on the 1,050-foot level. The ore is said to average 250 ounces silver and 75 per cent. lead. The ore shoot is about 5 feet wide and has been drifted 150 feet on level.

Patrick Stewart, manager of the Canadian Consolidated Mining and Smelting Co., has entered upon a vigorous policy of encouragement to mine owners, by reducing by 33⅓ per cent. the rates on freight and treatment to the smelter at Trail, B. C., on certain classes of ore. The camps which will benefit at once by this departure are those in the Salmon River section of Kootenai, including Ymir, Sheep Creek, and the North Fork.

Advices from Grand Forks, B. C., say that the shipments of blister copper from the Granby smelter there for the week ended February 2 were the largest in the history of the plant. The output was 440,000 pounds—45,000 pounds more than in the preceding week, and 1,000 pounds more than the best previous records. Receipts of ore from the company's mines aggregated 22,638 tons, which is just about the weekly average since January 1, when shipments were greatly increased to feed the full battery of eight furnaces. Receipts of ore from foreign mines totaled 535 tons, or 100 tons above the average.

J. L. Whitney, who has just returned to Spokane from Missoula, Mont., says that the Marsh mine is the talk of mining men in that city. United States Senator Dixon and Charles Cowell are largely interested in it.

Federal Mining and Smelting Co. has placed an order for a sorting plant of 150 tons daily capacity at the Morning mine near Mullan, Idaho, to prepare ore for shipment direct to the smelter. Much ore has been bared on the property.

Advices from Baker City, Ore., are that 2 feet of high-grade ore has been encountered in the Susan D. mine, formerly known as the White Swan. The ore was found in the new workings on a drift from the bottom of a shaft of 122 feet. It is announced from the same source that the Virtue mine, with a record of producing more than $8,000,000, has resumed operations after an enforced idleness of several years as the result of litigation.

Bunker Hill & Sullivan Mining and Concentrating Co., operating at Kellog, Idaho, brought its total disbursements to $12,456,000 by the payment of dividend No. 161, amounting to $81,750, in February. Its ore reserves are extensive and the grade of its ore much superior in its deepest levels to what it was nearer the surface. It is predicted that it can continue to pay dividends at the rate of $81,750 a month for at least 20 years.

Follow the Ore.—Many instances are recorded in mining where the ore seemed to have entirely run out, and many mines have been abandoned on this account. This is particularly noticeable in dolomitic-limestone, where the ore is found in large bodies, but it is also the case in some other rocks. If in such places a careful inspection is made of the walls there will probably be found a crevice through which the ore-bearing solutions escaped, and if this be followed there are good chances of finding another deposit. The Moose mine, Colorado, and the Ontario mine, Utah, both silver-lead producers, lost their ore, but in both cases another pocket was found by following mere cracks. Ten years ago when the Silver Ledge mine, in San Juan County, Colo., was shut down it was supposed that there was not a pound of ore left in it. At the same time, on Nos. 3 and 5 levels a stringer of ore yielded all the ore it contained. It was not until recently, when it was discovered that a horse of rhyolite from 5 to 20 feet wide separated this stringer from the main ore body, that the great deposits being opened today were struck. On No. 3 level the body of ore, consisting of gold and silver-bearing lead and zinc sulphides, disseminated through a sericite talc gangue, sometimes reaching the width of 30 to 40 feet, and contained between two good but irregular walls, supplied the mill to full capacity. The mill is closed until April or May, the management having determined to develop the ore bodies during the winter months, in order to block out reserves that would supply the mill continuously with at least 150 tons of ore per day. The ore bodies have now been opened on No. 5 level, and the deposit has every indication of continuing to great depth below this. It is intended to sink the shaft to the depth of 1,000 feet and prospect the ore bodies at the successive levels below No. 5. Two classes of concentrates were made in the mill during the past season. One a zinc concentrate running 45 per cent. zinc and 8 ounces silver; the other a 79 per cent. lead concentrate carrying 9 to 10 ounces in silver. They were produced with ordinary milling devices, crusher, rolls, Chilian mills, Richards hydraulic classifiers, and Wilfley tables. The lead product was shipped to the American Smelting and Refining plant at Durango, and the zinc product to the zinc plant at Blende.

The Moose Smelting and Refining Co. is planning to erect a new plant, of which they will build a 100-ton unit at once. This smelter will be used to smelt the ore taken from the old Moose mines near Alma, in Park County, and property immediately adjoining. The original Moose mines were first discovered by Captain Daniel Plumber in 1870 and 1871, yielding between $4,000,000 and $5,000,000. J. L. Seward, the chief engineer, has left Denver for Alma to lay out the improvements and get the mines in shape.

Tungsten Ore in Arizona.—About 12 miles south by a little east of Benson, Cochise County, Ariz., in the Whetstone Mountains, an attempt has been made to mine wolframite, the tung-

state of manganese and iron, from deposits that are thought to be unlike anything heretofore described in the literature of ore deposits. The mineral occurs in a light-colored granite that is intrusive in mica schist and limestone, being found near the contact of granite and schist and in a tongue of granite 60 or 70 feet long which runs out into the schist. Most of it is in segregations in the granite similar to hornblendic and biotitic segregations in granite at many other places. The ore appears to be an original constituent of the granite. The deposit was formerly worked and a few tons of ore were taken out and shipped. It is said that as mined and hand picked the ore averaged 10 per cent. of tungstic trioxide. No work has been done for 2 or 3 years, and the deposit is of interest mainly because of the peculiar occurrence of the mineral.

Metal Mining in New Mexico in 1910.—The Mogollon or Cooney district, in the southwest corner of Socorro County, contains several gold mines, chief of which is the Ernestine mine, which is and has been for years the heaviest producer of gold in the territory. The Socorro Mines Co.'s mill, at Mogollon, was operated throughout the year; and the Helen company and the Treasure Mining and Reduction Co. were also producers in 1910. In the Magdalena district, a lead-zinc camp, in the central-western part of Socorro County, the operations of the Ozark Smelting and Refining Co., the Tri-Bullion Smelting and Development Co., the Germany Mining Co., the Mine Development Co., and the Mistletoe Mining Co. should show an increased output. The 20-stamp mill of the Rosedale Gold Mining Co., at Rosedale, which has been operated on gold ores, was burned in September.

In Grant County there was much prospecting with churn drills and some development of copper ore bodies. The Chino Copper Co., of Santa Rita, acquired in 1909 a total area of 2,800 acres, including the Santa Rita mines, and has been prospecting for 2 years with churn drills and developing the properties by underground work, as well as making an output both in crude ore shipments and concentrates from the old Santa Rita mill. The company is building a 3,000-ton mill at Hurley, 9 miles from the mine, to treat ore from the Santa Rita mines. This mill will be similar to that of the Utah Copper Co. plant at Garfield, Utah. Other mines of the company will be worked by steam shovel and the caving system. In November, 1910, the Chino company's reserves were estimated at 30,000,000 tons, assaying 2.6 per cent. copper. In the Burro Mountain district mining and shipping was carried on by the Burro Mountain Copper Co. The Chemung Copper Co. was engaged in prospecting until October, 1910. The Mangus Development Co., which was prospecting with churn drills, stopped work temporarily in October. The mines of the Savanna Copper Co., in Burro Mountain and Pinos Altos districts, were worked under lease. In Lordsburg district the principal mines were the Bonnie, Eighty-Five, and Superior.

Colfax County placers maintained an even yield for the year. Shipments from Dona Ana County were not equal to those of 1909. Lincoln County maintained its gold output from amalgamating mills at White Oaks. Luna County produced chiefly lead, from Cooks Peak and Victoria districts.

The Oro Grande Smelting Co., at Oro Grande, was idle in 1910. Some placer gold was recovered at Oro Grande during the year. The Tularosa Copper Co., at Tularosa, completed a 100-ton mill and started shipping copper concentrates in November.

The Boston-Cerrillos Mines Co., at Los Cerrillos, Santa Fe County, which produced gold, silver, copper, lead, and zinc in 1909, was reported to have suspended work in December, 1910.

There was considerable activity in Sierra County, particularly in the Black Range district, near the towns of Chloride, Fluorine, and Kingston, and in the Las Animas district, near Hillsboro.

As a great part of New Mexico ore goes to the smelter at El Paso, Tex., the enlargement of this plant, started at the close of the year, is of interest. The Chino Copper Co. has contracted to ship its concentrates to El Paso. The Ray Consolidated Copper Co., of Arizona, will also ship to this plant.

The Director of the Mint estimates a production of gold, of \$397,974 in New Mexico in 1910, against \$252,800 in 1909 and an output of 683,111 fine ounces of silver in 1910 against 324,200 fine ounces in 1909.—*U. S. Geological Survey Report.*

Mercury Minerals From Terlingua, Tex.—The Terlingua mercury field, in Brewster County, Tex., has furnished some mercury minerals that are of unusual interest to students of mineralogy or crystallography. They are kleinite, montroydite, terlinguaite, eglestonite, and calomel. The first four were but recently discovered, and the chemical character of kleinite is still somewhat uncertain, though it is known to be a mercury-ammonium compound, the first such compound recognized in nature. Terlinguaite and eglestonite are oxychlorides of mercury; montroydite is mercuric oxide; calomel is the long familiar chloride of mercury. None of these minerals is important as an ore of mercury, the metal being obtained chiefly from cinnabar, but also in the native state.

Mining in Nevada, 1910.—In Churchill County, the Nevada Hills and Fairview Eagles were consolidated. In northern Elko County the Jarbridge district boomed. This being as yet a difficult place to prospect, not much has been done. Freight rate from Twin Falls, Idaho, \$50 per ton in summer and fall only.

In Esmeralda County the gold output was increased nearly \$2,000,000, and provided the Goldfield Consolidated had not been injured by fire the increase would probably have been greater. A steady production came from Rawhide. The Rawhide Coalition and the Rawhide Queen mines were consolidated in August, 1910. Silver-lead ore was shipped from the Lucky Boy district. The Pittsburg Silverpeak Mining and Milling Co. (120 stamps) took over the properties of the Silverpeak, Valcalda Gold Mining Co. in Silverpeak district. The United States Smelting Co. purchased the Eureka & Palisade Railroad in order to put it in commission and serve its Richmond-Eureka mines at Ruby Hill. Low-grade ore was discovered at Buckhorn, 20 miles west of Alpha on the Eureka & Palisade Railroad. In Lander County, Bannock, 14 miles southwest of Battle Mountain, attracted attention. Renewed interest was taken in the vicinity of the old Dean and Cortez camps southeast of Battle Mountain. The Austin-Manhattan Consolidated Mining Co. remodeled their mill. The Bamberger-Delamar properties, in Lincoln County, were permanently closed, and mines in Pioche district were cut off from shipments by floods carrying away part of the San Pedro, Los Angeles & Salt Lake Railroad.

The mines about Silver City and Dayton were the most active in Lyon County. In the Mason or Yerington district work was continued and interest was centered in the completion of the Nevada Copper Belt Railroad from Wabuska, on the Southern Pacific, to Yerington and Mason, and in the erection of a smelter at Wabuska.

In Nye County the large mines at Tonopah probably made an increased output, owing to greater mill capacity, in 1910. Both the deep and placer mines at Round Mountain and Manhattan, north of Tonopah, maintained steady production. At Johnnie and in the Bullfrog district, the mines and mills increased their yield of gold and silver.

The mines of the famous Comstock Lode, in Storey County, continue to make an annual production of over \$800,000 from the workings above the water level. It is reported that substantial progress was made in exploring the territory east of the larger workings. This work may be the means of opening new ore deposits and of reviving this district.

Whitepine County furnished approximately two-thirds of the tonnage of crude ore mined in Nevada. The consolidation of properties, which made it possible to mine the low-grade ores of Ely, was carried still further in 1910 by the Nevada Consolidated Copper Co. absorbing the Cumberland Ely, together with that company's interest in the railroad and smelter.

THE MINING INDUSTRY OF NICARAGUA

*Written for Mines and Minerals, by T. Lane Carter**

In the opinion of a great number of Americans the only thing that Nicaragua and the other Central American republics are good for is revolutions and fevers. Nicaragua has suffered from both these curses in the past. Both of them, however, can be removed, and will in time disappear.

Resources of the Country and Conditions To Be Encountered in Operation of Mines

Mining in Nicaragua has been hampered by malarial fevers in the swampy coast regions, although at the mines situated in the mountains few have suffered from fever. The extraordinary success of the United States Sanitary Corps in banishing malarial fevers in the Panama Canal Zone proves that the same happy results can be obtained in removing malaria from Nicaragua.

Revolutions have hurt mining in this country more than fevers; not so much by stopping work during the fighting, as by frightening away outside capital. A few months ago the worst revolution the country has ever known came to an end. Peace is restored, and the outlook for mining development work in Nicaragua is now better than ever before. Estrada, the new president, fully realizes the importance of developing the mines of his country. He is very friendly to Americans and Europeans, and will welcome them to Nicaraguan mines.

Recently an American was appointed to act as financial adviser to the new government of Nicaragua. Before long a start will be made on the construction of a railroad from Bluefields, the metropolis of the east coast of Nicaragua, to the west coast of Nicaragua. This line will be of great assistance in the development of the country.

The lack of capital is one reason why mining in Nicaragua is so backward. What has been done so far was accomplished by prospectors who with a little money made the mines pay from the "grass roots." We all know how hard it is to carry on mining without capital. It is as if a man tried to "lift himself up by his boot straps." Had a strong development company, with able technical and financial management, gone into the country a dozen years ago, the output, instead of being about $1,000,000 annually, as at present, would amount to ten times that figure.

Nicaragua has been a gold producer for several centuries, and while the Spanish adventurers did not have so much success in finding gold as in Columbia and Peru, still they found much of the precious metal in Western and Central Nicaragua. The gold is found in the hilly country about 80 to 100 miles inland, but the Spaniards never ventured past the coast swamps. Until 15 or 20 years ago the Pis Pis district, Fig. 1, which is today the most promising gold region in Eastern Nicaragua, was unknown to the white man.

During the rush to California in '49 and '50, many of the fortune seekers went there by way of Nicaragua. Some of them were so attracted by the chances of gold mining in Nicaragua that they remained. In this way several gold producers commenced work, and they have been turning out gold intermittently to this day.

So far gold is the principal mineral in Nicaragua that has claimed attention; for example, of the 500 mines and prospects about 490 are gold properties. This is in striking contrast to Honduras, the republic to the north, where silver appears to be the prevailing metal. No coal or promising copper deposits have yet been found, possibly because little search has been made for them.

Fig. 1. Map of Nicaragua

Another great obstacle in the way of the mineral development of the country has been the lack of railroads. There is not a railroad in Eastern Nicaragua, so that transportation facilities are today as in the time of Columbus. All mining machinery is carried from the coast in "pit pans" or canoes, paddled up the sinuous streams by Indians. To carry freight from Prince-pulca, the port on the Atlantic, to the mines, costs from 1.9 cents to 7 cents per pound, or $38 to $140 per ton. The lower figure is only possible to mines near the river; when freight is carried overland the expense is enormous.

For instance, in the mountains about 20 to 28 miles from the village of Tunky, there is a mine developing. To take freight on oxen or mules from Tunky to the property costs more than to bring it from New Orleans to Tunky. There are no roads, and it is therefore impossible to transport material by wagons. Through the dense tropical forests the natives cut a path with their machettes. Then the mules and oxen follow in this trail until their hoofs wear deep holes in the soil, and make a Nicaraguan highway. In the dry season this trail is bad enough, but in the wet season every time the animals take a step they sink to the belly in mud. With a barrel of flour or two sacks of beans strapped to his back, the animal has a hard time. Imagine a heavy piece of machinery, like a mortar box, or a boiler, being moved over such a road; then wonder how pieces weighing 6 and 8 tons have been transported.

Heavy loads such as mortar boxes or Huntington mills, are dragged with yokes of oxen by the use of heavy block and

* Mining Engineer, Chicago, Ill.

tackle. Progress of course is slow, but it is remarkable what can be moved in this way.

While it is possible to grow sufficient food for the miners on the soil of Nicaragua, it is only attempted at established mines. With an annual rainfall of from 300 to 125 inches, and a rich soil, the growth of vegetation in Nicaragua is rapid. One of the first things that is done at a new mine property is to clear the forest so as to plant bananas and plantains. Corn, sweet potatoes, yucca and sugar cane grow well, but on account of the ants many of the vegetables and fruits raised in the United States cannot be grown. To the mine owner in Nicaragua the production of food stuffs is most important, for it reduces his freight on imported articles.

Few countries in the world have a more liberal mining law than Nicaragua. There are no "extra lateral rights," or apex laws, but the law of vertical planes, similar to the law of Mexico, and the Transvaal, simplifies matters. The taxes on claims are probably the lowest in the world, being $2 per hectare (14,184 square yards) per year. There is no difficulty in acquiring mill sites or water-power to run the mills. Every facility is offered for the acquisition of the title. It is required that the owners keep the monuments of their claims in order, and also keep the boundary lines cleared. The mines are allowed to use for fuel or timber the wood in the surrounding forests.

The employer is required to provide for the treatment of his laborers in case of sickness or accident.

Fig. 2. Huntington Mill and Plates, Mars Mine, Pis Pis District

As regards labor, Nicaragua is far better off than some mining countries, Alaska for instance. Labor can be divided nto four classes; namely, Indian, Spaniard, American, Europeans, and Jamaicans.

The transportation of freight by canoes is practically in the hands of the Indians. For generations these natives of Nicaragua have gone about in these small boats, and it is doubtful if any race living could do this work as well. Taken away from the canoes, the Indians seem lost, and at other work are not satisfactory laborers. The wages paid the Indians vary from 40 cents to 80 cents per day, the employer supplying food and shelter.

The Spaniards or Nicaraguans are the miners of the country. Properly handled they do excellent work, being more satisfactory than the peons of Mexico. Fiêstas and "booze" account for most of the time lost by these miners. While they work fairly well on "day's pay," it is found more satisfactory to put them on contract. The wage per day for a Spaniard varies from 80 cents to $1. Miners working in adits and drives on contract can earn from $2 to $4 per day. Nearly all mining in Nicaragua is done by hand, there being no air drills. On the whole the rock is not very hard and breaks well, so that from 60 feet to 80 feet per month is advanced in a drift working double shift.

The expense of feeding the laborers varies at the different mines. Where all the food is imported, and there is a long land transportation from the river, the cost to feed a man per day will amount to $1. Under favorable conditions the cost is 55 cents. Compared with the figures of the gold mines of the Transvaal where the cost per day to feed a Kaffir is 6 cents, and a Chinaman 12 cents, one realizes what an item of cost the feeding of the laborers of the Nicaraguan mines is.

No systematic study has ever been made of the geology of Nicaragua. The engineer at once notices the absence of sedimentaries, and the vast extent of rock that he can designate "porphyry." Belts of highly crystalline limestone are found here and there. In Western Nicaragua, around the lake, near the volcanoes, the evidences of vulcanism are apparent, but in the eastern section of the country, in the Pis Pis district, the strata are not disturbed, nor are there evidences of andesite or any daloidal diabase "flows." If these "sheets" ever existed, no doubt the intense erosion of the country has carried them away.

In the Pis Pis district few dikes or large faults exist, and the outcrops of the large gold veins can be followed for miles. Most of the veins are replacements, with one wall well defined, generally the foot-wall. The veins dip from 65 degrees to 85 degrees.

The "wash" from the veins is sometimes rich in gold, and on the hillsides one frequently finds large pieces of ore which have weathered from the vein.

The evidences of intense denudations are apparent on every hand. The country rock is much effected by water action, as are the veins also. In the valleys, water level is from 50 feet to 100 feet below the surface, but on the hills not much water is encountered before the level of the valley is reached. It is probable that below the zone of oxidation will be a sudden change in the veins to sulphides.

The engineer is much surprised to find such low working costs in Nicaragua. There are cases where the cost per ton is $10 and over, but as a general rule the cost per ton milled in Nicaragua is from $2 to $3. When it is remembered that no mills in the country have a capacity of more than 100 tons per day, the reader realizes what a chance there is in this country for low working costs when the tonnage per day is raised to 300 or 500 tons. Few countries can then show lower mining costs.

The reason for low working costs in Nicaragua are that the veins are generally wide; water-power or hydroelectric power is available in most cases; and mine labor is fairly cheap and efficient. These advantages counterbalance the enormous transportation charges.

In nothing is the country more backward than in metallurgy. In some cases in the Pis Pis district the extraction of the gold is only about 33 per cent. At the Siempre Viva and Lone Star mines they have cyanide plants, and the extraction is about 70 per cent. At only one mine in the Pis Pis district is there a slime plant; namely, the Bonanza mine, where they have installed the clumsy inefficient decantation slime process. At the Bonanza the extraction is around 80 per cent., when with the average ore in the Pis Pis district the extraction should be from 85 per cent. to 90 per cent.

On account of the large quantity of alumina in the ore, the slime is very flocculent, and causes much annoyance, but judging from laboratory experiments the slime problem in Nicaragua can be solved.

After the ore passes through a crusher it is pulverized by stamps or Huntington mills. In the writer's opinion the best machine for Nicaraguan gold ores is the 5-foot Huntington mill, because so much of the ore is soft and sticky that it clogs the screens and sticks to the "shoes" of the stamps. Making the stamps heavier only augments the difficulty. With these ores fine grinding is not necessary as they are porous and the sand ideal for leaching. Crushing to a 20-mesh screen an extraction of 84 per cent. on the sand has been obtained. It will be seen, therefore, that tube mills will be required in the Pis Pis

district. Crushing in cyanide solution gave good results, and it would pay in most cases to do away with amalgamation and to crush the ores in a 25-per-cent. solution of sodium cyanide.

Often one finds very hard quartz in the vein, and if pieces of this material from 1 inch to 2 inches in size get into the Huntington mill the wear and tear on the machinery is heavy. Where the amount of this hard quartz is large the ore is first crushed in a Dodge or Blake crusher, then passed through rolls and broken to pea size. With ore of this size the Huntington mill is one of the best grinders in the world. It is not an impact crusher, but an attrition pulverizer.

The strengths of the cyanide solutions used vary from .2 to .3 per cent. It is impossible to use lime for neutralizing on account of the heavy cost of transportation; for which reason caustic soda is added on top of the sand in the tank; and spread uniformly over the charge. Ordinarily it would be added to the stock solution before it is pumped on to the sand.

The cyanide secret of high extraction of the gold in a sand tank is a close separation of the slime from the sand. In some countries, the Transvaal for instance, the presence of slime is not as detrimental as in other places. In the Pis Pis district this is an almost impalpable powder and a small percentage in the sand tanks prevents the extraction by hindering leaching. For getting rid of the slime, cone separators are used. At some mills the amount of sand caught in the tanks is 55 per cent. of the pulp from the mill, but as a rule it will be found best to catch only 50 per cent. in the tanks.

With the exception of the cyanide plant of the La Luz mine, the tanks of which are steel, the mills use wooden tanks, about 20 feet in diameter and 4 feet deep. These are imported from the United States, and must be carefully tarred to prevent the depredations of ants and to keep the wood from rotting.

The ordinary wooden zinc box is used with zinc shavings, for precipitation. Occasionally there is some trouble from copper, but this difficulty is overcome by the use of chloride of mercury. On account of the flocculent material which goes into the zinc boxes and settles on the shavings, the clean up is a very dirty one. Sulphuric acid is used in the "clean up;" but the transportation of acid in Nicaragua is not only very expensive, but very dangerous as well. There have been cases where the jolting and the heat has caused the vessels holding the acid to break, with disastrous effects on man and beast.

The cyanide gold bullion sent out of the country is rather base, not over 600 fine. For years the gold output of the mines has been entrusted to the Indians in the canoes, who carry it down the rivers to the coast ports. Strange to say, there has never yet been a loss, or a "hold up." The Indians will steal flour or sugar but they would not take the gold bullion.

The outlook for prosperity in Nicaragua was never better now that the United States is paying more attention to Central America. To develop the gold-mining industry, however, will be no easy task. There are many difficulties in the way, but the gold is there and if sufficient capital is put into the country and competent men are employed to develop the mines, Nicaragua will be known as a successful gold producer.

AMERICAN TIN MINING IN BOLIVIA

The annual report of the British legation at La Paz, on Bolivian trade, shows continued activity in tin mining, which furnishes the most important article of export. Shipments during the first 6 months of 1909 amounted to $6,767,000 (American currency). Among the operating companies the following is mentioned:

Andes Tin Co., an American concern, which has spent a great deal of money on the erection of a hydroelectric power plant. Its concentration plant is now in course of erection. Patches of very rich ore are found, and there is an abundance of water from the melting glaciers above the mines on the high peaks at an altitude of 18,000 feet. The mines themselves are at an altitude of 16,000 to 17,000 feet.

THE INTERNATIONAL CYANIDE TRUST

By Consul General Robert P. Skinner

To an inquirer who wished to procure cyanide of potassium and cyanide of sodium from outside manufacturers, I am only able to report that the one concern which at one time I had reason to believe was still independent is no longer in the market, and the trust, therefore, apparently is in complete control of the business. The formerly independent house referred to wrote quite recently: "We are not in a position to offer cyanide of potassium. We do not produce this article."

It is understood that the trust has obtained such general control of gas works waste in Germany and in other countries under long-term contracts as to render it practically impossible for competing concerns to be organized, and it is believed that the few not already in the trust who might produce cyanide of potassium are paid to refrain from doing so. Indeed, according to the published report of the Deutsche Gold und Silber-Scheideanstalt for 1909, a payment was made in the year covered of $121,201 "according to special agreement."

Some years ago, before the organization of the trust, cyanide was manufactured and was being sold with at least a fair profit for from 62 to 70 marks ($14.76 to $16.66) per 220 pounds. The price has been driven up from this level to 118 to 122 marks ($28.08 to $29.04) for cyanide of potassium and 122 to 128 marks ($29.04 to $30.46) for cyanide of sodium. Both of the materials named are indispensable in modern gold and silver reduction processes, the demand being particularly great in the United States, Mexico, and South Africa. It is believed that not a pound of either material is now shipped either from the German producing factories or from the associated concerns in other countries except under conditions dictated by the trust, which produces also many other chemical products, not all of which are controlled so absolutely as cyanide.

The published report of the Deutsche Gold und Silber-Scheideanstalt, which is both a manufacturing and holding company, states that it is the owner of the stock of the three American concerns as well as of eight other companies in Europe.

For the fiscal year ended March 31, 1909, the Deutsche Gold und Silber-Scheideanstalt paid out dividends amounting to 30 per cent., and in the succeeding year there was a distribution of 33 per cent., or $785,000. These enormous dividends were made possible after paying the "tantieme," or non-producers graft, "according to special agreement," amounting to $121,201, and a further "tantieme" to the board of supervising directors of $51,032. The report contains the statement that the American companies in which the parent concern was interested were obliged to reduce the scale of their operations, and could not show as good results as in previous years. This situation was considered to be merely temporary.

The exports from Germany of cyanide potassium and sodium, for the first 10 months of 1910, and for the full calendar years 1909 and 1908 were as follows:

Countries	1910 Tons	1909 Tons	1908 Tons
United States	1,098.3	1,349.2	1,394.8
Great Britain	117.4	147.0	148.7
Russia	199.9	140.3	217.5
South Africa	1,638.0	2,600.7	2,564.0
Japan	87.2	133.7	105.6
Dutch Indies	139.8	199.1	125.3
Mexico	1,065.6	1,118.1	19.1
Australia	110.2	216.1	77.9
All others	548.6	377.8	233.7
Total exports	5,005.0	6,282.0	4,886.6
Value	$1,548,190	$2,093,210	$1,628,150

MINING IRON UNDER THE SEA

*By H. W. Buker**

Method of Driving a Submarine Slope 7000 Feet Long At Wabana Iron Mine, Newfoundland

In Conception Bay, on the eastern coast of Newfoundland, lies Bell Island, the site of the Wabana iron mines, which during 1910 supplied 1,250,000 tons of ore to Canadian, European, and United States ports. It has now been established that the iron which outcrops on the island is only the fringe of great deposits which extend far under the bay. A submarine slope has been driven nearly 7,000 feet from high-water mark by the Nova Scotia Steel and Coal Co., and has shown that the ore improves in quality and thickness as it gets deeper. It is largely because of the proximity of these deposits to the coal fields of Cape Breton that the steel industry of Eastern Canada has grown to its present proportions, and the ore reserves which have now been proved to exist under the ocean, insure the prosperity of that industry for centuries to come. It is only 40 years since accident revealed the presence of the ore deposits, and not until 1893 was any attempt made to explore or develop them. Investigation was begun at that time by the Nova Scotia Steel and Coal Co., Ltd., which resulted in the lease of the deposit and its eventual purchase.

The north side of Bell Island contains a number of seams of red hematite iron ore, running from 50 to 55 per cent. in iron, three only of which are economically important at present. These seams or beds are interstratified with the sandstone and shales of the formation, with a common dip and strike, the former being about 8 degrees.

Early Development.—The work of the company, begun in 1895, at first was only open-cut mining, the earth covering being stripped and the ore then carried by an endless-rope tramway to a pier on the south side of the island. This pier was a block set out some distance from the shore and connected with it by a suspension bridge; a trestle work was built to it later.

FIG. 1, NEWFOUNDLAND, SHOWING LOCATION OF WABANA

At first the ore was used solely to supply the blast furnace of the Nova Scotia Steel Co., at Ferrona, but in 1899 the Dominion Iron and Steel Co. commenced operations at Wabana. This company purchased from the Scotia the lowest of the three parallel beds of ore which the latter had been operating, together with all their equipment. The Scotia company at once commenced to open up the middle, or Scotia, bed of ore in order to secure an uninterrupted supply. Twelve hundred men were kept at work that season, mining from the old property and developing the new, and when the time came for them to turn the Dominion property over, the Scotia bed was ready to produce all the ore required. Tramways had been constructed, a new pier built, and the Scotia went ahead producing ore without a break in deliveries.

The Dominion company secured the upper and lower of the three beds of ore and a block of submarine areas adjoining the shore and containing about 3 square miles. The land ore beds of the two concerns overlap, one company working in some cases directly underneath the other, but in the submarine areas each company owns all the ore in its holdings.

When building their new pier, the Scotia company took advantage of a great gulch near it to construct an immense storage pocket for ore. By very little work, this break was converted into a storage receptacle of much greater capacity than the one formerly used.

The Scotia Bed.—For 2 years the Scotia bed was "stripped," but in 1902 two slopes were begun. Work was carried on rapidly, and within a year these mines had been opened up and were being worked by the room-and-pillar method. Both slopes were sunk at a considerable height above tidewater, and one was driven out on the shore above tidewater mark, forming an adit. The slopes are carried from 8 to 10 feet in height, and 17 to 20 feet wide, in two sections, a 14-foot heading, and a side slice 6 feet wide. The sketch Fig. 3 indicates the method of drilling the holes in 8-foot ore. Another line of holes is put in when the ore is 10 feet high. The center cut holes are about 7 feet deep, and the rib holes 6 feet. All holes are bottomed with a diameter of 1⅝ inches, and 1½-inch 50-per-cent. dynamite is used for blasting.

The view of the drill at work underground, Fig. 4, and the picture of open cut mining, Fig. 2, indicate the marked vertical, or rhombohedral, cleavage of the deposit. This "blocky" ground causes trouble in drilling uppers, since the hole has a constant tendency to run out of line, requiring frequent changes in the position of the drill on the column. There is just enough moisture in the ore to make the cuttings ball up and pack behind the bit. The wet or down holes, however, are fairly easy to drill. Sullivan 3-inch differential valve piston drills are used, and 50 are now in operation. The Dominion Iron and Steel Co. employs 40 Sullivan drills, including a few 3¼-inch machines.

In the Scotia vein the drills are mounted on single screw columns without arms, but in the submarine slope and in the 14-foot bed of the Dominion company, the double screw column with arm is preferred. Tripods are used in open-cut work, and in driving raises or breakthroughs underground.

Air pressure for the drills is 80 pounds at the receivers, but at the ore faces is actually about 70 pounds, and in the submarine slope, now between 7,000 and 8,000 feet in length, the pressure falls to 60 pounds at the face.

Bonus System.—A runner of average ability puts in about 75 feet of holes per 9-hour shift. Good men have run up to 100 feet or more per shift. An interesting bonus system is employed by the Scotia company, and since it was established, in 1904, the efficiency of the drilling work has been materially increased. An account of this system was furnished *Engineering Contracting* in 1906 by Mr. A. R. Chambers, and reprinted in *Mine and Quarry* for November of that year. The following is quoted to show the results of the scheme:

"Comparing the drill sheet for October, 1904, with that for August, 1905, we see that each drill averaged 58.6 feet per day in October, 1904, as compared with 69 feet in August, 1905. This is an increase of nearly 18 per cent., but, excellent as this increase is, it is not so striking as the increase in the number of tons of ore broken down by each drill. In October, 1904, each drill averaged 26.2 tons per day; while in August, 1905, each drill averaged 44.5 tons per day—an increase of nearly 70 per cent. We note also that this remarkable increase in output was not obtained at the expense of more dynamite; for, in the 1904 sheet only .64 ton of ore was broken per pound of dynamite, as compared with 1.2 tons per pound in 1905." With reference to the decreased amount of dynamite per ton of ore, Mr. Chambers says that this has been brought about by requiring the drillers to pay more attention to placing the holes as accurately as possible—to give the dynamite the best leverage; that is, cut holes to meet within about 20 inches, and not overburdening side holes. "It is," he says, "also partly due to the fact that, whereas we used to run the drift 18 feet wide, with 12 holes, we now run it about 15 feet wide with 12 holes and side-cut to 18 feet wide with a couple of extra holes. The

*Reprinted from *Mine and Quarry.*

increased number of feet now drilled per day enables us to do this in the same time."

The following notes on the drill work in 1909 may prove of interest:

No. 1 Mine

Drill days	3,458
Total feet drilled	251,521
Average feet drilled per day per drill	72.7
Output, tons (long)	149,804
Tons per foot drilled	.5900
Tons per drill per day	43.3000
Drill repairs	$547.6600
Repairs per drill per day	.1500
Repairs per foot drilled	.0021

No. 2 Mine

Drill days	4,739
Total feet drilled	323,337
Feet drilled per day	68.20
Output	207,025.60
Tons per foot drilled	.6400
Tons per drill per day	43.6000
Drill repairs	$805.6600
Repairs per drill per day	.1700
Repairs per foot drilled	.0024

Before being sent underground, all drills are tested to determine the force of the blow, so that an efficiency rating can be assigned each machine. The testing machine is the invention of Mr. A. R. Chambers of the Scotia company. It consists of a Sullivan 3-inch drill, to the piston of which the piston of the drill under test is clamped. A system of pipes and gauges shows the relative efficiency of the new drill.

All drill steel is sharpened in a drill sharpening machine whose striking parts are made up of two Sullivan drills. This and the testing machine are located in the company's very complete machine shop, near the No. 2 mine.

Fig. 2. Open Cut Mining in the Lower Bed

The Submarine Slope—About 1905 the possibilities of developing the submarine areas began to attract the attention of the Scotia company. Further additions to its underwater holdings were secured, until it owned 35 square miles of submarine areas. At the same time the Dominion company increased its submarine holdings until it held 5 square miles. The Scotia company decided to drive a pair of slopes to the submarine areas, and, an arrangement having been entered into with the Dominion company by which the slopes were to be driven through the areas of the latter corporation, work was commenced in May, 1906. It was known that at distances of about 250 and 1,000 feet, respectively, serious faults would be encountered, so it was not considered advisable to make any expenditure for plant until these should have been passed successfully. The following description of the first 4,000 feet of this slope is abstracted from a paper presented by Messrs. R. E. and A. R. Chambers before the Canadian Mining Institute, early in 1909:

"In August the first fault was encountered. Fortunately, although this dislocation amounted to an upthrow of 29 feet with only 85 feet of strata intervening between the workings and bottom of the ocean, the volume of water encountered was trifling.

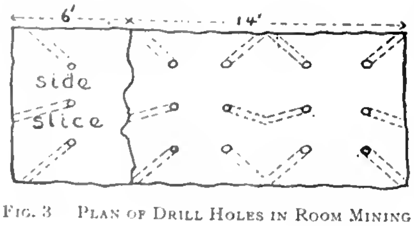

Fig. 3. Plan of Drill Holes in Room Mining

"From a study of the rock structure upon the land it was fairly evident that this upthrow would be followed by a corresponding downthrow running northeast-southwest, after driving about 800 feet approximately at right angles to the fault first encountered. It was consequently decided to continue the slope in the strata underlying the ore in order to maintain as uniform a grade as possible. The wisdom of this course was verified by encountering the ore beyond the second fault at the distance and height expected, and of greater thickness. This fault was more serious, containing 4 feet of clayey decomposed rock, and an increased flow of water. The soft ground was handled by careful spiling and the water could easily be handled by two No. 6 Cameron pumps. The quantity did not exceed 50 gallons per minute.

"Beyond this second fault no serious difficulties were encountered for a further distance of 1,800 feet, at which point a downthrow fault of 26 feet was reached. The cover had increased to a total of 293 feet, and in consequence a greater feeling of security was felt in providing against any difficulties which might occur. With the increased depth, however, a corresponding increase in firmness was found, and the clay encountered in previous faults was not met here. The slope was continued in the strata overlying the ore, but on an increased grade for a distance of 400 feet, when ore was again entered, having a normal thickness, and a normal dip of 12 per cent. The grade for the 400 feet was made 20 per cent., which by trimming will be subsequently reduced to 18 per cent. For this 400 feet the effects of the fault were noticed in the increased tenderness of the roof, necessitating timbers being placed skin to skin; and in the amount of water dripping from above. The total quantity of water was, however, in no way formidable and was easily handled.

"On entering the Scotia areas at a distance of nearly 4,000 feet from the shore the conditions were as favorable as could have been hoped, and more so in that the quantity of water handled was very small compared with what was expected.

"The advances up to December, 1910, were as follows:

	Feet
Slope commenced May 21, 1906	
Distance driven to December 31, 1906	704.60
Distance driven to December 30, 1907	1,916.10
Distance driven to December 24, 1908	3,965.00
Distance driven to December 30, 1909	5,400.40
Distance driven to December 17, 1910	6,815.62
(At a depth of 1,300 feet below the surface of the ocean)	
The month of least advance was August, 1907, in passing first fault, or	42.50
The month of greatest advance was November, 1908, or	247.81
In the 4 weeks from the 16th of November to the 14th of December, 1910, an advance was made of	270.10
In week ending January 23, 1909, an advance was made of	74.00

"This gives a record of 11¼ feet per day for a month. This gives a record of 12 feet 1 inch per day for a week. The size of excavation for this driving was 13 to 15 feet wide by 8 feet high.

"As the work proceeded it was ascertained by diamond drilling that the lower bed had increased very greatly in both thickness and richness. At the outcrop, this seam was about 11 feet thick, but it

increased gradually, and after passing the faults had more than doubled, while analysis of the ore showed that the iron content was much higher and the silicon correspondingly lower."

Method of Working.—Three 8-hour shifts are worked. When the air is cleared of smoke from the last shot, the drillers and loaders proceed to the face. The drillers and their helpers assemble the drills and columns, while the loaders throw back the ore from the face. The drills, of which there are two on this shift, are then set up 4 feet from the face, and about 20 inches from the rib or side, and each driller puts in five 12-foot center cut holes, B-1, 2, 3, 4, 5, and C-1, 2, 3, 4, 5, respectively (see Fig. 5), completing the round in about 6 hours. The holes are blown out with compressed air, when the shift is completed. After having cleared away the face for the drillers, the six loaders clear off the track, run in a trip of three cars and load up the ore thrown up the slope by the previous blast, which sometimes is 100 feet from the face. When the ore is reduced to a heap behind the drillers, one car only is used, and the loaders relieve each other, car about, three at a time. The loaders generally finish at the same time as the drillers and 40 to 50 tons are an average shift's work.

The blasters then load the holes drilled with 7 pounds of 50-per-cent. dynamite in each, tamping them securely with paper cartridges of clay prepared for the purpose. After the wires and blasting machinery are tested for strength and circuit, the round is fired. If the work has been done correctly, the center cut will be taken out as shown in the sketch, and the ore thrown well up the slope. Owing to the heavy burden on these holes they will be only about half shot out. A little high-pressure air is turned on at the face immediately after the blast, and the exhaust fans speeded up. In the course of a short while the air at the face is quite clear, and while still a little warm, work can be resumed.

FIG. 4. DRILL IN NO. 2 MINE. SHOWING ALSO THE BLOCKY NATURE OF ORE

The next shift then begins, loaders clearing face as before. The regular drillers now set their bars 4 feet back from the face and as close to the rib as possible, and drill holes A-1, 2, 3, 4, 5, and D-1, 2, 3, 4, 5, 12 feet deep. In addition to these, two spare drills are set up in the cut and drill holes E-1, 2, 3, and F-1, 2, 3, and G-1, 2, 3, H-1, 2, 3, respectively, 6 feet deep. As the extra drills do not come on the same shift each time, there are two spare drillers on each shift who, when not at this work, repair and advance ventilating pipes, swinging Sampsons, etc., and other odd jobs.

The order of blasting is now more elaborate than on the previous shift, and on the care taken in this work greatly depends the advance to be gained.

They first load and fire holes F-1, 2, 3, and G-1, 2, 3, 3 pounds to a hole. Next they fire the old bottoms of holes B-1, 2, 3, 4, 5, and C-1, 2, 3, 4, 5, with 3 to 5 pounds each, according to necessity. The third round is E-1, 2, 3, and H-1, 2, 3, 5 pounds to a hole, and finally A-1, 2, 3, 4, 5, and D-1, 2, 3, 4, 5, are fired, 5 pounds to a hole. This makes a total of about 200 pounds of 50-per-cent. dynamite to an advance of 8½ to 9 feet, according to the success of the work done.

The method of using short bars and setting up the drills on top of the ore heap was at first tried and practiced for some considerable time, but it was found that while saving a good deal of time in handling the ore, in the long run it did not pay.

The storage, thawing, and distribution of the explosives for both the mines and the submarine slope are carried on at a central station which comprises a small magazine, thawing house, with detached boiler room, and a shed for testing detonators, located at convenient distances apart.

The thawing is carried on in a small stone building, brick lined and wood faced inside, with an air space between the brick and stone, and the building is provided with a large entry for the reception and disposal of the explosive. It is heated by the ordinary hot-water system, but the radiators are closed in wooden boxes to prevent accidental contact with the explosives.

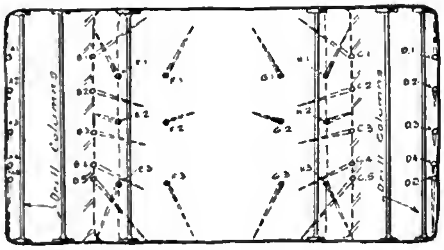
The various blasting crews, wiremen, thawers, magazine storekeeper, and detonator tester, are all under the supervision of an explosive inspector, who constantly inspects all operations connected with the use and disposal of all explosives, and who immediately reports to the underground manager any unusual occurrence, and, if possible, the cause of the same.

The Plant.—Sullivan rock drills are used in the slope. Compressed air at 80 pounds receiver pressure is supplied to the drills and pumps in both the slope and in the working mines by two cross-compound steam two-stage air compressors and one straight-line compound steam and two-stage compressor, having a total capacity of 7,200 cubic feet of free air per minute. This plant also drives small hoists underground and the fan engines.

The ventilating plant consists of one 4-foot and two 3-foot Sturtevant fans. The 4-foot fan is direct connected to a vertical air-driven fan engine, and is located near the upper part of the slopes, just at the bottom of the present workings of the

No. 2 mine, of which the slopes are a continuation. This fan is placed in the air-course, and is operated exhausting. The two 3-foot fans are placed as described below.

The intention was to sink the slope by double entry. In practice, however, it was found that the tendency was to place chief importance upon the slope farther advanced, with the result that it finally exceeded the secondary or ventilating slope by a distance of 2,900 feet. To provide for ventilating this long single slope, recourse was had to spiral riveted galvanized-iron pipe, connected with two blowers, with a suitable by-pass connection, so that they could be used either as blowers or exhausters. One of these was placed at the upper end of the pipe and the other, reinforcing it, about 1,000 feet further down. The first pipe used was 15 inches inside diameter, and was found to be too small to give entirely satisfactory results. Below the lower fan, 18-inch pipe was installed, which still continues to give a plentiful supply of air to the face of the slope. As the slope advances, new lengths of pipe are added. On account of the blasting, the pipe cannot be laid nearer than 150 feet of the face, but no inconvenience whatever is felt.



End Elevation

Dams.—To protect No. 2 mine from possible inundation, sites for mine dams were constructed at a point situated vertically below high-water mark. When approaching this point the face was narrowed to 6 feet and then gradually widened again, forming a **V**. No reduction was made in the height. The sides, top, and bottom were lined with concrete. A small pipe was placed in the roof as an outlet for air when the pressure should come on the lower side of the dam, and capacious air and water pipes were built into the floor. Timbers to fill the opening were made of 10″×10″ pine, tapering to 6″×6″ and piled at the mouth of the slope in the same position they would occupy in the dam and carefully protected from the weather.

Piping.—The air line is 8 inches in diameter as far as the workings in No. 2 mine and to the large Jeanesville pump, and 5 inches for the rest of the submarine slope. The water discharging line is 6 inches, being double from the large pump to the surface.

Testing Air Pipes.—The air pipes are periodically tested as follows: All pipe ends are carefully closed as near to the drills as possible, and a pressure gauge is connected to the section to be tested. The section is then filled from the mains, and the supply valve closed. The air in the line is then released until the gauge reads 50 pounds. The time is taken and the pressure allowed to drop by leakage until it reaches 40 pounds, when the time is again taken. The loss in cubic feet of free air will be approximately half the volume of the pipe tested. This divided by the time will give the loss per minute. As the amount of pipe in each section is not often changed this information is readily available. The conditions, with the exception of the time, will be practically constant. The pipe fitter is thus constantly familiar with the condition of his pipes. Corrections for temperature would be necessary for accurate results, but in practice are not needed.

Cars.—The cars used are of steel, of 30-cubic-feet capacity, holding from 1.7 to 1.8 tons of ore.

Tracks.—The tracks are of 28-pound rails, except near the face, where an 18-pound rail is used temporarily. The gauge is 2 feet.

Telephone System.—Telephones are installed in the slopes, connecting through a central office with all parts of the works, the office, and the houses of the manager and underground manager.

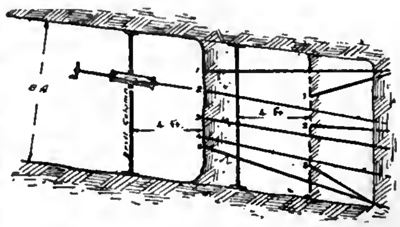
Efficient and modern electric pumps, fans, hoists, and other devices have been installed and the equipment of these mines is considered to be unsurpassed.

The writer acknowledges with thanks many courtesies and much aid in preparing this article to Mr. A. R. Chambers, manager of the Nova Scotia Steel and Coal Co., and to Mr. L. H. Johnston, manager of publicity for the company.

THE VALDEZ CREEK PLACER DISTRICT

*By Fred. H. Moffit**

Interest increased in the gold resources of the Copper and Susitna river basins and the adjacent coast region during the year 1910. Many prospectors in the vicinity of Valdez, Seward, and the head of Cook Inlet searched for lode deposits, but in the interior only placers received much attention. These interior placer districts include the Nizina River, Slate Creek, Valdez Creek, and Yentna River districts. The Valdez Creek district has attracted attention on account of the discovery of gold-bearing gravels that promise an extension of the known gold-producing area.



Side Elevation

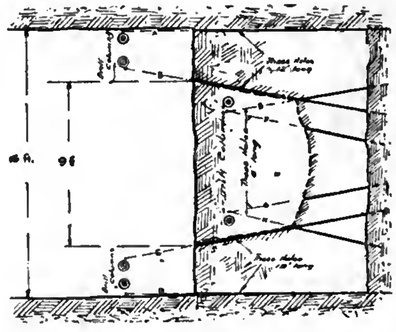


Fig. 5. Plan of Drill Holes in Submarine Slope

Valdez Creek is one of the upper tributaries of Susitna River, which flows into Cook Inlet. It is about 14 miles long and lies in the mountains flanking the Alaska Range, flowing into the Susitna from the east. Its broad valley is floored with gravels that are largely the product of glaciation. All its largest tributaries rise in the mountains south of Valdez Creek. They include Timberline Creek, White Creek, and Roosevelt Creek. Rusty Creek and Lucky Gulch are tributaries of White and Roosevelt creeks, respectively. The total gold production of the Valdez Creek district up to 1910 is approximately $260,000. The most productive part of Valdez Creek proper is in the lower 2 or 3 miles of its course and includes about 1 mile of the stream. In addition to the placers of the creek, Lucky Gulch, which is about 7 miles from the main Valdez Creek camp, produces gold, and prospecting on Rusty Creek has given good grounds for believing that that stream also will become a gold producer. During 1910 most of the mining on Valdez Creek was confined to four creek claims and to the Tammany bench claim. Mining began here in 1903, and at present the richest parts of the creek claims, so far as they are known, are nearly worked out. The Tammany bench claim, however, which is the richest property yet discovered in the region, continues to yield as it has in the past, and there is no reason to suspect that it will not do so for some time to come.

This part of Valdez Creek flows in a cañon cut in slate country rock and the overlying gravel deposits. The cañon

*Condensed from United States Geological Survey Report that will be ready for distribution about June 1.

Fig. 6. Scotia Pier and Power Plant

Fig. 7. Ore Shute to the Pier

has its greatest depth, 170 feet, in the vicinity of the so-called Monahan tunnel, which is the adit to the Tammany bench, just mentioned.

The creek claims on Valdez Creek that have received most attention are those known as Discovery claim and Nos. "1 below," "2 below," "2 above," and "3 above." No. "1 above" includes a deep cañon too narrow to permit mining. The richest of the productive claims were "Discovery claim," No. "1 below," and the lower half of No. "2 above." There is little variation in the character of the creek gravel. It ranges from 3 to 8 feet in thickness and consists of slate, schist, and granite, together with a small proportion of light colored porphyritic intrusives and dark basaltic and tuffaceous material. An important characteristic of the gravel deposits is the great proportion of large granite boulders. Such boulders are difficult to handle in the cuts and add much to the cost of mining. The gold of Valdez Creek differs considerably in appearance. Part of it is flat and smooth, but another part is rough and little worn. Much "ruby sand" and a little "black sand" is associated with it.

Fig. 8. Tramway to the Shipping Pier, Wabana Mines

AMETHYST COLORATION OF GLASS

Some time during 1910 a correspondent from Arizona sent in to us a piece of ordinary bottle glass. This glass he stated was originally white and had been colored while lying on the ground in Arizona. Old textbooks ascribed this kind of coloration to peroxidation due to manganese in the glass, although it might occur if the glass were in contact with manganese in the ground. Recent investigators have attributed the effect to the violet solar rays, that is, the radium rays.

Radium deoxidizes air and water, two of the most stable chemical combinations. J. H. Niemann has an article on "Amethyst Coloration of Crystal Glass" in the *Australian Mining Standard,* September 21, 1910. Some of his views agree with the correspondent's in Arizona, particularly that glass becomes colored in a few months in certain sections. He further states that when colored the glass darkens photo plates evenly all over; not in the speckled manner which is observed when radiographs are taken with monazite sand mixed with inactive tin grains.

The colored glass stimulates the growth of plants as powerfully as radio-active ores, owing to the decomposition of the air and the formation of probably a readily absorbed nitrogenous plant food. The glass also decomposes water. Water placed in an amethyst-colored tumbler bottom evaporates with twice the usual rapidity. Mr. Niemann has learned that glass becomes colored in the northern territory mineral bed of Australia in the Nyngan–Cobar district, New South Wales, in the Coolgardie and Kimberley districts, West Australia, and in one or two other districts which are visited regularly by frictional winds, after the said winds have traversed mineralized belts in which there is a strong probability that radioactive ores exist. To this list he may now add Arizona. By frictional wind he means winds that blow for some time in one direction, driving fine sand and radium emanation over objects on the surface of the earth.

In conclusion he states that if one has reason to suspect the presence of radio-active minerals, a sample should be taken from a few feet below the surface, since radium itself becomes liberated when it finishes its work of decomposition on surface material; also that it is only waste of time to use pitchblende as a guide when searching for the precious elements in Australia.

Sumner S. Smith, mining engineer in charge of United States mine rescue car No. 4, with headquarters at Rock Springs, Wyo., gives the following itinerary covering the movements of the car for the next few months: April will cover Scofield, Winterquarters, and Clear Creek. During May the car will visit Castle Gate, Kenilworth, and Sunnyside; and in June be at Hiawatha and Mohrland, all in Utah. The car will stop a week at each town, except at places where there is more than one mine, in which case each mine will have the benefit of a week's training. All mail intended for the car should be addressed, unless its station is known, to Rock Springs, Wyo., whence it will be forwarded

IRON ORES OF THE SOUTHWEST

*By C. Colcock Jones, M. E., Los Angeles**

Large Bodies of Easily Mined High Quality Ores—Smelting Methods With Oil and Electricity

It has long been known that in California, and more especially in Southern California, there were large and commercially valuable iron ore deposits, which, considered in connection with other known large deposits in the adjoining states of Nevada and Arizona, and in Lower California and other parts of Mexico, afforded a source of supply for one or more steel and iron plants large enough to supply local Pacific Coast demands—provided there were a solution to the fuel problem; and that the growth of population and other economic questions justified the necessary large investment of capital.

It is my purpose to show briefly in this paper that ample tonnage has been actually developed along the lines of the several railroads radiating from Los Angeles, which can be delivered at tidewater at a reasonable freight rate, that the enormous tonnages known to exist in Lower California are largely tributary to this port, and that as a center of several oil fields cheap fuel oil is assured. The stumbling block up to the present time has been the absence of a local supply of coal and coke and prohibitive price of the imported article; but the importance of the fuel question dwindles in the light of recent advances in iron smelting.

A word as to the geology of the ores in order to bear out certain assertions to be made hereafter. Geologically, the ores of the Mojave and Colorado desert regions and of Lower California belong to a well-recognized type of igneous contact ores, which are best described by quoting from recent bulletins of the United States Geological Survey—Mr. Charles K. Leith in his report on the iron ores of Southern Utah (Bulletin No. 338) says: "It early became apparent to me as it has been apparent to others, that the iron deposits of the West are prevailingly of a distinct and uniform type—an irregular replacement of limestone near the contact with igneous rock—a type fundamentally different from that of the important producing districts east of the Mississippi River and probably of different origin."

Also, from Bulletin 394 on Iron Ores of the United States, by C. W. Hayes: "This group of igneous contact ores is based exclusively upon its geological relations, and the deposits are widely distributed, though the most of them are located in the Rocky Mountains and Pacific States. The essential characteristics are steeply dipping lens-shaped bodies which closely follow the contact of an intrusive igneous mass and an intruded limestone. They occur partly within an igneous rock as dike-like veins, and partly within the limestone as replacements, but generally at the immediate contact. The limestone is always altered for a variable distance, sometimes several hundred feet from the contact. These ores appear to be due to ascending heated waters and vapors given off by the cooling igneous rocks. The ores include both magnetite and hematite."

Work on my own ore bodies and examinations of many other iron deposits of this region, confirms the essential characteristics so concisely stated in the foregoing extracts.

This particular form of ore occurrence has resulted in much greater surface exposures than are found in the Lake Superior iron regions, and in places where erosive action has been favorable, faces of ore are shown in intersecting gulches, several hundred feet in height and of as great or greater width.

Under such conditions the calculation of a definite tonnage is greatly simplified and the cost of mining, or rather in many instances simple quarrying, is reduced to its lowest terms.

Throughout the desert regions of California and Western Nevada and Arizona the intrusion of limestone beds by igneous rocks is one of the most common conditions, and there is scarcely a desert range of this nature that does not show some ledges of iron or float ore, and I venture the assertion that when industrial conditions and the demands justify it, systematic prospecting and mining will uncover as great bodies of ore with like tonnages as have been already exposed through the accidents of erosion.

For many years large deposits of iron ore were known to exist in San Bernardino and Riverside counties, but until the building of the Salt Lake Railway and the Tonopah & Tidewater Railway, all of them were too far from transportation to receive serious attention. These deposits are capable of being connected with the main lines of the Southern Pacific, the Santa Fe, the Salt Lake, and the Tonopah & Tidewater railroads by branch lines of from 1 to 50 miles in length.

Within the past few years a number of the known deposits have been patented and a large part of the tonnage is now owned or controlled by strong interests identified with transportation or manufacturing, which only await the successful outcome of certain experiments to actually engage in iron smelting.

These ore bodies have been purchased or taken up with an eye to that time when the economic conditions and growth of population will render the establishment of an iron or steel plant feasible, granting that the fuel question can be satisfactorily solved.

The various deposits lie within limits of from 150 to 300 miles of the port of Los Angeles. At a reasonable western freight rate in the inception of the business, say 5 mills per ton per mile for main line traffic, they come within the freight limits of 75 cents to $1.50 per ton. Add to that the cost of branch lines, mining costs and a fair profit, these ores can be landed at Los Angeles at not to exceed $3.50 to $4 per ton, and I have had offers for like ores from Lower California, Mexico, at this same price on dock at Los Angeles.

When it is realized that these ores run from 4 to 10 per cent. higher than the standard ore of Lake Superior in metallic content, that is from 60 to 66 per cent. iron, and carry practically no moisture to pay freight on, the low price of $3.50 to $4 per ton at San Pedro counteracts in a measure the higher price of fuel.

The two principal owners of iron ore in Southern California are: First, the Union Oil Co. through its subsidiary iron and steel manufacturing branch—the California Industrial Co.; and, second, strong interests said to be allied with the Southern Pacific Railroad, operating under the name of the Iron Chief Co.

The former of these companies has for many years been systematically acquiring iron properties in the southern part of California and in Lower California, Mexico, until its aggregate proven tonnage now amounts, I am informed, to 300,000,000 tons, about one-third of which is in California and two-thirds in Lower California, Mexico; and for several years past this company has been experimenting with fuel oil and gaseous fuel for smelting, preparing for the time when conditions shall reach a stage to render the smelting of iron profitable in Southern California.

The Eagle Mountain mines in Riverside County, 45 miles northeast of Mecca, a station on the Southern Pacific Railroad, 141 miles east of Los Angeles, contain probably the largest known deposit of iron ore in California, with the possible exception of the Minaret claims in Madera County. In 1908 and 1909 these deposits which had originally been patented by the Colorado Fuel and Iron Co. and several individuals, were acquired by the Iron Chief Mining Co. The deposit conforms to the type heretofore described, and is physically so situated as to definitely show 30,000,000 tons of proven ore capable of being cheaply mined, the average analysis of which is 64 per cent. iron, with phosphorus within the Bessemer limit.

There are a number of smaller deposits known in Riverside County on which the tonnage is a matter of conjecture, but with the establishment of an iron plant at tidewater it is just these smaller deposits held by individuals that would go far

* Read before the American Mining Congress, September, 1910.

toward developing a tonnage and opening deposits not now known, providing the usual economic policy were pursued of buying ores from various sources for a furnace mixture.

The only other deposit in California approximating in size the Eagle Mountain deposit is that of the Minarets in the high sierra of Madera County. At present this is almost inaccessible, but a branch railroad of 80 miles would make it equally available to San Francisco Bay or Southern California.

On the Santa Fe Railway, the California Industrial Co. owns large deposits 14 miles south of Newberry and 162 miles east of Los Angeles, and there are other known deposits north of Barstow.

On the Salt Lake Railroad, the Iron Chief interests have acquired the mines 1 mile north of Scott's siding, 190 miles east of Los Angeles, primarily as soft ore for mixture with the Eagle Mountain ores. A large amount of development work has been done, and an actual tonnage of 10,000,000 tons blocked out, with, conservatively estimated, three times that quantity as the total resources of the property.

Within a few miles of this deposit are other large iron outcrops.

On this same railroad 9 miles south of Kelso and 236 miles east of Los Angeles, in the Providence Mountains, I have proved up a body of 5,000,000 tons of soft hematite ore, Bessemer quality, capable of being quarried and loaded with steam shovels. This occurrence is one illustration of the large exposed outcrops so prevalent with these Pacific Coast ores. There is a quarrying face of absolutely clean ore of a 64-per-cent. grade, 350 feet wide and 250 feet high extending for a length of 800 feet.

On the Tonopah & Tidewater Railway 230 miles east of Los Angeles and 12 miles west of Silver Lake station the Colorado Fuel and Iron Co. owns one of the most extensive deposits in the state showing over 13,000,000 tons of exposed ore capable of being quarried and loaded with steam shovels.

There are tributary to all the railroads mentioned various other deposits of known merit, but enough has been said to indicate that, contrary to certain popular notions, the iron ores of Southern California are not controlled by any one set of men, and as soon as conditions are ripe and the capital can be secured a smelting industry will be established.

After carefully considering all the data based on my own observations and upon the figures supplied me relating to the two larger interests and by others, my conclusion is that, conservatively estimated, there are 200,000,000 tons of available high-grade iron ore, and double that amount of probable ore, in Southern California; and of this tonnage about three-fifths is owned and controlled by the combined Iron Chief and Union Oil interests, the other two-fifths being divided among individual holders.

In addition to this at the lowest estimate, an equal amount can be counted on from Lower California, Mexico, which will naturally seek an outlet to the northward, and the ownership of which by various individuals and corporations precludes more than any other factor the monoply of the iron ores of this district by interests adverse to their utilization, on account of cheap water transportation.

Several years ago an eminent Swedish geologist undertook to classify the world's supply of iron ore and his general deduction as to America was so pessimistic and out of keeping with the known facts that a more accurate estimate was undertaken by Mr. C. W. Hayes, of the United States Geological Survey in 1909, in which he credits the Pacific slope, combining Washington, Oregon, and California, with total available supplies of iron ore, 68,950,000 tons, and not available 23,905,000 tons. In the course of time it is to be expected that the Survey will get the actual facts and California will receive credit for something like the conservative estimate I have given.

Up to within very recently the smelting of iron ore has depended entirely on an available supply of cheap coke, the lack of which has prevented the development of the smelting industry on the Pacific Coast. But within the past year the Noble Electric Steel Co. at San Francisco has solved at its plant in Shasta County more perfectly than had previously been done in the world, the problem of making commercial pig iron with the electric furnace, and the process is a success.

In the case of this plant the close association of the iron ore bodies, the water-power for the production of electricity, and forests for the manufacture of charcoal, have, perhaps, furnished ideal conditions; but so far as Southern California is concerned the enormous recent development of fuel oil renders it practicable, when consideration is taken of the valuable by-product in the form of coke—both for use in the electric plant and the manufacture of electrodes—to effect an equalization between the cost of production of electricity by water-power with costly transmission lines, and from a compact plant producing the necessary power by the use of fuel oil either by steam or through the gas engine.

Los Angeles also has the added advantage that if from the development of large volumes of electricity in the building of the aqueduct there is any surplus for sale it can be more profitably utilized for the benefit of the community in general in such an industry as iron smelting than otherwise, providing it can be sold at a price low enough to warrant its use.

My own investigations have been along the line of a combination method, making a preliminary reduction of the ore by means of fuel oil or gaseous fuel and finishing up the operation in the electric furnace. The development of such a process promises more for the utilization of California ores than any other, for it is problematic if the coal or coke from the Washington or Alaska fields could be delivered at a sufficiently cheap price to warrant their use in smelting operations in Southern California.

As the matter now stands there is ample tonnage to justify the establishment of a plant at Los Angeles of a size in the beginning commensurate with the local demand; and for the moderate amount of solid fuel needed a high-grade coke product can be made by Professor Lowe's method from the refuse now going to waste in gas plants or that would be produced in making electricity on a large scale through gas engines as a motive power.

Pig iron is worth today on the Pacific Coast from $23 to $25 per ton, and we have the anomaly of importations of pig iron from China in competition with iron from the eastern United States.

The most ambitious project on the coast today is the plant of the Western Steel Corporation, now building on Puget Sound near Seattle. This company, in order to obtain a certain amount of pig iron from China, also contracts to use a large amount of Chinese iron ore. This, to owners of iron ore in Southern California, is conservation with a vengeance, for with any kind of interest on the part of the railroads in making extensions and furnishing dock facilities this tonnage could be shipped from Southern California on a sufficient margin of profit. The preferable plan would be, of course, to supply our own needs in pig iron first, utilizing our ores at home. There is at present a market for 100 tons of pig iron per day in this vicinity, and a trade in steel castings from electric steel could be built up to large and profitable proportions, without going into the manufacture of the heavier shapes and rails in the beginning.

Using fuel oil for the production of power, pig iron should be produced here electrically at from $16 to $18 per ton, and I am in hope that in the very near future our capitalists can be so thoroughly shown and convinced of profit in the business that the needed capital will be forthcoming.

In conclusion, a few words on the question of conservation. It has been suggested that among our other mineral products iron ore needs conserving for future generations. This I take to be the most extreme of all ideas in connection with this question. If there be any one product of the earth which, when

extracted from its ore becomes an absolute asset in the world in a finished state, it is that of iron.

The proper policy to pursue, particularly with regard to iron, as far as we Americans are concerned, is to manufacture all we can, as fast as we can, and as long as we can; supplying all our needs and the needs of the rest of the world so far as possible. This accomplishes not only the object of putting this metal in permanent form to be used and reused in commerce, with but a small fraction of a loss annually, but should such an unlooked-for thing as the exhaustion of our own iron deposits take place, we are even then in the best position in having all of the equipment for cheaply manufacturing iron ores brought from all other parts of the world.

I doubt if many men in this audience know of or remember one of the first acts that was done in good faith by the United States Government for the benefit of posterity. I speak of the time when our clipper ships and ships of the line, all wooden-bottomed vessels, were the pride of the nation and the envy of the world. In order that there might be no shortage for naval purposes, the Government set aside, removed from entry and reserved for future needs, large forests of the finest live-oak known, and stored up in this form and in the navy yards the pick of the oak lumber; in order to preserve the supremacy of our navy and merchant marine.

It seems almost laughable in view of the progress of the world, and no doubt many things now advocated in the name of conservation will seem as absurd to future generations as this live-oak conservation.

TRADE NOTICES

The Cananea Consolidated Copper Co., Cananea, Sonora, Mex., has just placed an order with the Westinghouse Electric and Mfg. Co., Pittsburg, Pa., for nine motors to be operated on three-phase, 60-cycle, 440-volt circuits. The order also included three single-phase transformers, and three three-phase transformers.

The Bureau of Steam Engineering, United States Navy, has recently decided to use the "Beard-Deputy-Marsaut" safety lamp, fitted with gas indicator, for use in the coal bunkers of their battleships and also around oil storage tanks. The American Safety Lamp and Mine Supply Co. has recently received a large order from the United States Navy for the equipment of the Atlantic and the Pacific fleets with this lamp.

Link-Belt Co. has announced a reduction in the price of original Ewart link-belt.

For many years, engineers have experienced difficulty in proper maintenance of brick settings of furnaces of all types. Ordinary fireclay has been commonly used as a bonding material, and as this fuses at a comparatively low temperature, the bond between the bricks is rapidly destroyed and cracks are opened up between the bricks, through which the gases of combustion enter, eventually weakening the brick and causing the walls to collapse. Another feature which is objectionable is that surfaces of refractory bricks become porous, the clinkers from the coals attach to them, and in removing these with tools, the bricks are broken. After several years research work on refractory cements to overcome these troubles, the H. W. Johns-Manville Co., New York. are now offering a line of cements called J-M Refractory Cements for furnace setting of various types, cupolas, lining brass furnaces, assayer's crucibles, oil burning, tilting and rotary furnaces, and for patching and facing bricks in place in the fire-zone under various conditions. These cements are rated to resist temperatures as high as 3,000° F. They also have produced a coating for walls, known as J-M Brickline Cement, which prevents clinkers from adhering and seals the pores of the brick. Realizing that the conditions under which these cements are used are variable, they have been made capable of modification to meet conditions as they come up, and the Johns-Manville Co. invite the trade to place before them any conditions that are troublesome and they will make a careful investigation and offer suggestions which will tend to overcome the difficulty.

The Scranton Acetylene Lamp Co. has discontinued its sales agency, formerly conducted by Francis H. Coffin & Co., and will hereafter conduct all departments of its fast growing business at the home office of the company, 144 Belmont Terrace, Scranton, Pa.

In the February and March advertisements of the Crawford & McCrimmon Co., through the accidental omission of a period and a capital letter, the sentence: "We protect the iron body with a hardened lead composition cast in." was run together with one following it, which should have been, "The wearing parts such as cylinder lining, rod seats, etc., the best quality of Phosphor Bronze under the sun." Of course it would have been evident to any one having experience with pumps, that the lead linings were only for the parts especially exposed to the action of acid waters, while the wearing parts were of bronze.

NEW INVENTIONS

Complete specifications and drawings for any of the following patents can be obtained from the COMMISSIONER OF PATENTS, WASHINGTON, D. C., at the following rates.

Single copies	5 cents each
Copies by subclasses	3 cents each
Copies by classes	2 cents each
An entire set of patents	1 cent each

PATENTS PERTAINING TO MINING ISSUED FEBRUARY 7 TO FEBRUARY 28, 1911, INCLUSIVE

No. 983,283. Coal and slate separator, Clarence Walter Honabach, Edwardsville, Pa.

No. 983,584. Coal elevator, Max C. Volk, Chicago, Ill.

No. 983,735. Slime filter, Elvin H. Lutz, Hay Springs, Neb., and Edward J. Sheda, Denver, Colo.

No. 983,363. Pneumatic mining machine, Martin Hardsocg, Ottumwa, Iowa.

No. 983,621. Automatic ore feeder, Charles T. Hutchinson, Oakland, Cal.

No. 983,616. Ore jig, Henry Foust, Galena, Kans.

No. 983,453. Method of treating ores by the blast-furnace process, Fredrik Adolf Kjellin, Stockholm, Sweden.

No. 984,406. Soft-coal crusher, John H. Wiestner, Philadelphia, Pa.

No. 984,498. Method of treating corrosive gaseous fumes or smoke, Clarence B. Sprague, Salt Lake City, Utah.

No. 983,881. Magnetic separator, Alvin Dings and Myron Dings, Milwaukee, Wis.

No. 984,355. Safety device for mines, Peter Darabos, Oakdale, Pa.

No. 984,222. Ore classifier, Frank G. Janney, Salt Lake City, Utah.

No. 984,090. Treatment of gold-bearing antimony ores, John Jones and Horace Sandford Bohm, Shandon Hill, Mount Morgan, Queensland, Australia.

No. 984,171. Rock drill, Daniel Shaw Waugh, Denver, Colo.

No. 984,326. Apparatus for disposal of waste rock from concentrating mills, Henry R. Wahl, Elvins, Mo.

No. 985,053. Apparatus for distilling shale and other bituminous substances, James Noad, East Ham, England.

No. 984,866. Aero ore concentrator and placer machine, Earl H. Tate, Los Angeles, Cal.

No. 984,567. Table adjustment for ore concentrators, Henry F. Jurs, Denver, Colo.

No. 984,633. Process of and apparatus for concentrating metalliferous ores, Henry E. Wood, Denver, Colo.

No. 985,266. Leveling apparatus for horizontal coke-ovens, Friedrich Aus der Mark, Sterkrade, Germany.

No. 985,660. Miner's cap and lamp, Lewis W. Cogswell, Taylorville, Ill.

No. 985,611. Machine for separating solutions from crushed ores, Edward P. Lynch, Los Angeles, Cal.

No. 985,447. Apparatus for separating precious metals from associated materials, Frederick H. Prentiss, San Francisco, Cal.

PRODUCTION OF IRON ORE IN SPAIN

*Written for Mines and Minerals, by Harry A. McBride**

Extent of the Deposits. Analyses of the Different Ores. Methods of Mining and Handling

Although Spain is a great producer of iron ore, the industry seems to be stationary, the output in 1909 being about the same as in 1899, while the other leading producers have been increasing their output by rapid strides.

Table 1 shows the production of iron ore in the principal countries in 1909 and the exports therefrom during the same year.

The failure of Spain to keep pace with the other nations in iron-ore production is due largely to the growing scarcity of ore in the Biscayan iron zone, from which more than one-third of Spain's entire production comes, and to the non-exploitation of mines in more recently discovered ore districts, owing in many cases to the want of transportation facilities.

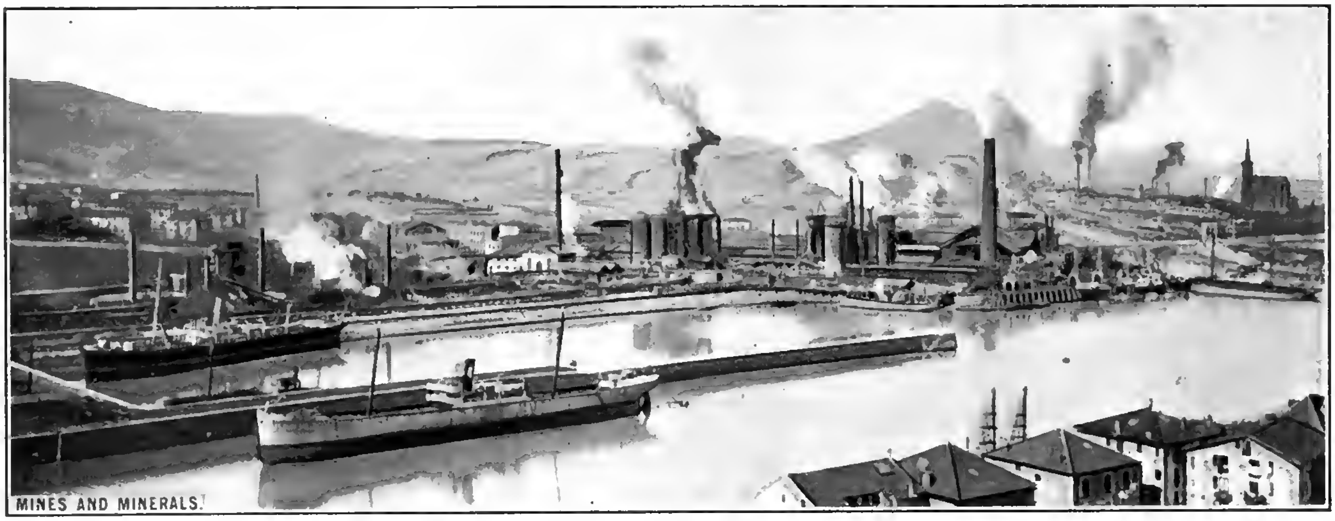

Fig. 1. Los Altos Hornos Steel Smelting Works, Bilbao, Spain

Table 1. Iron-Ore Production, 1909

Countries	Production Tons	Exports Tons
United States	53,882,415	401,567
Germany	27,500,000	4,250,000
Great Britain	15,450,000	
France	12,325,000	3,907,000
Spain	9,384,634	8,544,634
Russia	6,550,000	750,000
Sweden and Norway	4,093,725	3,387,943
Newfoundland	1,110,000	1,100,000
Total	130,295,774	22,341,144

In 1909, in the Province of Biscay, 3,871,927 tons of ore were mined, of which 3,297,414 tons were exported, 44,138 tons were consumed in home ports, and 530,375 tons by local iron and steel manufactories. The provinces of Guipuzcoa and Navarre export yearly 20,000 to 30,000 tons of ore by rail to France, through the station of Irun, and about 75,000 tons by water to England and Germany from the port of Pasajes. From the Province of Santander, via Santander and Castro-Uridales, 800,000 tons are exported annually, the greater part of which contains slightly more phosphorus than the Biscayan and Guipuzcoan ores, which are from .02 to .07 per cent. phosphoric.

Farther to the west, along the northern coast, are the ports of Rivadesella, San Esteban, Ribadeo, Vivero, and Corunna, whose exports amount annually to 400,000 tons of ore, containing from .75 to 1.50 per cent. of phosphorus. Practically all the ore from southern Spain, 3,500,000 tons, is non-phosphoric, and thus adaptable for the manufacture of Bessemer steel.

The mines most recently opened are located in the Province of Teruel, where a railroad 127 miles in length was completed in 1907 to afford transportation for ore from the mines at Ojosnegros to the port of Sagunto. The production of these mines in the year 1909 was over 400,000 tons, which has greatly increased during the present year. The extraction will, it is thought, reach 1,000,000 tons in 1911.

It is to these new mines that Spain must look if she would retain her present place as an iron-ore producer. It is hoped that recently discovered fields in the provinces of Lugo, Oviedo, Leon, Teruel, and Seville will soon be opened up and, through them, within 4 or 5 years, a new annual supply of 1,500,000 to 2,000,000 tons will be obtained; but it is also calculated that during this time the present output will diminish in about the same ratio, so that the total production of the country in 5 years' time will be very little greater than at present. Judging from the reserve supply, as yet untouched in many provinces, the Spanish output will be able to retain its present place for many years.

The following statement, based upon recently published reports of eminent engineers, shows the known deposits of iron ore in the Iberian Peninsula, in tons: Biscay, 70,000,000; Guipuzcoa, and Navarre, 10,000,000; Santander, 25,000,000; Oviedo, 55,000,000; Lugo, 65,000,000; Leon, 150,000,000; Estremadura, Segovia, etc., 10,000,000; Huelva, not counting sulphurous deposits, 10,000,000; Seville, 35,000,000; Malaga and Granada, 25,000,000; Almeria, 25,000,000; Murcia, 15,000,000; Teruel and Guadalajara, 135,000,000; Ciudad Real, 10,000,000;

*Consular Agent, Bilbao, Spain.

Catalonia, 10,000,000; Aragon, 40,000,000; Logroño, Burgos, Soria, etc., 20,000,000; deposits in Portugal, 15,000,000; total deposits in Spain, 710,000,000; deposits in Portugal, 15,000,000; grand total in the Iberian Peninsula, 725,000,000 tons.

If the present rate of export of Biscayan ore continues, it is calculated that the reserve supply will become exhausted in about 18 years, but as the exports tend to decrease the supply will probably last at least 30 years. Earnest efforts are now being made to bring the people of this province to realize that in a few years their greatest industry will have ceased to exist, and to induce the establishment of manufacturing plants and other business, in order that the now important city of Bilbao may better withstand the impending blow to its commerce.

Bilbao, the capital of Biscay, is the chief center of exportation. Over 3,000,000 tons are shipped annually from this port to England and Germany via Rotterdam. The other noteworthy ports of shipment are Santander, Seville, and Almeria. Many cargoes of ore are now shipped to Philadelphia from Sagunto. This movement will approach 200,000 tons in 1910. annually in the kingdom, by far the greater part is unsuited for smelting furnaces.

Bilbao is today the center of the smelting industry in the country. There are two large establishments under the same management located here. Their seven large furnaces at Los Altos Hornos, shown in Fig. 1, are of the latest types and the rolling mills are equipped with modern machinery. The consumption of iron ore in Spain in 1909 is estimated at 840,000 tons, of which 530,375 tons were consumed in the Bilbao works. The output of these latter works in 1909 was as follows, in tons: Pig iron, 255,627; Bessemer steel, 148,345; Siemens steel, 60,225; steel plates, etc., 149,866; tin, 8,015; coke, 215,627.

Products of these works are shipped to all parts of Europe, America, Asia, and Africa, and recently large contracts for steel rails were filled for Turkey and Finland. At present they are manufacturing material for the new Spanish battle ships, now building at Ferrol. Some of the ore for these battle ships came from the mines of Galdames, shown in Fig. 3, which are in the province of Biscay.

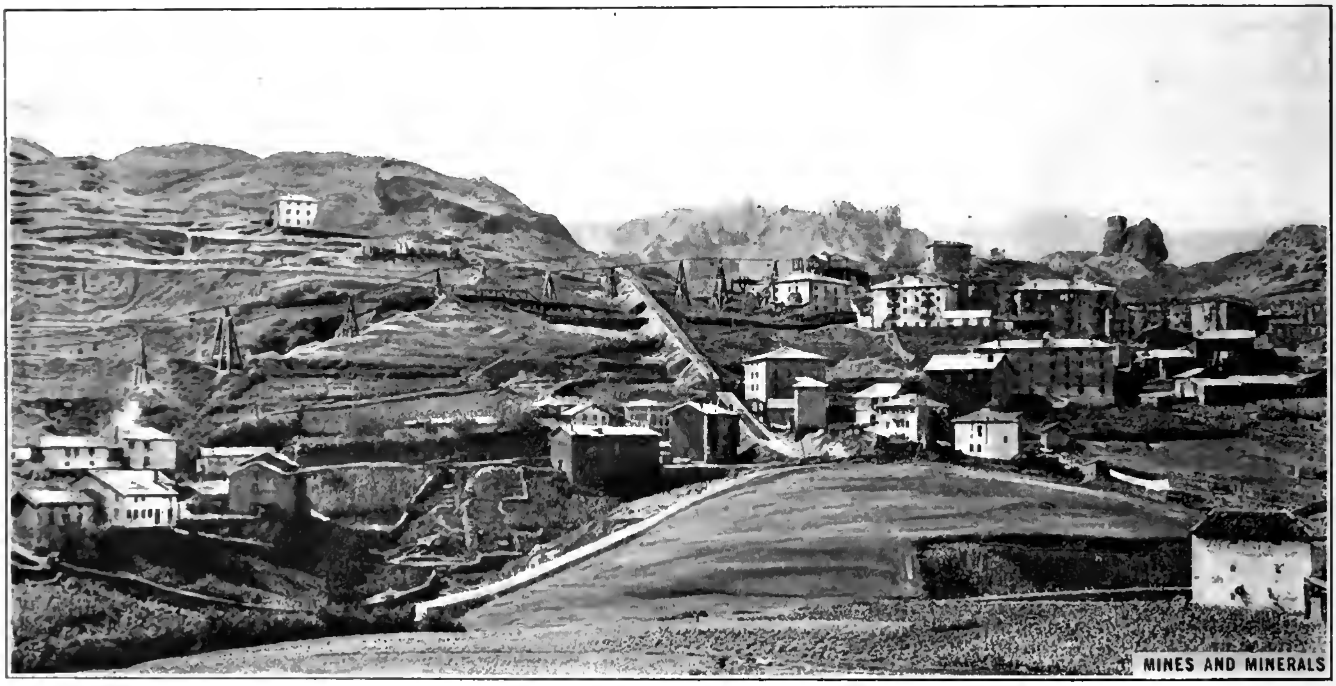

Fig. 2. Triano Mines, Near Bilbao, Spain

The average price per ton for Biscayan ores f. o. b. Bilbao, since 1906, with their average percentages of iron, is given in Table 2.

Table 2

Description and Year	Calcined Superior Grade	Calcined Second Grade	"Rubio" Superior Grade	"Rubio" Medium Grade	"Rubio" Inferior Grade
Per cent. of iron in crude ore	56	52	50	48	46
Per cent. of iron in dried ore	57	53	55	52	50
Prices:					
1906	$3.76	$3.27	$3.52	$3.15	$2.42-$2.67
1907	4.24	3.76	4.00	3.40	2.91- 3.15
1908	3.15	2.67	2.79	2.42	2.18- 2.30
1909	3.76	3.40	3.64	3.40	2.67- 3.15
1910	3.88	3.52	3.76	3.52	2.79- 3.27

In comparison with the position held as a producer and exporter of iron ore, Spain takes very low rank as a manufacturer of iron and steel products. This is largely due to the excessive cost of fuel, most of which has to be imported from England. Spanish coal from the Asturian mines is used to some extent, but of the 4,000,000 tons which is produced

Spain has several districts that are unusually rich in iron ores of high quality. Up to the present time, Bilbao has turned out the most ore; and it is estimated that the total quantity of unworked ore in the several districts amounts to 710,000,000 tons. The ores of the south of Spain are virtually untouched, although, so far as can be ascertained, they are of at least as high quality, and probably can be worked fully as cheaply, as those of the north. Between Malaga and Cartagena there are some large and easily worked deposits of high-class ores, a few of them running up to as much as 65 per cent. iron, and at least one or two of them within 20 miles of the coast. The ores of the south of Spain are well adapted for the Bessemer and open-hearth processes and it is a general characteristic of these ores that they contain considerably more manganese than those found in the north, reaching up to as much as $4\frac{1}{2}$ per cent., and averaging in some districts $3\frac{1}{2}$ to 4 per cent.; while they exist both as hematite and as magnetites, the former occasionally running more or less into spathic ore. It has been found that ores of this class are admirably adapted for mixing with other high-class ores, such as the hematites of West Cumberland and Lake Superior.

The rocks associated with the Bilbao iron ore belong to the Cretaceous formation. Blue limestone and shales are found above it, and limestone and schistose grit below it. The latter is recognized as the floor of all the deposits. The ores are classed as follows: Rubio, a brown hematite or hydrated ferric oxide ($Fe_2O_3+H_2O$), which forms the great bulk of all now produced; campanil, a red hematite or ferric oxide (Fe_2O_3), containing a somewhat less quantity of water in combination; vena dulce, also a hydrated ferric oxide (Fe_2O_3), found in veins, of a soft and porous nature, and more or less intimately mixed with both of the above kinds; spathic ore, siderite or ferrous carbonate ($FeCO_3$). The upper portion of the deposits generally consists of rubio. It is full of cavities, some of which contain earth and clay; and, consequently, it requires more careful selection than the other kinds. It has always a honey-combed appearance. Brown hematite and spathic ore are sometimes found mixed in broad bands, locally called *pedrisco*.

Rubio contains on an average about 50 per cent. metallic iron, as delivered in cargoes, and campanil a little less. Down to a certain depth in the mines the quality seems to improve. Reduced metallic yield generally arises from want of care in selection, or from wet weather at the mines, when the mineral is so coated with muddy water that it is difficult to detect impurities. In Table 3 are average analyses of the four kinds of Bilbao ore.

In examining these analyses the following points seem noteworthy. Rubio and campanil do not differ much in richness; but with rubio the associate minerals consist more largely of silica with combined water; and with campanil, of lime and carbon dioxide. Vena is richer in iron and manganese, and freer from silica than rubio and campanil. In lime and carbon dioxide it is on a par with rubio, and in freedom from combined water it is more than equal to campanil. It is, therefore, the richest and purest of the three kinds. Spathic ore has less iron, and more silica, combined water, carbon dioxide, and sulphur, than any of the others named. If calcined, however, it loses 25 per cent. of its original weight, and then becomes nearly as rich and pure as rubio.

The mining consists of the removal of ore by open-cut mining, in steps 30 to 60 feet high, and of a considerable length. In some cases a tunnel at the lowest level of the ore is driven in as far as the working face. A winze and mill holes are made down to the tunnel and through these the ore is shot and loaded into cars in the tunnel. The quarry levels are worked by this milling system down to and even below the tunnel, but in the latter case a shell of unworked mineral is retained around it, to protect the rolling stock from the results of blasting, etc. It is customary to drill deep holes into the working faces with jumpers, longer and larger ones being employed until a depth of nearly 30 feet is reached. A small charge of dynamite is then inserted and fired by a fuse to bull the hole into a chamber, after which is introduced a larger quantity of dynamite, and the explosion of this brings down a considerable quantity of ore. Quantities of from 2,000 to 3,000 tons are then brought down by a single blast. Vena ore can be worked out with a pick. After a blast the fallen masses of ore are attacked by men and boys with hammers, wedges, and bars, and broken into pieces that can be handled; impurities are here separated, and taken to the dump pile. The cost of quarrying and assorting varies according to circumstances. In a few campanil mines it is as low as 25 cents per ton; but in rubio mines, where more care is necessary, it may reach 50 cents. Of this from 5 to 10 cents per ton is for explosives and tools, and the remainder for labor.

Fig. 3. Iron Mines at Galdames, Province of Biscay, Spain

Two systems of aerial tramways are used, the Hodgson and Bleichert. In the Hodgson system an endless steel wire rope is made to travel by means of an engine fixed at the lower end. The buckets are hooked on to the rope at intervals, and move with it, passing over the pulleys as they come to them. The full buckets travel in one direction, which is generally down hill, and the empty buckets in the opposite direction on the return rope. At either terminus they are switched on to an outer rail, to be loaded or tipped, then run around on two rollers attached to the hanger, and finally entered on the return rope. At each angle for changing the direction of the route they are switched by hand. Stations must not be more than 2 miles apart and there may be several endless ropes on each set of towers, but two is the usual number. The quantity of ore conveyed in this way is about 2,000 tons per rope per week of 72 hours. Each bucket holds 400 pounds and one passes every 26 seconds, which is equivalent to 28 tons per hour. The place where the hanger grips the wire rope is furnished with

a seating of rubber, which acts as a spring, and prevents damaging the rope. The system will not do where the inclination exceeds 1 in 4, as then the hangers are liable to slip upon the rope in wet weather. To obviate this difficulty, the Bleichert system was introduced. In this the main rope is stationary,

Table 3. Average Analyses of Bilbao Iron Ores

Constituents	Rubio. Brown Hematite Per Cent.	Campanil. Red Hematite Per Cent.	Vena. Purple Red Hematite Per Cent.	Spathic. Ferrous Carbonate or Siderite Per Cent.
Ferric oxide, Fe_2O_3	80.71	78.426	85.71	
Ferrous oxide, FeO				
Manganese monoxide 77½ per cent. MnO	.92	1.303		
Manganic oxide 69½ per cent Mn_2O_3			3.50

Metallic iron, dry, Fe	56.50	54.900	60.00	
Iron in damp ore	50.29	48.870	51.60	40.00
Iron in calcined ore				53.33

the buckets traveling on it, as on a rail, and being hauled by a traction rope; when the gradient exceeds 1 in 4 the system becomes self-acting. The relative costs of construction are: Hodgson system, about $10,000 per mile, single line; Bleichert system, about $20,000 per mile; but the latter system is capable of conveying nearly one-half more than the former per annum. The working cost is about the same in each case, from 15 to 25 cents per ton per mile. In both systems a powerful brake is required to regulate the speed, and apparatus to keep the rope in uniform tension. There are a number of gravity planes which operate at a cost of from 6 to 8 cents per ton.

MINING LAWS IN SANTO DOMINGO

Written for Mines and Minerals, by C. A. Haussler

There are Americans who appear to be under the impression that the mining regulations of the Republic of Santo Domingo are similar to those of the United States. They are quite different and should be thoroughly understood by any one proposing to embark upon the mining enterprises in that island.

The Dominican Government is divided into three sections: legislative, executive, and judicial. Some Americans have supposed and assumed that special legislation is necessary whenever a new concession is granted in Santo Domingo, and that all mining rights emanate from the congress, that is, from the legislative power. This is not correct, for while congress can make the laws it is the function of the executive branch to enforce them.

Dominican laws are based upon the Code Napoleon, and under this system mining rights constitute property quite apart from land or surface rights or the actual ownership of the land. It is the duty of the President and his ministers to enforce the laws affecting all persons, the mining-concession holder as well as the land owner, in accordance with the specific mining laws that existed at the time the concession was granted. This law, therefore, is in fact a contract between the two parties aforesaid, made for them by act of congress, and the government is not a party thereto.

All existing mining concessions in Santo Domingo are those granted under the laws of 1876 and 1904, the latter having displaced the former, which in turn was abrogated this year, but not yet succeeded by a new law.

Concessions made under either of these two systems hold good respecting the laws in force at the date of the grant; thus a concession in 1876 is governed today and for all time, by the law of 1876; a concession granted in 1904 must be likewise subject to the law of that date. This of course assumes that the concessionnaire has in all cases complied with the law and paid his taxes, thus keeping the concession alive.

As might be expected of people absolutely ignorant of mining, all the Dominican mining laws, up to the present, have been defective in numerous respects, some clauses being unreasonably favorable to the concessionnaire or the land owner, while others are a serious detriment to both.

According to the law of 1876, any one could apply for a mining concession anywhere and even upon anybody's land, providing the land owner was duly notified. Within three months from the date of such notification, the landlord could claim his so-called "preference rights" which would enable him to take possession of the concession if he reemburse the concessionnaire for all expenses incurred in prospecting and developing the property. Under the law of 1876, a government tax of 2 per cent. was imposed upon the gross mineral product of the property, no other import being demanded, hence by this law the only effective forfeitive clause was that of non-production. Immense tracts of land were tied up in this way; the concessionnaire simply conducting one small productive operation, at any one spot upon the concession, no matter how large the concession may have been. It appears probable, however, that most of these old concessions have now been forfeited, since no mining whatever is going on in the island.

According to the law of 1904, the land owner in claiming his "preference rights" is entitled to 66.6 per cent. of the production of the concession, but he must assume charge of the operation and supply the concessionnaire with 33.3 per cent. of the net profit of his work. In all the concessions so far granted under this law, as far as known, none of the land owners could afford to claim their preference rights, and, consequently, the concessionnaries retain their full possession.

In case the applicant should be a share owner in the peculiar undivided properties known as "communeros," the other coowners are not entitled to any participation, no matter how small a share the concessionnaire may hold in the communero.

Under the law of 1904 there is no government tax on the product, hence the exploitation of the concession is in law no concern to the government as long as the holders pay the yearly tax of $10 per 100 tareas (64 cents per acre) when for precious metals, and $5 per 100 tareas (32 cents per acre) for concessions taken for all other metals and mineral products.

The non-payment of this tax is the only cause for forfeiture.

It is well to note in this connection that land is not taxed in any manner whatever in Santo Domingo.

A rich island like Santo Domingo, wherein there is good cause to expect considerable mineral wealth, should be provided with a code of good and just mining laws similar to those now successfully in operation in Mexico.

The Dominican Government stands in urgent need of competent advice in framing the proposed new mineral code, and such information can only be obtained from experienced mining men familiar with similar laws in different parts of the world.

The United States laws would never do in Santo Domingo, nor would the Mexican and South African (Transvaal) mining laws; unless modified to suit local conditions.

The Code Napoleon considers in a broad way that the mineral in the earth belongs to the state, while our common English law regards the owner of the land as possessing everything from the heavens above, to the depths beneath, within his surface boundaries. It is perhaps a debatable question which of these two fundamental principles is best adapted for the development of a new country.

MINES OF MISSOULA COUNTY, MONTANA

*Written for Mines and Minerals, by J. P. Rowe**

Placers on Nine-Mile and Cedar Creeks. Developments on Veins in Other Districts

Missoula County, in the western part of Montana, is bounded on the north by Sanders County, east by Powell County, south by Granite and Ravalli counties, and west by the high precipitous Bitter Root Mountains and the southeastern end of the Coeur d'Alene Mountains. The summit of these mountains is the dividing line between Idaho and Montana. Missoula County has an area of about 5,000 square miles, and the Missoula River flows northwesterly through it. The Missoula River, whose name changes to Hell Gate, Missoula, and Clarks Fork of the Columbia, depending upon its locality in the county, has many minor tributaries. The entire area of the county is made up of mountains and intermontane valleys, and in all save the valleys conditions are such that ore-bearing veins might be found. There are at present six mining districts where ores are found in various geological formations.

Mountain making in this territory was probably all accomplished from the close of the Laramie epoch to or through the Miocene, when dynamic disturbances fractured and fissured the rocks and injections of igneous material formed laccoliths, bosses, stocks, sills, batholiths, and dikes.

The intermontane valleys during the Neocene epoch contained lakes, and in several localities lake-formed beds from deposits of volcanic ash furnish excellent specimens of the Neocene flora. The rocks in the mining districts are chiefly granites and quartzites, except at the northwestern end of the country or the eastern Coeur d'Alenes, where they are largely siliceous shales.

The mining in Missoula County is confined chiefly to gold placer, gold quartz, copper, and lead-silver minerals, besides some lignite deposits found in the Neocene lake beds that are being worked in a desultory way.

It is not possible in a necessarily restricted article of this kind to give a detailed description of each mining district in Missoula County; however, this article is sufficiently broad to enable the reader to form a fairly good idea of six ore-mining districts of the county and the conditions of mining in the placer and lignite beds.

Of the several placer properties in Missoula County, the ones now being worked are the Nine-Mile placers, the Windfall placers, and the Kansas City Commercial Co.'s dredging property on Cedar Creek.

Fig. 1. Flume, Cedar Creek, Montana

The Nine-Mile Creek placers have been worked since 1874. These placers are about 12 miles from Huson, a station on both the Northern Pacific and Chicago, Milwaukee & Puget Sound Railroads. Several placers of more or less note have been worked in the past on this creek and some of them are still paying. The small creeks leading into Nine-Mile Creek furnish the best placer grounds. From a general examination of the Kennedy Creek placer it appears that this company has considerable good ground, plenty of water, and a remunerative dredging proposition.

The Windfall Placer Mining Co., operating on Windfall Creek, in the extreme western portion of Missoula County, has one of the most extensive placer deposits in the county. The Windfall company owns 300 acres of virgin placer ground that extends 2 or 3 miles along the creek, besides 80 acres of timber land. The placer, which is 12 miles from the railroad, varies in width from 100 to 500 feet and has an average depth of about 35 feet. This ground averages about 15 cents per cubic yard. The company expects to clean up nearly $100,000 during the coming season. It is estimated that the ground tested will yield over $5,000,000, and it will be worked by hydraulicking and bed-rock flumes. The company has an estimated water supply of 1,500 miners' inches during the working season of about 6 months.

Fig. 2. Dredge on Cedar Creek

The Cedar Creek placers, discovered in 1869, have been worked almost continuously since. In the early days this creek boasted a population of 10,000. The LaCasse Brothers, until recently, owned and operated the ground near the head of Cedar Creek, about 15 miles from Iron Mountain. At present, however, the only operating company on Cedar Creek is the Kansas City Commercial Co. This concern owns 570 acres of placer and operates a 100,000-cubic yard per month dredge, which, costing about $100,000, is capable of digging 55 feet below the surface. The ground is said to yield 25 cents per cubic yard in gold valued at $19.75 per ounce The dredge shown in Fig. 2 is run by electricity generated at the company's power plant 3 miles down Cedar Creek from the dredge. The amount of current generated at the switchboards of this plant is 2,300 volts, but this suffers a line loss of nearly 10 per cent. before it reaches the boat. The coal burned in the boilers of the power house is Montana subbituminous coal that costs $7 per ton laid down at the company's bunkers. The company plans to construct a ditch for 2 or 3 miles, and by using a large Pelton water wheel, which has already been installed, generate the electricity by water-power, thus saving the price of fuel and labor of stokers, which in a year is no small sum.

Ten of the 15 miles from Iron Mountain, or to the Amador mine, is traveled by means of a large gasoline speeder over the Amador Mining Co.'s old railroad track, but from this place to the camp a wagon road has been made.

The dredge is operated 10 months in the year, with three shifts of men, each working 8 hours. About 30 men are employed, with wages for the boatmen running from $3 to $5 per day.

The Clinton mining district is in the eastern portion of the county in rather a rough country, 2½ miles from the town of Clinton. Transportation facilities are the best, as the main

* Professor of Geology, University of Montana.

lines of the Northern Pacific, and the Chicago, Milwaukee & Puget Sound Railroads pass through this town. The haul from the district is all down grade and the ore can be transported to Clinton from the mines for $1 a ton.

The mountains are rather high and mining by tunnels is possible to a depth of 800 to 1,000 feet for the most of the properties. The country rock, largely hornblende granite, is the

Fig. 3. Upper Tunnel and Ore Bins, Iron Mt. Tunnel Co.

western portion of a granitic batholith, which extends east for several miles to the Copper Cliff and the Garnet mining districts of Granite County. This granitic mass was pushed through the sedimentary shales, sandstones, and limestones, and in localities especially near the contact, metamorphism has changed limestones to marbles, sandstones to quartzites, and shales to slates. The age of the batholith and later vein formation is probably Post-Laramie. There are a few dikes of porphyry, some of which cut the veins, and a few small faults are found. For the most part the veins of the Clinton mining district vary in width from 2 to 24 feet. There are several nearly parallel veins with a general northeast and southwest strike that dip about 60 degrees to the west. The ore is composed largely of the copper minerals malachite, azurite, and some native copper in the oxidized zone, chalcocite and covellite, with some bornite and chalcopyrite in the zone of secondary enrichment; and in the primary zone, chalcopyrite with some bornite. The gangue is quartz with small amounts of pyrite, siderite, and some barite as accessory minerals. Several groups of claims have by consistent development work been proven of value, the best known and best developed being the Cape Nome, the Hidden Treasure, the Aladdin, and the Triangle. Although the discovery of the district was in 1878, active development did not start until about 6 years ago.

The Cape Nome property, in Missoula, comprises three patented claims. There are two veins which extend through this property. One of them, known as the main vein, is from 2 to 8 feet wide, and the other, called the "blind lead," about 70 feet west, has a width of nearly 8 feet. This company has done considerable development work and has gone to a depth of over 500 feet. There are two main tunnels; the upper one is driven on the vein, while the lower one is a cross-cut. A double-compartment shaft was sunk 500 feet, and two levels were driven on the vein from this shaft, the 300-foot level and the 500-foot level. The former level has developed the vein nearly 700 feet, and the latter over 900 feet. The presence of an ore shoot whose exact size is unknown, as the levels have never been driven through it, has been proven. From the 300-foot level to the surface and for a distance of many feet on the vein, the ore shoot is ready for stoping. There are about 4,800 feet of tunneling, shaft sinking, etc., done on this property. The surface improvements are first class for a new property, and consist of boarding and bunk houses, shaft house, and blacksmith shop. The equipment consists of two 120-horsepower boilers, a 40-horsepower hoister, sinking and stationary pumps, besides the necessary mining tools and supplies. The locality is ideal, there being water and wood for all ordinary mining and domestic purposes.

Smelter returns from carload shipments of mine-run ore gave 5 to 6 per cent. in copper, and 7 to 12 ounces in silver.

The Hidden Treasure property consists of eight patented claims and has been developed by means of an upper and a lower tunnel. There is a vein about 20 feet wide between porphyry and granite that extends through the group and is parallel to the Cape Nome vein. It is southwest of the Cape Nome property and can be worked to a depth of 700 or 800 feet by the tunnel method. The ore is chiefly chalcopyrite, carrying a few ounces of silver. In the upper tunnel a fairly good ore shoot has been exposed, yielding 8.5 per cent. copper and 4.68 per cent. silver, when the samples were taken across the vein. The lower tunnel is now in 1,400 feet and a wide vein is exposed carrying fairly good values in copper and silver. This property has proved its worth as a copper mine and the near future should see it a large producer. There is plenty of wood and water on the property for all mining purposes.

The Aladdin group comprises three claims, and has running through it the Cape Nome vein. It lies directly northeast of the Cape Nome property. There are several shallow shafts and surface tunnels on the property besides the 1,800 feet of drifting done at the 500-foot level in 1907 and 1908 through the Cape Nome shaft by the Speculator Mining Co., of Butte, Mont. This is a promising property and will doubtless some day develop into a good mine.

The Triangle property comprises 11 claims; the two most developed being the Triangle and the Grass Widow. There are two nearly parallel veins extending through the Triangle claims, and one vein that extends through the Grass Widow. The country rock is granite, and the ore is largely in parallel stringers of chalcopyrite. The main Triangle vein has been drifted upon for a distance of 540 feet and has a maximum cover of about 400 feet. The Grass Widow has been developed through the Triangle tunnel. The veins of the two claims being parallel, a cross-cut tunnel driven from the main tunnel on the Triangle claim cuts the Grass Widow vein at a greater depth, with less expense than any other method. Besides the eleven

Fig. 4. Mill, Iron Mt. Tunnel Co.

claims, this company has a lease on the upper workings of the Hidden Treasure claim and owns 120 acres of the East Clinton town site, besides a mill site at Clinton. The mine is being rapidly developed, and the company expects to build a 100-ton concentrator at Clinton early in the spring.

There are several partly developed groups of claims in the Clinton district, but the ones mentioned are the most important, and give an idea of the ore deposits and mining conditions

of the district. It is probable that this will be an important copper-mining district in the future.

The Lo Lo mining district is not well known, as no shipping properties have been developed. There are several east-west veins on both sides of Lo Lo Creek, some gold bearing and some copper. The country rock is largely quartzite, but silicious shales are also present. While there is no igneous rock near the most promising veins, however, to the south and west the mountains are composed almost entirely of granite and gneiss.

On the south side of Lo Lo Creek, about 7 miles from the town of Lo Lo, there are true fissure veins, striking almost east and west, and dipping to the south. The vein that has been most developed assayed about $8 per ton in gold 150 feet below the surface. It is 4½ to 5 feet wide with quartz, iron pyrite, and iron oxide as the gangue minerals. Assays were made from material taken from the outcrop on one of the three claims examined and from another outcrop not in the property, but from one of the veins that passes through the property, and both assays gave about $60 per ton in gold. Not much is being done at present in this district owing to insufficient capital to do proper development work. Transportation is not to be a serious problem from any part of this district.

The Lothrop mining district is situated southwest of Lothrop, a small town of the Coeur d'Alene branch of the Northern Pacific Railroad, and on the main line of the Chicago, Milwaukee & Puget Sound Railroad. The ore deposits are of copper minerals. The district is not well known and but two properties are at present being worked. The country is part of a great anticline of quartzites and jasper slates. There are several dikes of porphry on both sides of the best deposits, and the country is quite badly faulted. The deposits in the Lothrop district for the most part are bedded, generally quite wide—from 10 to 60 feet. The ore is largely chalcopyrite in stringers that branch in every direction within the mineralized zone. The bed appears to have been fractured and the fissures formed channels for the waters carrying the ore in solution to circulate. There are, in places, small openings filled with quartz druses, but generally the fractures are filled with either chalcopyrite or quartz. Near the town of Lothrop a small vein about 2 feet thick cuts the country rock. It contains considerable barite, besides the quartz gangue, and yields a small amount of gold.

Some of the thin seams in the impregnated zone of stratified rock yield more than 10 per cent. copper, and are identical with the Snowstorm copper ore of Idaho. Beautiful specimens of chalcopyrite in quartzite are sometimes found; however, the best of these strata are but from 1 to 2 inches thick and are surrounded by barren or very lean strata. The impregnated strata, north of the West Fork or Petty Creek, dip north at an angle of from 10 to 45 degrees; south of the West Fork the veins dip in a southerly direction. Most of the properties of this district could be worked for several hundred feet by tunnels. At one place on the Hailstorm property a depth of 2,000 feet from the outcrop could be gotten. There is plenty of wood and water for all mining and milling purposes.

There are many properties around Lothrop that are being gradually developed, but the Hailstorm and Coppersmith properties have taken the lead. The district has never been a shipping locality but several of the properties seem to warrant thorough development.

Before describing the Iron Mountain and Carter districts it will be interesting to know that on the south and west sides of the railroad which follows the Missoula River to St. Regis, and then up the St. Regis River, the mining properties other than gold are copper, and on the opposite side the deposits other than gold are primarily lead. This condition begins in the neighborhood of Lothrop and continues to the Amador copper property, near Iron Mountain, and to the north and west it prevails in the Monitor and Bullion mines. Opposite the railroad, across the river, near Iron Mountain, is the Iron Mountain lead-silver mine; the Mountain Gem mining property; the Glen Metals; O. R. & N.; the lead-silver properties at Carter; and still farther northwest on the lead-silver side of the river is the Saltese district with the Tarbox, Ben Hur, Last Chance, Bryan, and other lead-silver properties. This country has not been studied sufficiently to even attempt an explanation of the occurrence. It is true, however, that the lead-silver deposits are found largely in the eastern portion of the Coeur d'Alene Mountains, and the copper deposits are found largely in the Bitter Root Mountains.

The Iron Mountain and Carter districts have been worked for some time, and a considerable amount of pay ore has been taken from the deposits in these localities.

The rocks probably belong to the pre-Cambrian period and are largely silicious slates. The bedding planes of the slates have a southerly dip and strike northwest and southeast. The veins are found generally following the dip and strike of the bedding planes of the country rock, and appear to have been formed in crushed or faulted country rock. There are several parallel veins that strike across the country in these districts and their continuity for several miles to the Saltese district, seems certain. The writer visited several of the mining properties in these districts and traced the veins on their strike for several miles. The width of the zone of vein formation is from ½ to 1½ miles, and the length is 30 miles. The ore for the most part is argentiferous galena, with varying amounts of zinc. The mines at present in operation, beginning with the Iron Mountain Tunnel Co., near Superior, and continuing west, are the Mountain Gem, the Glen Metals, the King and Queen, the O. R. & N., all containing silver-lead veins; and the Carter Mining and Milling Co.'s gold property. The Iron Mountain Tunnel Co., has been rather a large producer and is now mining and concentrating about 100 tons per day.

The Iron Mountain Tunnel Co.'s property, shown in Fig. 3, is located 3 miles from the Chicago, Milwaukee & Puget Sound Railroad, and 4 miles from the Northern Pacific Railroad. A good wagon road, all down grade, connects the mine and mill with the railroads. This mine has been developed by means of several tunnels and in the 80's some very rich lead carbonates were taken out, running as high as 600 ounces per ton in silver. At present the company is operating the mine through the new 5,600-foot tunnel and taking out the ore below the tunnel level, which is 1,600 feet below the surface. The only ore shoot that has been so far worked is 500 feet wide, and it has been stoped to the 1,750-foot level. The vein at the 1,850-foot level is 22 feet wide, with bunches and kidneys of ore throughout. There is at present a stope 100 feet high the entire width of the ore shoot. The three-compartment shaft is down 250 feet below the tunnel level. The ore shipped last June gave the following smelter returns: Lead, 23.2 per cent.; zinc, 12.5 per cent.; silver, 43.5 ounces per ton.

The company now has a modern 100-ton concentrating mill, shown in Fig. 4, and only concentrates are now shipped to the smelter.

If this property is representative it promises well for the future of the district.

There has been considerable ore shipped from the active development work now in progress on the Glen Metals, O. R. & N., King and Queen, and other properties in the neighborhood of Carter.

The veins of the Saltese district are undoubtedly a continuation of those occurring at the Iron Mountain mine and those at Carter. The chief difference between the veins of the Carter and Saltese districts is that the latter carry a large amount of arsenopyrite and antimony, intimately associated with the galena. The amount of zinc present in the Saltese veins is smaller than at the districts farther east.

In the Saltese district the vein extends with a general strike northwest and southeast, and a southerly dip through the chief

properties. The outcrop and tunnels show that the deposit continues through the Tarbox, Ben Hur, Last Chance, and Bryan properties, all of which have been worked for carbonate ores. There are other lead-silver properties in this district, but at the present time none are shipping ore.

The copper properties at the town of Saltese could probably be said to belong to this district. The principal copper mine, named the Monitor, shipped several thousand dollars worth of ore, and until last summer's forest fires, its future looked bright. The Monitor has a shaft 700 feet deep with several levels and many hundred feet of drifts. The surface equipment, consisting of shaft house, air compressor, engines and hoisting machinery, several bunk and boarding houses, and 5,000 cords of wood, were completely destroyed by the great forest fires that swept through this section of Montana in 1910. Other copper properties that have been more or less developed are the Copper Dome mine, the Optimo, the Keystone, the Bald Mountain, the Jumbo, and the Boston-Colby. None of these, however, except the Monitor have been commercial producers.

The other mining interests of Missoula County consist of lignite deposits that are quite thick in some localities and cover large areas. They were formed during the Neocene epoch and are found in almost every intermountain valley of western Montana or in the old Neocene lake beds. The deposits best known are those near Missoula, those near De Smet, and those up Nine-Mile Creek. Part of the deposits near Missoula are owned by the Hell Gate Coal Co., and the Standard Lime and Brick Co., both of Missoula. The former company has been operating for some time, and sells the fuel to the people of the city at from $4 to $5 per ton delivered. The seam of the Hell Gate Coal Co. is about 7 feet thick and intercalated somewhat with bone, dips 15 degrees or 20 degrees to the north, and has a general easterly and westerly strike. According to drill holes reported to have been made several years ago, a section through the Missoula coal beds gave 52 feet of clean lignite in going 290 feet below the surface. One seam is reported to have measured between 17 and 20 feet thick. The Missoula lignite gives the following proximate analysis: Moisture, 9.31 per cent.; volatile and combustible, 41.17 per cent.; fixed carbon, 39.60 per cent.; ash, 9.92 per cent. This analysis was made from a selected piece and does not represent the amount of ash that would be found in the run-of-mine product. The fuel ratio is .96 and the caloric value is about 7,500 British thermal units, or 4,167 calories. This lignite makes a fairly good domestic fuel, but slacks too badly on being exposed to the air to be of value as a shipping fuel. It is a good quality of lignite for making producer gas, and recent experiments also show it to produce an illuminating gas.

ALUMINUM BRONZE

Aluminum alloys with copper in all proportions and produces homogeneous mixtures. When the aluminum goes beyond 10 per cent. the bronze gets brittle, and a 12-per-cent. mixture is hard enough for hard dies. For sand casting the 10-per-cent alloy is generally used, as it is hard and tough and has the properties of a strong metal. The great difficulty in casting aluminum-bronze is its oxidation when melted. It must be poured without agitation, to avoid dross. Dross formed in melting may be skimmed off, but that which is formed while pouring enters the casting. Another difficulty is the shrinkage. By the use of sufficiently large risers, and the avoidance of sharp corners in the casting, and an ample gate, this shrinkage may be overcome. The toughness of aluminum bronze is greater than that of any metal except steel. It works hot better than copper, as it is softer at a red heat and it is not black-short like copper and zinc alloys.—*Brass World.*

GENERAL ORE MINING NOTES

F. Augustus' Forty-Seven Varieties Luck.—It is a newspaper report that F. A. Heinze, ex-copper magnate, has procured gold properties from which $25,000,000 is to be gleaned this coming year. These properties are adjoining the Dome mines in the Porcupine gold fields, Ontario, Can. A number of Nome, Alaska, men are said to be in on the ground floor in the new diggings, and the following is what one says: "One prospector has stripped the vein for a distance of 50 feet and polished it in places, so that gold is visible all along. His trench is 3 feet deep and he asks $200,000 cash for it as it lies. A party of Alaskans offered the owner of this claim $5,000 a shot for all ore that could be blown out with two sticks of dynamite, but was refused. The field is situated 155 miles from Cobalt. The Toronto & Northern Railroad has already completed its construction for 100 miles, and 55 stage coaches are carrying passengers between the end of the railroad and the new Eldorado." According to reports they play "try your luck" as follows: Instead of three shots for a nickel and every time you hit the baby you get a cigar, one pays $5,000 a shot and gets all the ore the shot lifts. The report gives no information as to who originated the game, though it states the Nome men are glad to have Heinze in the new camp with them.

New American Tunnel Record.—Unless something turns up to beat it, which seems improbable, a new American tunnel-driving record has been established at the Laramie-Poudre irrigation tunnel by the force under Contractor James A. McIlwee. During the month of January, the east heading, using water Leyner drills, was advanced a total of 609 feet through solid granite, the progress for the last 4 days of the month averaging 28 feet each. This exceeds any record made by the Los Angeles aqueduct and has been beaten only by the Simplon tunnel.

First "Process" of 1911.—To Dr. O. B. Dawson, of El Paso, Tex., belongs the honor of "inventing" the first process devised this year. It is so extremely simple that it is to be wondered that it has not been "discovered" before. After crushing, some 5 or 6 tons of the ore are charged without fluxes into a rotary furnace and heated by oil or gas or any old kind of fuel. The furnace is then "closed against the air" and 20 pounds of sulphur per ton of ore are added. After rotating for 20 minutes, the product, which is in the form of fine metallic shot, is discharged into a water "laundry (sic)." "All the mineral in the ore has been reduced to metal and nothing has been fused. The charge is ground more finely and passed onto a concentrating table," where all the metals are presumably caught. Among the many advantages claimed for this ingenious process are that "minerals may be reduced to metals at a cost of about $1 to $1.20 per ton," that even this cost will be more than made up because "there can be no loss in sliming as all mineral is reduced to metal," and no high temperatures will be required "as no fusion of the rock takes place," and consequently the heat necessary is only that required to reduce the mineral to metal, "which is low by reason of the exclusion of the air." Thanks to Doctor Dawson, America has come into her own and the metallurgists of the Fatherland had better look to their laurels. This reads like another Thermos-bottle furnace.

Closing of the Tombstone Consolidated.—The attempt on the part of the Development Co. of America to unwater the Consolidated mines at Tombstone, Ariz., has been abandoned permanently on account of the excessive cost of the project. This will prove a setback for the camp, the loss of a pay roll estimated to have been as high as $2,000 a day being a serious matter.

Missouri Zinc Area Widening.—During the year 1910 two new zinc-ore camps in the Joplin district were put on a paying basis; namely, the North Fork camp, at Neck City, and the Thom's Station camp, north of Joplin. The ore at Neck City

is of high grade and is in soft ground, while at Thom's Station the ore is partly free and partly disseminated.

Zinc Smelting Companies Mining Ores.—Following the policy pursued by the American Zinc Lead Smelting Co., the Granby Mining and Smelting Co., the American Metal Co., through its subsidiary the St. Paul Mining Co., and the Empire Zinc Co., a subsidiary of the New Jersey Zinc Co., began the work of prospecting and mining on their own account in 1910. This makes four of the largest companies smelting zinc ore to enter the Joplin field for the production of part of their ore supply.

Leadville Zinc Ore.—An adjustment satisfactory to the shippers has been reached at Leadville by the buyers and producers of zinc ore. The decision of the smelters to make some changes in their schedules that would reduce the profit, especially on oxidized zinc ore, was followed by a temporary suspension of work by a number of the larger producers. Now, however, the smelters have agreed to stick to the old rates, and work has been resumed with a prospect of an early increase in production.

Portland Gold Mining Co. Meeting.—The annual meeting of the stockholders of the Portland Gold Mining Co. was held at Cheyenne, Wyo., in February. The most interesting feature in the year's work was the opening of the new Portland mill that treats about 350 tons daily, and the beginning of drainage from the company's mine through the Roosevelt tunnel. The treasurer's report shows that during the year just closed 67,515.20 net tons of ore of a value of $1,241,168.30 were mined. Receipts from all sources were $2,345,210.06, out of which expenses of $1,970,360.08, and dividends of $240,000 were paid. Including ore on hand, cash in bank, etc., the total assets at the close of business were $5,402,898.48.

Cost of Mining in Cripple Creek, Colo.—A comparative statement of the cost of mining operations, contained in the annual report of the Elkton Consolidated Mining and Milling Co., of Cripple Creek, Colo., gives the cost of breaking ore (labor only) in the properties of the company on Raven Hill, at 56.8 cents per mine car, and 81 cents per ton, while the cost of breaking waste rock is 92½ cents, or $1.32 per ton. The total cost of ore shipped (including underground labor and power) was $2.44 per ton. The average wages per shift of the entire mine, including the salaries of manager, superintendent, and office force, was $3.70. The Elkton company has paid $2,704,460.47, exclusive of the dividend of $37,500 paid February 25. The dividend number was 101.

Dead and Don't Know It.—The Las Vegas *Age*, Nevada, says: "James Patterson, shot and reported killed by the half-crazy Indian Queho, is much incensed over his death, and that Patterson is oiling up his old musket preparatory to going on a hunt for the man who killed him. Patterson says such reports are damaging to the mining interests of the Southwest, both on the Arizona and Nevada sides of the Colorado River."

Calumet & Hecla Consolidation.—The opposition to the consolidation of the Calumet & Hecla subsidary companies must have been disappointed, as all the companies voted for the merger. The consolidated corporation is to be known as the Calumet & Hecla Mining Co., $10,000,000 capital stock, par value of the share $25. The valuation of the several properties entering into the consolidation is agreed to as follows:

Calumet & Hecla	$4,270,850
Seneca Mining Co.	150,000
Ahmeek	1,000,000
Allouez	425,000
Centennial Copper	125,000
Laurium	100,000
Osceola Consolidated	1,201,875
Tamarack	330,000
La Salle	151,475
Superior	450,000
Total	$8,214,200

The property and assets of the several companies are taken in full payment of 328,568 shares of stock.

American-Mexican El Tigre Mine.—W. L. Rynerson, who is working some of the El Tigre, an American property in Sonora, Mex., says the 250 insurrectos under Colonel Blanco, who captured the camp, were well behaved and did not molest any American person or thing. They purchased merchandise from the El Tigre Mining Co.'s store. The Mexicans, however, had to help the cause without delay or there was confiscation.

Drainage Law for Colorado.—Among the bills presented to the Colorado Legislature, is one of interest to the metal-mining industry of the state. This bill authorizes the creation of drainage districts in the various mining camps similar to public-improvement districts in the various cities. The funds needed for driving a drainage tunnel will be raised by a special levy on all mining properties to be benefited, and what remains after collection by the regular politicians will be paid into the hands of a board of supervisors, which will be in charge of the drainage tunnel work. Possibly as much as 30 per cent. of the money raised in this way would go into the tunnel. A similar bill failed to pass 4 years ago. The Roosevelt tunnel was then started and now the complaint is made that many prominent companies in Cripple Creek are draining through it which have never contributed to its construction. If a mine owner is content to go without a drainage tunnel, while another must have one, why should he pay for its construction? If, however, a tunnel is constructed that unwaters his mine he should donate at least part of his former cost of pumping.

Cow-Bell Hoisting.—At a large Michigan iron mine, where Kimberly-style skips are used, the skips run with practically no noise and the skip tenders have to watch carefully to keep from dumping ore into the shaft, thinking that the skip is in position. One night the top men removed a bell from a cow which had wandered near and placed it on the skip. This bell would ring when the skip started and stopped, as well as when it was in motion, and was found to be so convenient that soon all the skips and cages upon the property were equipped with cow bells. Where the bells came from has not been inquired into by the management, but they would gladly supply any bells which would be needed to keep the skips and cages equipped, as it has been found to be more convenient and safer than when not so equipped.—E. S. Dickinson.

Cripple Creek Drainage Tunnels.—At the beginning of March the discharge from the Roosevelt tunnel, Cripple Creek, was at the rate of about 9,000 gallons per minute. Contrary to expectations the drainage seems to be derived pretty generally from the camp and not entirely from the mines immediately on the line of the tunnel. It was originally supposed that the north and south dike traversing the district would have to be crossed before the mines on the east side could drain into the tunnel, but from the action of the water in some of the mines on that side it would appear that the dike is broken by a fault which allows the water to pass it. It is estimated that the life of the Cripple Creek mines to the level of the Roosevelt tunnel will be about 8 years. In order to prevent suspension of work when this depth is reached, the directors of the Cripple Creek Deep-Drainage Tunnel have authorized its mining engineer, Mr. T. R. Countryman, to begin preliminary surveys for a new tunnel which will tap the workings 500 feet below the level of the present Roosevelt tunnel. It is said that work will be begun as soon as possible on the new enterprise.

The American Mining Congress is actively agitating the adoption of workmen's compensation laws by the various coal mining states with the object of providing a fund by a small tax on coal production, to furnish indemnity for the victims of mine disasters and a pension for aged mine workers. Recently a committee of the Mining Congress drew up a draft for a law of this character, which is now being submitted to the legislatures of many mining states for their consideration. The Mining Congress is also working for more efficient inspection and regulation of coal and metal mines with a view to decreasing the loss of life in mine disasters; the standardization of electric practice in mines, the general revision of the mineral land laws, etc.

REPORT ON THE POVERTY GULCH MINE

*By Charles W. Henderson**

Geology, History, Description of the Ores, Cost of Labor, Freight, Treatment, Power, and Supplies

Part I. Preliminary.—The object of this report is to describe in detail the operations of a mine through the various stages of prospecting, developing, and mining, with maps, plates, and specifications for plant and buildings, followed by subsequent assumptions regarding profit or loss that might ensue from marketing of a certain number of tons of ore per day.

Conditions surrounding the report are that the property consists of four overlapping claims located in Section 18, T. 15 S., R. 69 W., in Cripple Creek district, Colorado. All claims are 1,500 feet long by 300 feet wide. The ore deposits consist of mineralized sheeted zones in breccia and connected with two dikes. The character of the ore and the mineralogy are the same as that in the Portland mine nearby. The values occur in three shoots A, B, and C, having the following dimensions:

Shoot	Length	Width Feet	Average Width Feet	Values	Average Value
A............	500	0–12	3	0–$150	$15.00
B............	700	0–10	3	0–$150	$13.00
C............	300	0–40	16	0–$150	$20.00

The ore in shoot C is formed by solutions from two dikes, one basic and the other phonolite, and the ore deposit follows down on the intersection of these dikes which dip 60 degrees

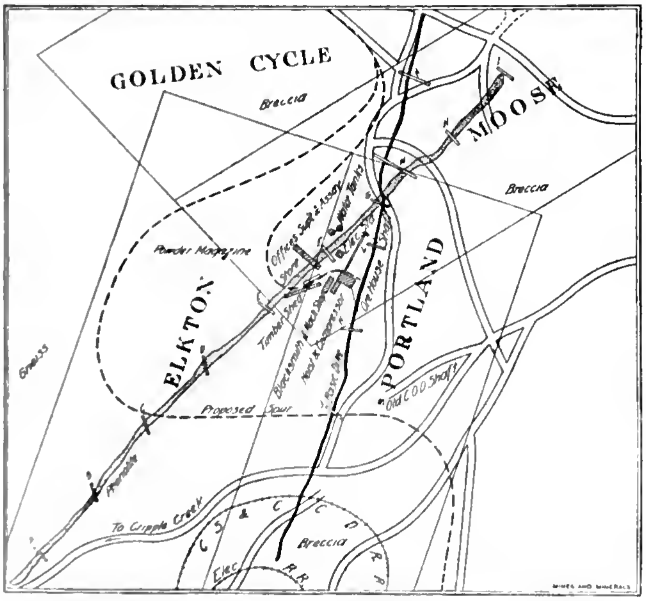

FIG. 1. MAP SHOWING LOCATION OF MINE

to the west and 50 degrees to the east, as shown. In order to plan the developing and prospecting of the property so that at the end of 3 years the mine will be producing 200 tons for 24 hours, it would be necessary to design a surface plant capable of handling this tonnage from a depth of 100 feet. At the end of the development period there should be a reserve of 18 months ore supply blocked out. At the end of the development period, the mine, it is assumed, will produce 780 gallons of water per minute, and therefore a pumping plant necessary to handle the flow must be designed. Assume that 54 per cent. of the water is intercepted at the 600-foot level and the rest is pumped from the bottom.

The mining district in which the property is located is in a group of hills some 7 to 12 miles southwest of Pike's Peak in the western part of El Paso County, Colo. It is 30 miles west of Colorado Springs and 75 miles south of Denver, near the center of the territory embraced by the Pike's Peak sheet of the Geological Atlas of the United States, issued in 1894. The general elevation of the district is from 9,000 to 10,000 feet above sea level. It is situated between Beaver and Oil Creeks, two tributaries of the Arkansas River. The former on the east has several tributaries which rise on the southern face of Pike's Peak, while Oil Creek, on the west, drains a large surface of the plateau west of Pike's Peak. The creek from which the town and mining district derive their name is one of the numerous branches of Oil Creek which has cut deep gorges near the rocks on the way to the main stream. The area covered is 6 miles in length and 5½ miles in width, in high rolling grass-covered ground between the two main ranges of the Rocky Mountains in Colorado.

The climate of the region is dry and the vegetation correspondingly scanty. There are three railroads entering Cripple Creek. One, the Colorado-Midland, enters from the north, the Colorado Springs & Cripple Creek District Railroad enters on the east, and the Florence & Cripple Creek Railroad, from Florence on the Denver & Rio Grande Railroad, enters from the south. These railroads furnish easy access to Colorado City, where are the custom chlorination mills of the Golden Cycle, the United States Reduction and Refining Co., and Portland Gold Mining Co.; to Pueblo or Denver, where are smelters of the American Smelting and Refining Co.; to Salida, where an independent company, the Ohio & Colorado Co., has located its smelter.

In addition, the district is traversed by electric passenger lines belonging to and connected by switches to the Colorado Springs & Cripple Creek District Railroad, called the Short Line, by which any mine in the camp can be reached at the expenditure of from 10 to 25 cents, and with no more walking than is necessary in any suburb of a large city.

The accompanying sketch map shows the situation as regards railroad and smelter points, and the United States Geological Survey Topographical map shows the steam and electric railroads in the district.

History of the District.—The Pike's Peak gold excitement in 1859 and the collapse of that boom occurred many years before gold was known in Cripple Creek. In 1874 H. T. Wood, who had been on the United States Geological and Geographical Survey under Hayden, from observations made several years before while on the survey, formed a party and started out to make investigations in the region now known as Cripple Creek. He found some float, and in August, 1874, formed the Mount Pisgah Mining Co. The usual rush was made to the region. A number of shafts and tunnels were opened, but the rich ore bodies discovered later by the more fortunate prospectors of the present Cripple Creek were not encountered. From the old openings found it is now evident that the unsuccessful explorers of 1874 were in the very heart of the Cripple Creek district.

The second mining excitement was in 1884 and was started by the alleged discovery of fabulously rich gold deposits west of Mount Pisgah. During this rush about 5,000 people were soon on the ground. They found that the prospect of rich gold had been salted and the originator of the scheme fled to escape being lynched, after which the district was rapidly deserted.

The first to discover valuable gold deposits in the Cripple Creek district was Robert Womack, who owned a ranch in that section, and who, led on by his frequent discoveries of frag-

* EDITOR'S NOTE.—The Poverty Gulch mine is the subject of a Mining Thesis by Charles W. Henderson. It appealed to the Editor to such an extent that he asked for and was granted permission to publish it. To those who would learn how to make a mine report it is recommended; to those interested in economical and scientific mining it is recommended; to those who do not know it all, it will meet with approval. Owing to the length of the Thesis it is necessary to divide it into sections, each of which is a complete article replete with useful information.

ments of rich ore, continued his search for the source of these pieces until, in the fall of 1890, he found ore in place and located the El Paso claim on which Gold King mine, in Poverty Gulch, is situated. He took some specimens of ore to Colorado Springs, and, on the strength of these in the winter of 1891, E. C. Frisbee and E. M. De La Vergne went into the region, making their headquarters at the Broken Bow Ranch of George W. Carr, near the site of the present town of Cripple Creek, and prospected with success. They were the first to really open and develop valuable mines in the district. The first paying mine was the Gold King, in Poverty Gulch, which was opened by Frisbee on the El Paso claim, and from which ore was shipped in 1891. Other discoveries followed, and shortly after the opening of the Gold King, De La Vergne opened the Raven mine. Thus successfully started, the region began to develop. In the spring of 1892 the rush began, and for the third time people streamed in. More discoveries were made and the region rapidly developed. The record, however, of the two previous attempts to find gold made many people skeptical as to the real value of the discoveries. The developments in 1892 and 1893 were so encouraging that in the latter part of 1893 and 1894 capital turned toward the district, and in the fall of 1894 there were over 100 mines, more or less developed, of which nearly all are strong mines today.

The production of the district from 1891 to 1894, inclusive, has been estimated by the mint of the United States at Denver at $5,543,967, and by various local authorities at over $7,000,000. The district has produced to the end of 1909 in gold $203,451,312, and 1,002,940 ounces of silver.

In all the central part of the area, where the hills are made up of volcanic material, there are but rare outcrops to aid the geologist in outlining the various formations. The slopes are usually smooth, covered with a scanty growth of grass or of aspens, or with a mantle of slide rock, effectually concealing the contacts of formations.

The group of hills containing the mines of the Cripple Creek district are almost entirely made up of volcanic rocks, and the result of investigations proves that there is here a small vent, in and about which the sequence of phenomena has been remarkably complete and typical of a true volcano. The principal material is fragmental breccia, or tuff, resulting from a succession of explosive outbursts. Massive rocks occur, representing in part bodies that have been largely destroyed in succeeding explosive periods of the volcano, and in part intrusive bodies of various sizes and shapes belonging to later eruptions.

The formation through which the volcano burst, and upon which its superficial materials lie, is the granite-gneiss complex of the Colorado Range. Pike's Peak and the southern end of the Colorado Range are composed mainly of massive reddish granite, both coarse and fine grained. Southwest from the peak and toward Cripple Creek, bands of gneiss are occasionally met with, and the evidence that the gneisses are formed from the granite on zones of shearing is locally very distinct.

Extending from Cripple Creek to the Platte cañon on the north boundary of the Pike's Peak sheet, is a line along which the granite and derived gneiss contain numerous large and small included fragments of quartzite, quartz-fibrolite schists, or quartz mica schists, and other similar rocks. The igneous rocks of the Cripple Creek district are found resting upon or penetrating this complex of granite, gneiss, and included schist fragments, which are here micaceous or fibrolite quartz schist and much decomposed.

The basic dikes are usually inconspicuous on the surface, but are exposed in prospects and in the mine workings.

The Pre-Cambrian crystalline complex which forms the general plateau of the region was perforated by a volcanic explosion. The deep pit thus formed was filled with a breccia composed of fragments of phonolite and allied rocks, and of granite, gneiss, and schist. The walls of the pit are steep and rather irregular. They exhibit local bench-like flattening, and in some places overhang the breccia. While the breccia may in a few places rest upon an uneven surface of erosion, it occupies in the main a steep-walled chasm extending to unknown depth, and constitutes a typical volcanic neck. The breccia is cut by intrusive bodies of syenite and trachyphonolite, these two rocks showing frequent gradations from one to the other. The intruded bodies are usually of very irregular shape and have been peripherally shattered to such a degree that their contacts with the breccia are very obscure. These rocks generally form stock-like masses of thick, irregular sheets. The breccia is also cut by numerous dikes of phonolite, and this rock forms intrusive sheets and masses of considerable size in the prevolcanic crystalline rocks.

Ore Deposits.—The ores of Cripple Creek district are almost exclusively gold bearing. A little silver generally occurs in most of them, and in a few cases its quantity is sufficient to be of importance. The chlorination and cyanide mills do not pay for the silver in the ore. No other metals occur in any of the ores in quantities of commercial value. The ore consists usually of country rock, more or less impregnated with and replaced by quartz and other minerals, among which the most abundant are fluorite, opaline silica, and kaolin, with iron pyrites and other iron minerals, manganese oxides, and more rarely small quantities of galena, cerussite, anglesite, malachite, acanthite, tetrahedrite, stibnite, sphalerite, calaverite, native gold, oxidized tellurium minerals, gypsum, calcite, and numerous other minerals in still smaller quantities. The stibnite, the sphalerite, and the copper minerals, including tetrahedrite, are very rare.

The ores differ from those of many gold districts in often, but not always, consisting simply of country rock, either eruptive materials, or granite containing more or less secondary quartz and associated minerals, while in most gold districts, and in fact, in parts of the Cripple Creek district, the ore consists of well defined bodies of these materials. The characteristic ore of the district is an intimately mixed mass of quartz and purple fluorite, prominent from its purple color. The gold occurs in the ore as free gold, as tellurides of gold, and possibly as auriferous iron pyrites. In the veins the free gold usually predominates in the upper parts of the ore bodies, but within a depth of 100 feet, and in some cases much less, the telluride of gold associated with more or less iron pyrite usually appears, and gradually takes the place of free gold.

The average tenor of gold in the ores is about $30, or 1½ ounces per ton, and at various mines ranges from 1 ounce to 3 or 4 ounces. Ore at less than $12 per ton is rarely mined. Small amounts of ore up to 2,500 ounces gold have been mined. The gold in the Cripple Creek district is found in vein deposits, which generally occur in fissures in the country rock, which usually represents slight faulting, while more rarely they occur in other positions. The veins intersect all rocks in their course, and have been formed mostly by replacement along the fissures and not by the filling of open gaps.

The ore bodies were in almost all instances casually related to fissures. They comprise lodes or veins, and irregular replacement bodies usually in granite. These two types are not sharply distinct. All the ore bodies are characterized by the narrowness of the fissures and by the comparatively small volume of material deposited on these fissures.

Productive ore bodies occur in all the rocks of the district, with a possible exception of the schist. They are most abundant in breccia and in granite. Many lodes follow phonolite or basic dikes.

The structure most characteristic of the Cripple Creek lodes is the sheeted zone which occurs in various degrees of regularity, and in widths ranging from a few inches to over 100 feet. The fissures are usually very narrow, although there are a few notable exceptions to this rule. Evidence of tangential movement or faulting along the fissures is rare.

The fissures were probably formed about the same time

as the intrusion of the basic dikes, and represent a late phase of volcanic activity. They were probably opened under a relatively light load by local compressed stresses due to a slight subsidence of the solidified breccia and associated intrusive rocks forming the volcanic neck.

COST DATA

Labor.—The wage scale per 8-hour day is general throughout the district.

Hoisting engineer	$4.50
Blacksmith	4.50
Machine runners	4.00
Time keepers	4.00
Shift bosses	4.00
Watchman	4.00
Ore bosses	4.00
Timbermen	3.50
Machine helpers	3.50
Firemen	3.50
Trammers and muckers	3.00
Ore sorters	3.00

Freight Charges on Supplies.—Rates from Denver to Cripple Creek are:

	Per 100 Pounds
First class	$.80
Second class	.75
Third class	.70
Fourth class	.65
Fifth class (or carload lots)	.55

Below are some of the classifications as regards mining machinery:

First class: Steam or electric hoists (when less than carload); drill sharpeners; compressors.

Second class: Blacksmith blowers; ore buckets; blacksmith tools; blacksmith forges.

Third class: Ore cars; ore sacks; air receivers L. C. L.

Fourth class: Wire cable; drill steel; bar iron; sheet iron; pipe fittings; sledges and hammers; steel shafting; bolts and nuts, screws, washers, rails, fastenings, track bolts, etc.

Commodity rate ($.55 per 100 pounds), pipe.

Treatment and Freight Charges.—(1) Custom chlorination or roast-cyanide mills at Colorado City, based on payment of $20 per ounce for gold content.

	Freight and Mill Treatment Per Ton
Up to ½ ounce ore	$4.00
From ½ ounce to ¾ ounce ore	5.00
From ¾ ounce to 1 ounce ore	5.50
From 1 ounce to 1½ ounces ore	6.00
From 1½ ounces to 2 ounces ore	7.00
From 2 ounces to 3 ounces ore	8.00
From 3 ounces to 5 ounces ore	8.50

(2) Smelter rates, f. o. b., Denver, Pueblo, or Leadville.

	Per Ton Treatment Plus Freight
From 5 ounces to 7½ ounces ore	$5.50
From 7½ ounces to 10 ounces ore	6.50
From 10 ounces to 12½ ounces ore	7.50

Lumber.—The average price for lumber is $20 per 1,000 (board measure). More specifically, lumber for mine timbers is sold as follows:

Delivered	*Each*
8-inch stulls	$ .70
10-inch stulls	1.25
12-inch stulls	1.50
14-inch stulls	2.00
16-inch stulls	2.50
18-inch stulls (this size is used only in very wide stopes)	3.00
6-inch lagging	.55

The stulls are from 15 to 20 feet long. Purchaser pays the freight, which is about 15 per cent., and then deducts same.

Coal.—Steaming coal, $6.50; delivered, $6.75 per ton; blacksmith coal, $20.50; delivered, $20.75 per ton; lignite, about $4.

Electric Power.—Standard power rates (Central Colorado Power Co.):

	Per H. P. Year
First 100 horsepower	$39.00
Next 400 horsepower	27.00
Fixed Charge	
Next 500 horsepower	21.00
Over 1,000 horsepower	12.00
Energy or Consumption Charge	*Cents Per Kilowatt Hour*
First 40,000 kilowatt hours	1.3
Balance	.5

Schedule (December, 1908). Pueblo & Suburban Traction and Light Co., water power plants, Victor, Colo. Motors, 1 to 100 horsepower, alternating current. Single-phase 110 to 230-volts, direct current 500 volts.

A Fixed Charge of $1.50 per Horsepower per Month	*Per Cent.*
Plus 1½ cents per kilowatt hour, with a load factor of	10
Plus 1¼ cents per kilowatt hour, with a load factor of	20
Plus 1$\frac{1}{10}$ cents per kilowatt hour, with a load factor of	30
Plus 1 cent per kilowatt hour, with a load factor of	40
Plus 1 cent per kilowatt hour, with a load factor of	50
Plus $\frac{9}{10}$ cent per kilowatt hour, with a load factor of	75
Plus $\frac{8}{10}$ cent per kilowatt hour, with a load factor of	100

Other Supplies.—Cost to lessees or to small operators where large quantities are not bought:

Candles, per box	$ 3.50
Powder (40 per cent.), per 100 pounds	15.50
Fuse, per 100 feet	.65
Caps (per 100), per box	.85
Coal, per ton	6.50
Machine steel, per pound	.09
Making up drills (.20 for a drill, .10 for a shank), per drill	.30
Sharpening machine steel, per bit	.10
Assays (custom) three for	1.00

Water.—Water for domestic purposes of the miners is supplied by regularly organized water companies, which obtain the water from the melting snow of Pike's Peak. Water for the different mills of the camp, and for washing the ores at the mines, is supplied by the pumping operations in the lower levels of the deep mines.

Acquirement of Property.—It is assumed that the claims in question were acquired by location by the members of the operating company.

(*To be continued*)

DR. R. W. RAYMOND'S RESIGNATION

At a joint meeting of the Board of Directors and of the Council of the American Institute of Mining Engineers, Dr. R. W. Raymond tendered his resignation as secretary. He has been relieved from the many executive and administrative duties which have been increasing steadily, and which with the suggested extensions of the activity of the Institute must further multiply.

Doctor Raymond has been appointed Secretary Emeritus of the Council, the Institute thus retaining his services for special editorial and other duties for which he is so well qualified by training and experience. Doctor Raymond, one of the founders of the Institute in 1871, was elected vice president and became president in that year, following David Thomas, who resigned because his advanced years did not enable him to perform the duties of his office to his own satisfaction. He was annually reelected president in 1872, 1873, and 1874. In 1883 he was appointed secretary to succeed Dr. T. M. Drown, who had resigned. He was elected secretary in February, 1884, and has been annually reelected since that time.

Doctor Joseph Struthers, who has been connected with the Institute as assistant secretary for 8 years, and as editor for 5 of these years, has been elected Secretary of the Board of Directors and has been appointed Secretary of the Council. Doctor Struthers was editor of the *Mining Industry* for the years 1900–1903 (Vols. 8, 9, 10 and 11), and prior to that time was for 15 years on the teaching staff of the Department of Metallurgy of the School of Mines, Columbia University. He has been Field Assistant of the United States Geological Survey, in charge of the preparation of numerous reports for the Mineral Resources, and Special Agent of the United States Census, in a like capacity. In connection with the work of the Institute, he is a member and treasurer of the Board of the United Engineering Society, Chairman of its House Committee, and Secretary of the Library Conference Committee, which has general supervision of the libraries of the engineering societies in the United Engineering Society Building, 29 West 39th Street, New York City.

DRY PLACER MINING MACHINES

Written for Mines and Minerals, by E. B. Wilson

Knowing that there are placer deposits in the arid lands of the southwestern United States and the north and northwestern Mexican states, men have been working for years to devise machines that would treat the material successfully. One of the early difficulties was the necessity of having water for the steam power needed to excavate and treat sufficient quantities of ground to make the undertaking a commercial success. Some of the machines gotten up were elaborate; for instance, the Bennett dry-placer machine, in which a number of Hartford, Conn., people were heavily invested. Probably this machine would have worked successfully on a rich placer where there was plenty of water, but it never could work anywhere else to advantage. This is mentioned to emphasize that the phrase "dry-placer machine" does not necessarily make a dry-placer machine.

Different Methods That Have Been Used for Concentrating With Little or No Water

A fairly good machine that has some merit is known as Wood's dry-placer machine, Fig. 1. It was worked in Nevada on rich ground about as follows: The dirt was screened, as in Fig. 2, through one-quarter mesh sand screen, then placed in the hopper of a Wood machine. The upper part of the machine consists of a frame covered with heavy cloth across which are wooden riffles. This frame and cloth form the upper part of a bellows, and being set on an angle the puffs of wind cause the lighter particles to travel down the incline, while the riffles hold back the heavier particles composed of gold and black sand. When the riffles are full the frame is lifted out and the material caught dumped into a tub. After sufficient concentrate has accumulated in the tub, it is put over the machine and this second treatment holds the gold while the black sand becomes the tailing. The former is sacked and shipped, but the latter is panned in water before sacking. Fig. 3 shows an old dry placer once worked by Mexicans by tossing the dirt in the air

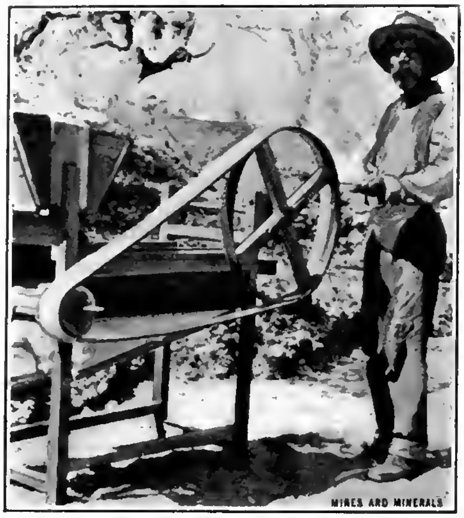

FIG. 1. WOODS DRY PLACER MACHINE

to allow the wind to blow away the dust from the heavier particles that fell on a blanket. The old placers discovered in 1828 by Mexicans at the mouth of Cunningham cañon, in Santa Fe County, near the town of Dolores, interested Thomas A. Edison some 20 years ago. He therefore constructed an extensive plant to recover the gold by means of static electricity, but this failed because the requisite dry gravels could not be obtained. About 1900 Mr. Edison again undertook to overcome the difficulties connected with dry-placer mining by means of the machine shown in Fig. 4. The device was described in the *New Zealand Mines Record* in 1904 as follows: "The revolving roller *b* discharges the gravel from the hopper *a* upon a shelf *c*, from which it falls into the air-blast created by the centrifugal fan *d* discharging its air through the screens *e* and *f*. The parting-board *g* divides the heavier portion of the gravel—the gold and iron or black sand—which falls into the

FIG. 2. SCREENING PREPARATORY TO DRY WASHING

chute *h* from the lighter portion falling into the tailing-chute *i*. The lattice *k-k* is simply to prevent eddy currents of air going down the chutes *h* and *i*. The end *m* is open. By a suitable adjustment of the speed of the fan, the position of the parting-board *g*, and the rate of feed of the gravel, a concentrate was obtained, the details of which are given below:

"Total gravel excavated, 33.8 cubic yards; weight, 137,464 pounds; total gravel treated in mill, 38,896 pounds. This was divided among the five sizes as follows: A, 8,911 pounds; B, 7,022 pounds; C, 8,040 pounds; D, 8,075 pounds; E, 6,848 pounds. The results are shown in the following table:

Size	Amount Treated Pounds	Weight of Gold in Concentrate Milligrams	Weight of Gold in Tailing Milligrams	Percentage of Gold Saved
A.........	8,911	513.2	147.40	77.7
B.........	7,022	1,737.5	66.65	96.3
C.........	8,040	3,478.0	75.70	97.8
D.........	8,075	3,667.0	340.46	91.5
E.........	6,848	2,542.5	26.41	99.0
Total....	38,896	11,938.2	656.62	95.0

"The concentrate is further treated in order to reduce its bulk and increase its value, by passing it over an Edison magnetic separator, which removes the magnetic black sand. Black sand is found almost without exception in all placer deposits, and being the heaviest constituent of the gravel, with the exception of the gold, it usually forms the bulk of the concentrate."

The conditions for the success of a dry-placer machine are: The operating must be cheap; it must have a large capacity; it must save a high percentage of gold; it must save all sizes of gold, from a few thousandths of an inch to the size of peas or larger. The necessary requirements for air separation by means of a blower appear to be: A free fall of the gravel through a horizontal current of air; a blast free from all puffs; a blast of perfectly uniform velocity throughout its entire cross-section; all particles of gravel and gold must enter the blast at a uniformly low velocity; and, the material treated at any one time must not vary in size beyond certain limits.

Machines of the semidry type are designed to work alluvials where water is insufficient for dredging. They are constructed on platforms provided with trucks to move on tracks under their

Fig. 3. Old Dry Placer in Altar Gold Field

own power. A dipper, or endless bucket chain digs and raises the gravel at one end of the platform. At the other end a tailing stacker disposes of the tailing. The machine is, in these particulars, similar to an ordinary dredge save that the buckets are lighter, this being possible because all work is done in plain sight and extra strains may be avoided; also, because bed-rock need not be dug into, as it may be more economically cleaned up by hand.

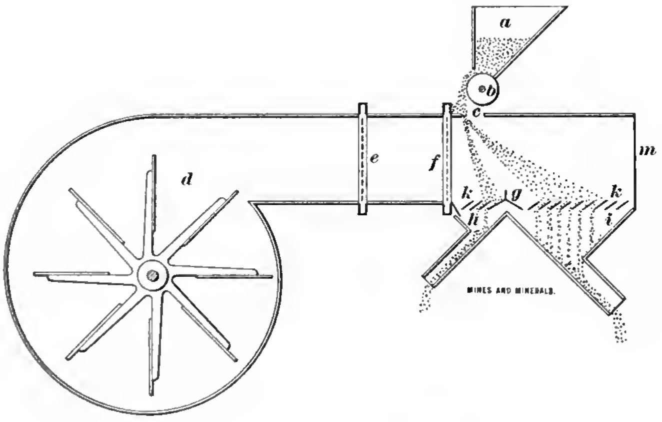

Fig. 4. Edison Dry Placer Machine

Separation is effected by the lifting force of water, driven by propeller blades. In this process it is necessary that a rising column of water shall lift all the sand and leave behind all the gold, however fine. It has been found by experiment on a commercial scale, that gravel, screened to $\frac{1}{4}$ inch, may be cleanly separated from its gold content. Therefore, all dirt is delivered by the bucket chain to a grizzly and the undersize to a rotary screen with $\frac{1}{4}$-inch mesh. The gravel is brushed by steel brushes over the grizzly for nine-tenths of the circumference. This arrangement is unnecessary, because the particles tumbling over each other clean themselves. If this is done under water, separation of coarse and fine gravel is very complete. The coarser material is carried to the tailing stacker after passing over a device wherein are saved any nuggets too large to pass the screen.*

The finer material is fed by gravity into a tank 7 feet in diameter and 5 feet high, containing water. In the middle of this tank stands an upright tube 2 feet in diameter. This does not reach to the bottom of the tank, so that water and sand have free ingress. Within the tube is an upright shaft, to which are fixed two sets of propeller blades.

When these propellers are made to revolve at the speed required, the water within the tube is forced rapidly upward. Its place is taken by water from the tank. The result is a hydraulic elevator fed constantly by water in the tank.† The force is so graduated as to raise sand and gravel, but not the gold, which remains at or near the bottom of the column, according to its fineness. Surrounding the top of the column is a launder into which the uprising water flows outward in all directions, and, losing force, drops the gravel and sand which it has lifted and which is automatically conducted to the tailing stacker. The very fine sand and mud in suspension do no harm if the water be kept sufficiently cleared by the addition of fresh water from time to time. Clayey gravels, and most of them are, require more water for treatment than clean gravels.

The machine described worked near Newhall, Cal., and handled gravel at the rate of 20 cubic yards per hour. Power was supplied by a 9-horsepower Fairbanks-Morse gasoline motor, and water was delivered by a 2-horsepower motor, pumping 700 gallons per hour from a 90-foot well through 1,200 feet of 2-inch pipe.

Often the impression prevails that there is no water in the dry-placer districts, a surmise which is correct, so far as surface water goes; however, if a well is driven in a "coulee" the chances for obtaining water are excellent, although the water may not be fit to drink. With a small quantity of water considerable work may be done where only the heavy sand is to be washed. The excavator and washing machine, shown in Fig. 5, is intended to work where there is sufficient water for the excavator boiler and the engine connected with the concentrating machinery. If, however, there is sufficient water, the sluice boxes to the rear of the concentrator can make use of it to advantage.

The machine was photographed near Quartzite, Ariz., where there is little water available. The excavator consists of a railroad crane having a 75-foot arm to which is attached a scraper bucket. This radius permits a large territory to be excavated before the machine needs moving. As seen in the illustration, the bed frame of the excavator rests on rollers, these on suitable rails and cross-ties so that it may be moved as desired. The gold-bearing dirt is about 8 feet deep before bed rock is reached, and it is said that the first three yards delivered to the hopper produced $1.23 in gold.

The bucket is arranged both to dig into and scrape up the earth, even close to bed rock, hence little hand labor is needed

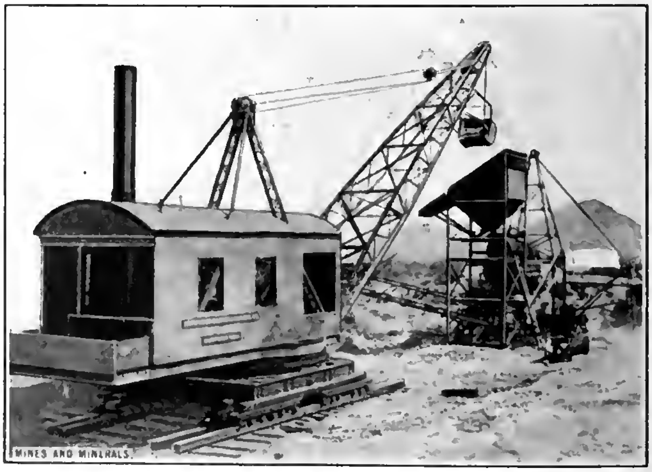

Fig. 5. Excavator and Washing Machine

in cleaning up the gold on bed rock. It has a capacity of $1\frac{1}{2}$ cubic yards, which makes it possible to deliver a large quantity of dirt to the concentrating hopper during the course of the day.

*Gold Dredging, page 146.

† Those acquainted with the agitation of gold slimes in cyaniding will notice a similarity between this apparatus and some agitators.

To the rear of the excavator is seen the concentrator mounted on the steel frame. At the top is a steel hopper containing a grizzly that terminates in a chute for the disposal of the coarse rock that passes over the bars. Below the hopper is a rotary screen which sizes and dry-washes the dirt that passed through the grizzly. The coarse material from this screen passes to the traveling-belt tailing stacker shown to the left of the tower, and the fine material that goes through the screen is washed through the sluice extending from the rear of the tower.

Where a dry placer is worked there is usually clay baked to the gravel, and to separate this there should be some kind of scouring action, such as is given by screening. When the gravel is almost cemented with clay the Quenner dry pulverizer, described in the November, 1910, issue of MINES AND MINERALS, will be found useful, as it is run by gas or oil engine power and pulverizes the material sufficiently to liberate any gold. The introduction of gas and oil engines will aid materially in working dry placer deposits, and as the conditions for recovery are better understood from experience it is probable that much gold will be won; however, a good many schemers will work out plans for separating the unsuspecting avaricious from their money by using the phrase "dry-placer machine."

HAND JIG FOR SMALL MINES

*By J. M. Calderwood, M. I. M. M.**

For the coarse concentration of ores containing lead, zinc, copper, tin, and iron, jigging machinery is universally employed. Although a great variety of designs are in use, they are practically alike in principle, whereby the separation of the mineral from the gangue takes place on a screen or bed of material, the ore particles arranging themselves into layers according to their specific gravity. This is effected by an up-and-down current of water in the jig box, the pulsations being imparted by a vertically operated plunger. All jigs are dependent for good work on approximately sized material, based on the character of the ore, and a suitable adjustment of speed and stroke of plunger for the class of material worked. Mechanically operated jigs make clean concentrates when treating properly sized material, and, in addition, a middling product which is generally treated by regrinding machinery and concentrating tables.

In districts where water is scarce and the scale of operations does not permit of a large expenditure, it is possible to produce small quantities of ore which would yield a shipping product, if suitable appliances could be installed. For this purpose a jig operated by hand has proved its usefulness, especially in the treatment of lead, zinc, and copper ores. With sulphide ores, good results can be obtained, provided the ore is fine enough and several sizes carefully screened for treatment. At the Messina copper mine, in the Northern Transvaal, a number of hand jigs were installed when output was commenced in 1906, and, although a large concentration plant has since been erected, these small jigs are still in use for working up jig middlings, retreating Wilfley table product, cleaning concentrate, etc.

Until the concentration plant was built the method of preparing the copper ore for shipment was as follows: The ore from the mine was trammed to the sorting tables, cleaned by a water spray, and the larger pieces of copper ore handsorted and bagged for shipment. The residue from the tables was then wheeled to the screens where several sizes were made and delivered to the hand jigs arranged in rows. Fig. 1 gives sufficient detail to show the construction of these jigs, which were cheaply and easily made, generally from bush timber and old packing cases. As will be seen from the sketch, the ore box, having a screen bottom, is moved up and down in the water tank by means of the lever, which is given a quick down stroke with somewhat slower recovery, and just sufficient play or loose motion to give the required movement. The work is soon learned and carried out in an expert manner by young native boys, and even the smallest piccanins employed become quite skilful in turning out clean concentrate and separating the tailing. The box is filled by shovel, and a few minutes jigging is sufficient to allow the heavier mineral to settle on the screen and the tailing to collect on top. The top layer of tailing is first removed by means of a tin scraper, and then the concentrate. The concentrate is not removed each time the tailing is scraped off, but allowed to accumulate until in the judgment of the operator there is sufficient accumulation of clean product, which is then dried and bagged for shipment. The tank or hutch is kept full of water and the fine material and slime settles in the bottom and is emptied as often as necessary by removing the screen. The quantity of clean water required is small, and is chiefly to make up for the loss by splashing and for refilling the tanks. The fines can be retreated in another jig having a smaller mesh screen if of sufficient value. The mesh of the jig screen depends upon the size of the screened material treated, and the proportion of fines desired. For coarse ore, $\frac{1}{2}$-inch aperture iron wire screen cloth is used, and for finer material $\frac{1}{4}$-inch to $\frac{1}{16}$-inch screen cloth, although for close work even finer screens may be used. The capacity of the hand jig depends upon the class of material treated and the grade of ore. From $\frac{1}{2}$ ton to 1 ton of material

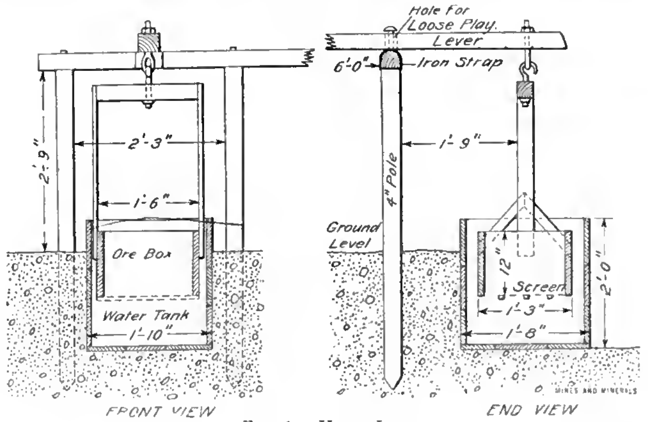

FIG. 1. HAND JIG

per day can be handled by each jig, according to the grade treated and the experience of the operator.

The results obtained compare very favorably with the word done by mechanical jigs, as regards the value of the concentrate and tailing produced. The initial outlay is small and the cost of operating a battery of hand jigs is merely a question of native labor, repairs to screens, etc., as constant white supervision is not necessary with a good gang of trained piccanins. The operation of the jigs may appear to be tedious, and it certainly is when compared with the work done by the large mechanically operated jigs, whereby clean concentrates are automatically turned out and the tailing passes off without handling, but their importance and usefulness has been recognized and employed on many occasions where conditions have been feasible for their adoption.

A paper by F. W. Hinrischen relates to investigations as to the cause of, and means of prevention of, accidents arising from the poisonous and explosive gases evolved from ferrosilicon. These gases are chiefly phosphoretted hydrogen derived from the calcium phosphide. Some samples also contain arseniuretted hydrogen. The most dangerous grades are those containing from 30 to 70 per cent. of silicon. This article is well worth careful consideration by manufacturers, carriers and users of electric ferrosilicon. F. W. Hinrischen. (Mitt. Kgl. Materialprufungsamt, xxviii, 283.)

THE SOUTH UTAH MINE AND MILL

Written for Mines and Minerals, by Leroy Palmer

Description of the Methods Employed in Mining, Milling, and Handling the Ore

The South Utah mine, better known as the Cactus or the Newhouse, has had a checkered career. It was first exploited by a French company which worked it to the 100-foot level and built a small concentrator. It proved unprofitable, failed to meet the bond requirements and was finally sold under the hammer. It then fell into the hands of Samuel Newhouse, of Salt Lake, and his associates, who organized the Newhouse Mines and Smelters. Extensive equipment was installed, including a 600-ton concentrator, and it entered its second epoch. While copper was at its highest price it paid two dividends aggregating $600,000, but with the slump soon found itself unable to meet the interest on the bonds, and it went through a reorganization process from which it emerged as the South Utah Mines and Smelters. While the reorganization was going on the mill was remodeled and the mining system materially altered, so that when the property was started under its third management on September 1, 1910, the operative methods were as different from those employed by the second management as these were from the first.

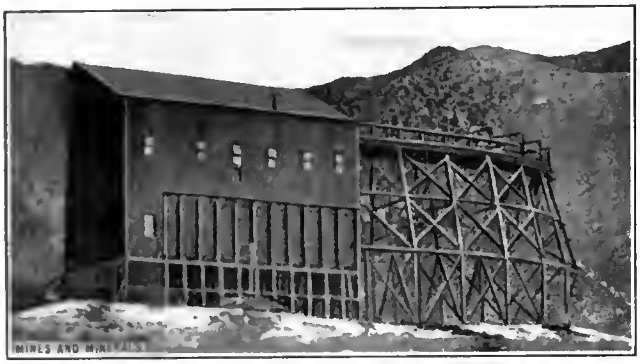

Fig. 1. Trestle and Ore Bin, South Utah Mine

The location is on the west side of the San Francisco Mountains 1½ miles from the town of Newhouse, and 4½ miles northwest of Frisco, the site of the Horn Silver mine. The San Francisco range is divided into three massifs, the southern of which, known as the Grampian Hills, consists mainly of blue lime. The Horn Silver fault runs along the base of these hills. In the saddle between the southern and the central massif is seen a fault which branches from the Horn Silver fault and shows monzonite on the north and blue lime on the south side. The central massif extends to the north to Copper Gulch, which cuts across the range in a northwesterly direction. The higher portion of this massif is composed of limestones overlain by quartzite, a body of monzonite being intruded into the limestones which have been extensively altered, and which show on the contact garnet and the lime silicate minerals often found accompanying contact metamorphism. An extensive outcrop of smaller rock, but somewhat more of a dioritic nature, is found toward the north of the central massif and was evidently part of the same intrusion; it is in this rock that the deposits of the South Utah are found. On the northern of the three massifs a fault exposes a face of rock which gives some idea of the sedimentaries, an upper layer of red quartzite about 1,000 feet thick, several hundred feet of white quartzite, and beneath, limestone of undetermined thickness. A detailed study of the district has never been made and no definite conclusions have been drawn as to the age of the rocks, but the intrusion of monzonite occurred after the sedimentary depositions.

The ore occurs in the monzonite in a zone of fracture and brecciation of irregular width, which follows the general direction of Copper Gulch, averaging N 30° W. The dip is practically vertical, being only slightly to the northeast. An interesting fact about the discovery is that the only surface indications were a slight copper stain, but sulphides were found in a winze when it had been sunk but a few feet below the surface. This is supposed to be on account of the disintegrated nature of the ore zone allowing erosion to take place as fast as oxidation and thus keeping the unoxidized portion near the surface. The width of the zone of faulting is from 15 to 30 feet, but the ore deposits are in some places much wider. There are no well defined walls, but instead rather indefinite boundaries between the mineralized and barren portion. There are some evidences of cross-faulting, and in one place is a long slip on one side of which the ore is very hard and firm and on the other comparatively soft and crumbly.

Rounded boulders of country rock have been found in the upper 100 feet of the vein, and this was at first supposed to indicate that the deposit filled what was once an open fissure and that these boulders had fallen into it. Later belief is that they are fragments from the walls that have been rounded by the action of the circulating waters. The solutions ascended through this shattered zone and in the cracks and tiny openings deposited pyrite and chalcopyrite, for the most part of very low grade, but in some portions there was a natural concentration which resulted in the deposits of high-grade chalcopyrite which has been shipped in small quantities from time to time. In some portions erosion did not keep pace with oxidation and here were found small amounts of native copper and carbonate, but in the main the sulphides were found from the surface.

The French company sunk a single-compartment shaft to the 100-foot level and worked through that, the Newhouse company sunk this shaft to the 600-foot level and drove a tunnel 6,600 feet long to it at this point. The shaft caved above the 100-foot level, so the hoisting machinery was moved inside the mine to the 200-foot level and operated from there. In the later years of the Newhouse company an incline was sunk from the 600-foot to the 900-foot and levels driven every 100 feet. As a water supply, Wah Wah springs were purchased, the water from them collected in a 36,000-gallon reservoir and carried in 8 miles of spiral-riveted pipe to a 300,000-gallon reservoir above the town.

Under previous management a system of square sets was used, and later a large tonnage was mined by stripping the surface with a steam shovel and working by the milling system, two large raises being driven for this purpose. The square-set timbering, when installed in one system, was not sufficient in itself to hold the wide vein, so pillars of ore of a thickness averaging 35 feet were left across the entire width. This left a considerable tonnage of ore which the present management desired to recover. To do this, short drifts, usually not over 10 feet long, were run into the pillars all around them at intervals of 20 to 60 feet, as the ground would stand. The pillar was then undermined and came down of its own weight, the ore running out of the short drifts. The mouth of each drift is over a "finger chute," so called because the chutes from one pillar run together and thus bear a rough resemblance to the outspread fingers of a hand. These chutes lead frequently by way of an old stope, to two large chutes installed by the previous management to the 600-foot or haulage level. In this way all of the ore in the old pillars is drawn off to the haulage level by gravity. The work is contracted at the rate of 10 cents per ton and one man handles 30 to 40 tons per shift. As the ore is by nature blocky and breaks in large pieces, the mouth of each finger chute is protected by a timber grizzly with 8-inch openings. The larger pieces are sledged or plugged with a small air hammer drill and shot.

In case the pillar does not break readily when it is undermined by the drifts, one of them is continued well into it, with

the uppers pointed up, and continued until the pillar shows signs of weakening, when it is left to break of its own weight.

Between the two "glory holes" which were used when the ore was being taken out by the milling system there were two large bodies of ore which it was desired to recover. The 250-foot level was chosen to work from, as it presented the most firm formation in the upper portion of the mine. Short cross-cuts were driven into the ore bodies from all sides, and from the ends of these, raises inclined toward each other were driven. As soon as the softer ore was reached the pillar commenced to work and the ore was run over grizzlies and into chutes as described.

Below the 600-foot level only a little square setting had been done, and a system of back stoping was introduced. The ground is blocked off into stopes and pillars, the size being varied to suit the nature of the formation, an average width being 10 to 12 feet for the pillars and 20 to 30 feet for the stopes. The length of the stope is the full width of the deposit, which may be anything from 100 to 200 feet. The pillars and stopes are staggered on the different levels; that is, a pillar put over a stope on the next lower level and vice versa. A 5′×7′ drift is driven the full length of the pillar, and at intervals of about 30 feet, also suited to the nature of the ground, inclined chutes are driven into the portion to be stoped, these chutes varying in length from 5 to 10 feet. From one of these chutes a short drift is driven to the center of the proposed stope, then turned at right angles and carried to both walls, thus extending the entire length of the stope through the center. This drift is then widened the full width of the stope and the first slice in the extraction of ore has been made. A raise is put up to the next level from each stope and the air pipes carried down them. As the stope fills, these pipes are taken off from the bottom so that no pipe is lost, and the raise provides a means of exit. When a slice has been carried across a stope, a sufficient amount of ore is drawn off through the chutes to allow the men to work the roof by standing on the remainder; uppers are put in with stoping drills and the roof blasted down. Only sufficient ore is drawn off to allow of convenient working space between the remainder and the roof, and the process is repeated, the stope being always nearly full of the broken ore. At present all of this is allowed to remain in the stopes, but as the ground above is worked out it is to be drawn off, the numerous chutes permitting it to be taken out gradually so as to allow a uniform settling of the ground above. To go into one of these stopes, 200 feet long, 20 feet wide, and nearly 100 feet high without a stick of timber gives one the first impression that such a system of mining must be precarious, but the formation is firm, giving a good wall and roof, and accidents are exceedingly rare. The ore that is drawn from the chutes is hand trammed to the incline and dumped to a 150-ton ore pocket from which it is loaded to 1½-ton skips, hoisted to the 600-foot level, and dumped to the cars. By this system of stoping 12½ tons of ore are taken out per shift to each miner and mucker, and 5½ tons to each man engaged in mine work, including office force, engine crew, etc. A little water is encountered in the lower levels of the mine, but not an amount which makes pumping a serious problem, a small electric sinking pump raising it to the 700-foot level where a 3½″×6″ outside center-packed duplex Worthington electric pump raises it to the haulage level.

The ordinary working drifts are made 5 ft. × 7 ft. They are driven by putting in a round of from 9 to 20 holes (some of the ground is very hard) with a piston drill. Both the single and double machines are used, the average progress being 3½ feet with 2¼-inch machine, and a foot more with a 3-inch. Hammer stopers are used with which one man can break 15 to 20 tons to a round, not bad work for the hard ground that must be drilled. Very few timbers are used in the drifts, only an occasional set of 10 in. × 10 in. being necessary. The stopes have no timbering and all required in the chutes are two 10 in. × 10 in. × 9 ft. long, with a 7-foot cap and two 6 in. × 10 in. × 4 ft. for braces at the mouth. The vertical shaft is driven in ore with one compartment 4 ft. × 4 ft. The hoist was operated by compressed air, but when it was moved to the 200-foot level a 52-horsepower variable speed 440-volt induction motor was geared to it. The incline is driven in the vein with a pitch of 50 degrees and with 8-foot pillars of ore on each side. It has one 5′×5′ compartment with a manway of the same size and is timbered with ten 10″×10″ sticks with 2-inch lagging. The hoist is similar to that used at the vertical shaft, and the skip has a capacity of 1½ tons.

The tunnel is 6,600 feet long and 6 ft. × 8 ft. in cross-section. It is driven through a lime formation which requires little timbering and a roomy station is cut at the shaft. Near the shaft it runs through the ore for a short distance, but not so far but that it can be shifted to the lime with small expense when the time comes for the extraction of this ore. The haulage road is laid with a 36-inch track over which the cars are hauled in trains of 14 by a Baldwin-Westinghouse locomotive. The gates at the main chutes underground are operated by air.

The coarse-crushing department is located at the mine, Fig. 1. Above the bins, which have a capacity of 600 tons, is a dumping cradle, shown in Fig. 2, capable of holding seven cars. The cars are run into this cradle in which they are held closely by means of angle irons which fit over the upper edge of the car body. The cradle is connected to an air-operated 7″×12″ duplex hoisting engine by means of a ⅝-inch cable which makes

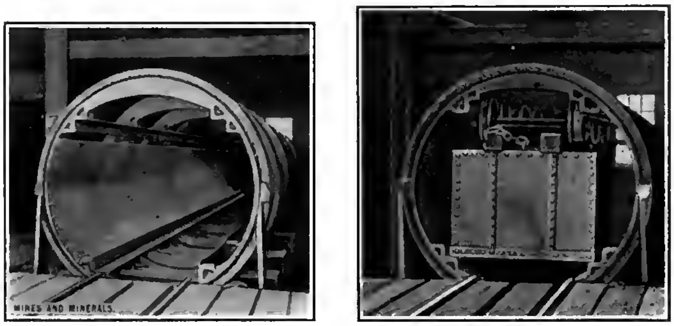

Fig. 2. Rotary Dumping Cradle

two turns around the cylinder and is attached to the drum of the hoist. By this the cradle is revolved and the seven cars dumped at one operation. Fourteen of the 4-ton cars can be dumped in 5 minutes, making all allowance for switching. The bin is fitted with a 2-inch grizzly of railroad iron from which the coarse ore is fed by hand-operated gates over 2-inch punched grizzlies to three 20″×10″ Blake crushers making 235 revolutions per minute and discharged back to the bin beneath the grizzly, from which it is unloaded through sliding gates in the flat bottom to the railroad cars.

The crushers are driven by a 75-horsepower induction motor which receives its current direct from the transmission line at 2,000 volts. There are also two generator units in which a 100-horsepower, 2,000-volt induction motor is direct-connected to a 75-kilowatt, 250-volt, direct-current generator for the haulage system, and in Copper Gulch, near the old shaft, are three 75-kilowatt Westinghouse transformers, stepping down from 2,000 volts to 440 volts for use in the mine. A manway has been kept open in the old shaft and the wires lead down it.

The mill, shown in Fig. 3, is a mile and a half from the mine, on the outskirts of the town, situated on comparatively level ground. The topography of the site is not all that might be desired, as it makes it necessary to elevate the ore more than had greater slope been obtainable. Such a site could have been obtained by building at the mine, which would also have dispensed with the railroad haul; but opposed to this was the fact that at the present site the water can be delivered by gravity, whereas, if the mill and town had been situated at the mine

there would have been a continuous expenditure of about 175 horsepower in order to raise mill water against a head of 600 feet. The saving in continuous pumping compared with hauling the ore down grade outweighed the disadvantages of the lower site on which the designer decided to build.

The ore is loaded at the mine to 50-ton cars with side dump and hauled in trains of four to the mill. This is approached by a trestle 750 feet long, the last 75 feet of steel. The ore is delivered at the top of the mill to the bin built of steel with a capacity of 1,200 tons and with bottom sloping toward both sides from the middle to deliver ore to both sections of the mill. This capacity is not sufficient to provide any adequate reserve supply of ore, so that an accident which shuts the mine down for any length of time must necessarily put the mill out of commission.

The mill is built in two units, and while these differ in some minor points, the general scheme is the same, so that only one will be described. The present capacity of a unit is 400 tons, but plans are being considered for modifications, which it is hoped will increase this to 500 tons. Each bin is equipped with four plunger feeders, two of which are operated at a time to feed the ore to a 24-inch rubber belt conveyer. This conveyer is fitted with an ingenious device in the form of a powerful magnet which is suspended just above it to pick out pieces of steel, such as hammerheads, moyles, drills, etc., which have gotten into the ore, and prevent their going into the rolls.

The conveyer discharges to elevator No. 1, which is run dry, has an 18-inch belt, a lift of 70 feet, and a speed of 460 feet

Fig. 3. South Utah Mill

per minute. It raises the ore to the top of the mill and discharges it to a 42″×60″×60″ conical trommel with 15-millimeter punched openings. The oversize of this trommel goes to a 24″×24″ chute made of 2″×8″ timbers laid crib fashion, and discharges to the coarse dry rolls on the main floor of the mill. These are 15 in. × 36 in., make 68 revolutions per minute, and are set to ½ inch. The rolls discharge to No. 1 elevator and the ore goes again to the trommel. A small Gates crusher with a 2-inch punched grizzly has been installed between the trommel and the rolls, the oversize of the grizzly going to the crusher which discharges to the rolls. But at present the ore is soft and the second crusher is not in use. The location of the rolls is not the best that can be chosen, as all oversize is dropped clear to the main floor and raised to the top of the mill a second time. Plans are being made to place these rolls directly below the trommel and discharge to the elevator at that point so that the lift of the return may be materially lessened.

The undersize of the first trommel goes to a double conical trommel the same size as the first, which is run wet. The inner screen has 9-millimeter punched holes and the outer 3-millimeter punched. The oversize of the 9-millimeter goes to the fine rolls, which are duplicates of the coarse, but run wet, with a speed of 93 revolutions per minute, and are set to ¼ of an inch. These discharge to elevator No. 2, which is a duplicate of No. 1, but run wet. The elevator dumps to a conical trommel with 3-millimeter perforations whose oversize goes back to the fine rolls and undersize to the double-conical trommel. The oversize of the 3-millimeter screen on the double trommel goes to a double bull jig with 1½-inch stroke, making 130 revolutions per minute. This jig makes a finished concentrate through a side-discharge gate, a coarse middling over the tail-board, which is sent to elevator No. 2, and a fine middling through the hutch, which is sent to elevator No. 3. The undersize of the double trommel goes through the screen line.

Here are two sets of two, and one set of four, trommels, each trommel 42 in. × 72 in., making 10 revolutions per minute. Each set is driven independently of the others by its own belt and each trommel is controlled by a clutch. All have punched steel screens, the finest being slotted. The first set has 2-millimeter openings; the second 1½ millimeters, and the third ¾ millimeter. The oversize of the first set of trommels feeds three three-compartment and three two-compartment Hartz jigs; the oversize of the second set feeds four two-compartment jigs, and the oversize of the third set (four trommels), feeds four three-compartment jigs. The stroke varies from 1½ inch on the bull jigs to ½ inch on the finest, and the speed from 130 to 180 revolutions per minute. All of the fine jigs make a tailing rejection, the three-compartment jigs make concentrate on the first and second compartments, and middling on the third, and the two-compartment jigs make concentrate on the first and middling on the second compartment. All work entirely through the hutches.

The jig middling discharges to a very simple but satisfactory dewatering device consisting of a trough set at an angle of 10 degrees with the horizontal, in which is a 16-inch belt, with scrapers bent on each end. This discharges to elevator No. 3, which has an 18-inch belt, a lift of 40 feet, and a speed of 550 feet per minute. It discharges to four 42″×72″ trommels with 1-millimeter slotted screens, the oversize of which goes to a slope-bottom bin, and the undersize is divided among the ¾-millimeter trommels in each screen line. The four 1-millimeter trommels and the slope-bottom bin are used for both units.

The bin feeds two 6-foot Walker-Huntington mills with 1-millimeter screens, making 72 revolutions per minute. A third Huntington is installed as an auxiliary. The Huntington discharges to the No. 3 elevator on its side of the mill, which raises the product to the 1-millimeter trommels.

Table System.—The undersize of the four ¾-millimeter trommels goes to a distributing tub which feeds four three-compartment classifiers which are in general principle similar to spitzkasten. There are 20 No. 3 Wilfley tables in two rows, making 240 strokes per minute, and two classifiers feed each row. The first compartments of each two classifiers originally fed two three-compartment jigs, but this was found unsatisfactory and they were cut out. Considering one pair of classifiers and one row of tables, the second compartment goes to a distributing tub which feeds four tables and the third compartment to a similar tub which feeds three tables. The overflow of each classifier goes to a settling tub, the spigot discharge of the two feeding three tables and the overflow going to eight Callow tanks. The spigot discharge of the Callow tanks is carried to the lower floor and the overflow is used as table water. The first seven tables make concentrate, middling, tailing, and slime, and the last three concentrate, middling, and slime.

The concentrate from the jigs and the first five tables in each row is run through the floor directly to 1-ton cars which are drained and hand trammed to the railroad cars outside. The concentrate of the last five tables in each row discharges to boxes from which it is shoveled to small cars and trammed to the railway cars.

Lower Floor.—On the lower floor are six No. 5 Wilfley tables with elevators and three rows of five Johnston suspended vanners. Each Wilfley treats the middling of two of the tables on the upper floor, making concentrate, tailing, and middling, the latter being retreated on the same table.

The vanners make 120 strokes per minute. The middling of the seventh and eighth tables in each row above goes to a

distributor which feeds three vanners, and the middling of the ninth and tenth tables goes to a distributor which feeds the other two vanners in the same row. Each of the other two rows of five vanners is fed from a distributor which receives the settled pulp from the eight Callow tanks which accompany each row of tables. The table concentrate goes to individual boxes at the tail of each table and the vanner concentrate by a launder to one box. All concentrate is shoveled out and trammed to the railway cars.

All slime is collected in two 3,000-gallon tanks from which it is removed by a 6-inch centrifugal pump. Two pumps are installed with common intake and discharge, and one is held in reserve. The pump discharges to a 3,500-gallon settling tank with cone bottom, the settlings going to the four $\frac{3}{4}$-millimeter trommels on the side of the mill nearest the tank and the overflow to five sets of 4,000-gallon tanks. Each set consists of three tanks, the middle one being set $\frac{1}{2}$ foot above the others. The middle tank of each set receives the slime and subjects it to a partial settling, the overflow going to the tank on each side, in which it is further settled. The overflow of the outside tanks is clear water which is laundered to a 16th tank and used on the jigs. This tank also receives the water from the compressor jackets.

The tanks are tapped through goosenecks from the bottom, and the thickened slime divided between the two units, mingling with the overflow of the settling boxes below the classifiers, and thus going to tanks to be further settled and treated on the vanners.

Skimmers are set in all of the tailing launders and as much water as possible taken off, only an amount sufficient to carry off the tailing being left. This water goes to a sump in each section which also receives the drainage from the concentrate cars and a 4-inch centrifugal pump raises it to the slime tank on the lower floor. A duplicate pump is installed in each unit and held in reserve.

Three-phase, 60-cycle, 440-volt Westinghouse induction motors are used throughout. The mill is very flexible, each group of machines being under the control of a clutch, and each individual machine being subjected to control by a clutch or a loose pulley.

Following is the motor equipment for the entire mill:

Machines	Number Motors	H. P. Each	Total H. P.
4 rolls, 28 jigs, 6 elevators	2	20	340
2 conveyers, 24 trommels	2	150	
52 Wilfleys, 30 vanners	2 4	20 5	60
2 Huntington mills, 2 dewatering belts	1	75	75
1 6-inch slime pump	1	40	40
2 4-pound return water pumps	2	30	60
Total horsepower			575

The total 575 horsepower divided by 800 equals .72 horsepower per ton of ore treated per day. This is a very low figure, especially considering the elevating of water and ore that is necessary.

Hydroelectric power is purchased from the Beaver River Light and Power Co., and received over a transmission line 60 miles long at 44,000 volts. It is delivered to the basement of the power house where there are four 400-kilowatt Wagner transformers, one of which is held in reserve, stepping down to 440 volts. The current for the mine is stepped up from 440 to 2,200 volts in two 125-kilowatt Westinghouse transformers, a third being installed in the set as a reserve. The electrical equipment at the mine has been noted. The transformer room is equipped with three 44,000-volt multi-gap lightning arresters and three choke coils.

The power house was originally equipped with Babcock & Wilcox water-tube boilers, Westinghouse-Parsons steam turbo-generators, and steam-driven air compressor. None of these is in use since the connection with the electric power except one Ingersoll-Sergeant two-stage, piston-inlet compressor with a capacity of 2,000 cubic feet of free air per minute. The valves have been taken out of the steam cylinder of this and the flywheel belted to a 300-horsepower Westinghouse induction motor. The air is taken to the mine in a 6-inch line.

Owing to slight changes being made in the mill from time to time and that pending the final adjustments the lower grades of ore are being worked, a statement of the cost of production of copper is not advisable at the present time. The mining system seems to be a desirable one for the ground encountered, as it is cheap and safe, accidents being of rare occurrence. Mining costs are in the neighborhood of 90 cents per ton on a daily output of 800 tons. Miners are paid \$3 to \$3.25, and muckers \$2.50 to \$2.75. No timbermen are employed. The mill provides for a thorough working of the ore, but the equipment has been so modified since it was first installed that it does not suit the building and is the cause of some inconvenience. Mill men are paid \$3 to \$3.25 per day, and milling costs about 50 cents per ton.

During the month of January the mill treated 22,090 tons of ore, a little more than 700 tons per day. Concentration was at the rate of 10 tons into 1, 2,091 tons of concentrate being shipped. The extraction approximates 70 per cent. and the value of the concentrate 10 per cent. copper with 1 to $1\frac{1}{4}$ ounces silver, and \$1.25 to \$1.50 gold. During December and January the production was 380,000 pounds per month, but this will be increased as the better ore is treated. The figures given above show the very low grade of ore being milled.

FIG. 4. CACTUS CLUB

A considerable dump of tailing has accumulated and as the winds are high in Wah Wah valley they have caused a natural concentration of the surface so that for a few inches in depth an average of several samplings shows considerably better than 1 per cent. copper. A 24-inch haulage road has been laid to the dump and 1-ton cars can be hauled to the mill by means of a small hoist. In this manner 100 tons of ore already crushed can be delivered per day.

Newhouse was the first "company town" built in Utah, and was made necessary by the fact that the mine is situated at the edge of a desert basin which has no other interests. The town contains 42 cement-finished three- and four-room houses, 30 two-room houses, two boarding houses, cement store building, club house, and opera house. Employes of the company are eligible to membership in the Cactus Club, Fig. 4, upon payment of an initiation fee of 50 cents and monthly dues of 25 cents. This gives the privileges of the reading room, piano player, billard room, and bar. Out of its profits the club has built one of the boarding houses and the opera house. A free dance is given every week and other entertainments from time to time. It has done much to make the place, which is in an out-of-the-way spot, attractive to those who are called upon to live there.

The future of the company seems to depend on its being able to handle a considerable quantity of a reasonable grade of

ore. The mining and milling can be done cheaply, but on the ore so far treated the most economical management could hardly more than break even. So far only the lower grade has been treated, as it has been desired to hold off the better until the mill is in shape to do its best work. The entire force in mine, mill, and office for the present output is 225 men, which compares with 400 under the method of square-set mining. If the mill will stand it, 1,000 tons can be treated per day with only a small increase in the force, and it would seem that a good profit should be made on 2-per-cent. ore.

The writer wishes to acknowledge the courtesy of E. H. Lundquist, general manager, Rollin Madison, mine foreman, and Joseph Bruner, mill foreman, as well as all other employes from whom information was sought.

CANADIAN MINING INSTITUTE MEETING

The thirteenth annual meeting of the Canadian Mining Institute, held at Chateau Frontenac, Quebec, March 1, 2, and 3, was an intellectual function, with an elaborately staged and strictly adhered to program. Probably all members have received or read perfunctory accounts of this meeting; therefore these, our impressions, are indited to those unfortunates who missed connections. We missed connections for Quebec at Montreal, and then a strange thing happened, unheard of in the states; namely, the station agent had our ticket transferred from the Grand Trunk to the Intercolonial, so that Quebec was reached in daylight. Expecting to cross from Levis to Quebec in a sleigh or ice boat we were disappointed to find less ice in the St. Lawrence than in the Hudson at Albany. During the day we were present at a dozen or so wedding parties, probably missed as many more, and were coming to the conclusion that Quebec was the most marriageable place on earth, when some one said it was the last day for weddings.

The people of Quebec, anticipating our arrival, held their first "Mardi Gras" on Tuesday evening; at least this was the impression, for most all the townspeople were in the parade, and we were the observers.

On the morning of Ash Wednesday the members were welcomed to Quebec by the authorities, requested to ride on the street cars free, and to become guests at the Garrison Club; all of which courtesies were accepted with pleasure, although it is feared the members lacked time to fully appreciate them. After listening to President Adams's pleasing address, the opening session adjourned until evening.

Wednesday afternoon the members went to Montmorency Falls in a snow storm and found the falls frozen inactive; this, however did not reflect on the excursion committee's ability to pack us in a three-story lean-to and have us lifted 250 feet perpendicular at an angle ± 100°. Arriving at the top, the committee introduced us to Foxen and Polar bears, but not to the rosy cheeked damsels who were snowshoeing. Then, thinking some in the party were not keeping Lent, ushered us into an excellently appointed club house, where they warmed the cockles of our hearts. To return to Quebec it was necessary to take that three-story house with us, and this was worse than going down a 1,200-foot shaft in 12 seconds, on account of our anxiety for the safety of the ladies in case the rope broke. The following day was devoted to business, and the night to funny business.

Professor Kemp gave an illustrated lecture on glacier climbing. It is not exaggeration to state, after seeing his illustrations, that with "suckers" on his feet we believe he could outclimb Cook and beat a fly walking on the ceiling. The man who believes photographs are truthful reproductions should listen to Professor Kemp's lecture on agriculture and land agents. While his remarks were true of some land agents, his illustrations were preposterous. After some singing, Mr. Smith attempted to recite "Hetty McEwen," but either he forgot his lines or he is too emotional for such staging. Doctor Day took his place and sang 20 verses of "I Gave Her Kisses One, Kisses One, So I Kept a Kissing On." Just before Mr. Miller was sued for breach of promise some one had the hardihood to sing "Landlord." It was quite sad to hear the lawyer for the Crown malign, and the jury fine, Mr. Miller; but if any one thinks all the grafting is done in the United States he should have heard Justice Penhale settle the dispute over the fine. The breach of promise did not get a thing except a glass of beer every time she fainted, which was quite often, unless it was a revengeful thrill at the way the culprit was abused. Friday, in addition to the regular program, Doctor Douglas gave an illustrated lecture on earthquakes, and G. C. Rice an illustrated description of the Pittsburg Testing Station. The evening was devoted to the banquet, which was not a Lenten festival. Colonel Penhale presided with rare judgment and theoretical precision. We say theoretical, for while he rang the bell on time, he could not stop the acceleration the speaker had acquired in the interval. Among the songs at the banquet was "Drill Ye Terriers Drill," "Are Ye's Ready," "Then Let Her Go," "Fire," "Bang," "All Over." This song occupies the same important place in ore mining that "Down in a Coal Mine" does in coal mining. In the rendition of either of these classics, the listener, if possessed with an ear for harmony, can frequently detect a load of "pathos."

While it was understood that some Yankees would attend this meeting, nevertheless, as a comparative stranger who had never tested the sociability of Canuck engineers, there was a certain anxiety, which proved needless, for the good fellowship so universal among real mining engineers in the States sat on the brows of the Canadians like a halo.

"Oh, we're all frank-and-twenty
 When spring is in the air;
And we've faith and hope a-plenty
 And we've life and love to spare.
And it's birds of a feather
 When engineers get together."

On Saturday morning Messrs. Constant and Garrison, while leading a personally conducted exploration party through old Quebec, discovered the "North Pole."

The statesmen present were James Douglas, Frank L. Nason, G. C. Rice, Walter R. Ingalls, F. L. Garrison, A. R. Ledoux, David T. Day, H. C. Constant, Heinrich Ries, C. H. Richardson, J. F. Kemp, Eugene B. Wilson. There were others whose names unfortunately have escaped the writer.

WORLD'S PRODUCTION OF ZINC IN 1910

M. M. Rudolf Wolff, Kreuger & Co. give the world's production of zinc for the last 3 years as follows:

	1910 Tons	1909 Tons	1908 Tons
Belgium	169,998	164,511	162,189
Silesia	138,100	140,625	138,092
United Kingdom of Great Britian	86,262	79,152	72,874
France	50,586	49,237	48,701
Roumania	60,876	58,799	53,586
Holland	20,661	19,233	16,983
Poland	12,500	12,926	13,941
Austria	13,200	13,146	11,889
Spain	6,440	6,011	6,263
Italy			75
Total Europe	558,623	543,646	524,593
Australia	600		1,169
United States	238,770	239,478	183,040
Total production	797,993	783,124	708,802
Average price in London	23-0-0	22-3-0	20-3-6

DEVELOPMENTS IN CYANIDE PRACTICE

Written for Mines and Minerals, by Percy E. Barbour

Mechanical Improvements Permitting the Application of the Process to Different Kinds of Ores

Chemically the cyanide process has changed little since the Forrests and MacArthur completed their elaborate and comprehensive experiments. It is true that much importance attaches to the discussion of the varied chemical formulas and practices, but the strength of the cyanide solution to be employed is still a variable, due to the ore, local conditions, and the personal equation; the comparative merits of potassium cyanide and sodium cyanide, the importance of and the relative amounts of lime and acetate of lead to be used, are all the subjects of more or less discussion. But mechanically the developments have been so great that it may be said that, were it otherwise, the cyanide process would today be only applicable to a few especially favorably adaptable ores.

The treatment of slime is the most important matter in the cyanide process today. A mill built 10 years ago at a cost of nearly $500,000 was a total failure on account of the large amount of slime produced, which could not be treated economically. Five years later the slime problem seemed so simple, in view of then recent developments, that the filter press was applied as the solution of the problem. Today, 5 years later still, there is only one wholly filter-press plant of any size in the country, and it is unlikely that it would be duplicated if an increased capacity were desired, although the working costs are satisfactory.

While previously it was the cyanide millman's main object in life to make the minimum amount of slime, the best practice today is to slime the entire product. Slime is generally considered the product which will pass a 200-mesh screen. No one machine has yet been devised which will economically reduce the ore, as it comes from the mine, to slime in one operation.

Eliminating the discussion of the preliminary crushers, the point where the slime first appears as a quantity to be dealt with is taken up in this article. This will be after crushing to

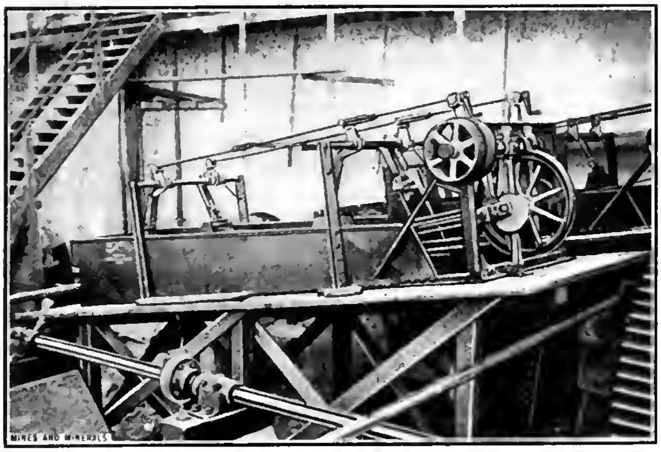

Fig. 1. Dorr Classifier

a 16- or 20-mesh screen, because when crushed this fine, almost every ore will make considerable slime. Various modifications of the hydraulic cone classifier have been used at this stage of the treatment to eliminate that material which has already attained the desired fineness. The latest machine for doing this, and one which is being very widely adopted, is the Dorr classifier, described in June, 1908, issue of Mines and Minerals. The machine shown in Fig. 1, can be set so that the discharge will fall into the feed-hopper of a tube mill, thus the amount of mill head required for hydraulic classification is reduced to a minimum. The machine requires no addition of clear water, as do the cone classifiers, thereby effecting a large saving in the water consumption. It makes a clean sand and a slime at one operation, is cheap, consumes little power, and requires no attendance. At the 600-ton mill of the Goldfield Consolidated there are 6 double-rake classifiers which discharge into the

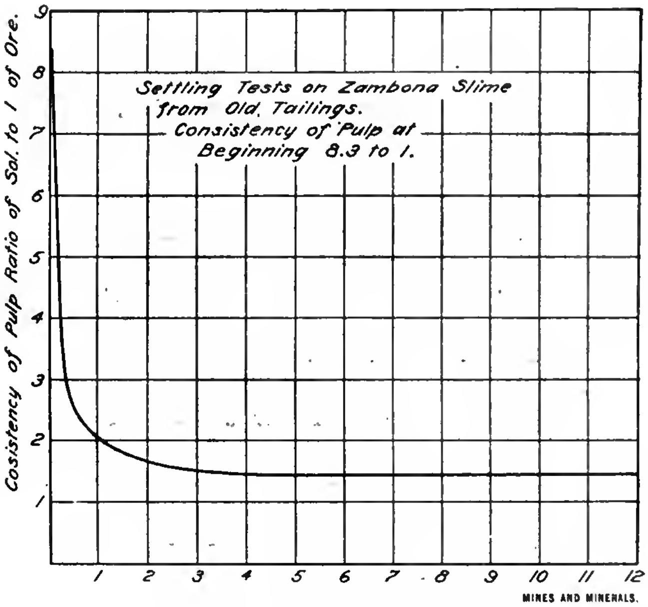

Fig. 2. Settling Tests on Zambona Slime

tube mill feed-hopper. Each machine handles 65 to 70 tons of battery sand per day, 16-mesh and under, and delivers to the tube mills a sand free from slime and containing the proper quantity of moisture (30 per cent.) for efficient tube-mill work.

Tube milling presents one of the most interesting, most anomalous, most complicated, and perhaps least understood of any of the mechanics of the cyanide process. It is by no means mysterious; but the matter of testing and comparing various types of tube mills involves such complications and often such dissimilarity of conditions that the tube-mill field is one of the broadest and most interesting for the technical investigator. A tube mill consists of a cylindrical steel shell from 4 feet to 6 feet in diameter lined with some hard tough lining. The mill usually revolves on hollow trunnions, one of which forms the inlet and the other the outlet for the pulp product. Danish flint pebbles are charged into the mill, and these falling and rolling on each other and on the tube-mill lining as the mill revolves, crush the particles of ore in the thick pulp in which the pebbles work. The efficiency of the tube mill is the measure of the slime produced per horsepower consumed; but this imposes the most unfair relative conditions for judging the comparative merits of two tube mills in different localities. For example, tube mills at the Black Mountain mill in Sonora, Mexico, treat an ore which is soft and crushes almost like volcanic ash, while the Goldfield mills treat a hard quartzose andesite. A comparison of daily tonnage through these different mills is obviously both unfair and misleading, as one ore is soft and the other is hard, the one requiring a short mill and the other a long mill. Until some better method of classifying conditions and comparing results is devised, the comparison of types of tube mills except when operated on the same ores at the same time will always be open to discussion.

The size and proportions of tube mills are for the same reasons disputative subjects. With an ore which slimes easily, the necessary fine grinding may be accomplished in the first 10 or 12 feet of the mill; with a harder, tougher ore, a 22-foot mill may be required in order to give more pebbles sufficient

time to work on the sand. The proper diameter of the mill is likewise a question. One of the most prominent manufacturers of tube mills says: "The small-diameter mills are very inefficient." As the results of a series of tests on mills of three different diameters, running side by side on the same ore and under the same conditions, an engineer of standing reports "the efficiency of a tube mill is inversely as its diameter." The

Fig. 3. Pachuca Tanks

speed of a tube mill is fixed within narrow limits. If run too slowly the pebbles simply slide on the lining, causing excessive wear and giving poor grinding effect. If the speed is too high the pebbles are held against the shell by centrifugal force and no grinding is accomplished.

An extensive series of tests* conducted at El Oro, on three tube mills of the same make, but of different diameters and different lengths, led to the following conclusions:

"The efficiency increases proportionately to the amount of pebbles contained in the mill."

"The efficiency increases with the coarseness of the sand fed to the mill."

"The efficiency decreases proportionately to the rate of feed."

In a paper† on the "Economics of Tube Milling" are given results of working tests on tube mills 5 feet diameter by 23 feet long, made at the Colorado Springs plant of the United States Reduction and Refining Co. These tests demonstrated that the greatest grinding efficiency was obtained with these mills when the pebble charge was 19,000 pounds. With a pebble charge of 25,000 pounds the amount of fine grinding was increased, but at the expense of a disproportionate increase in the horsepower required. With 19,000 pounds of pebbles the charge filled the tube to within a few inches above the center line. The percentage of solution to ore in the tube-mill pulp was varied, and it was found that both the amount of fines made and the amount of power required was affected. It was demonstrated that when the amount of solution in the pulp reached about 35 per cent. the best and most efficient work was done. This is in accord with other good tube-mill practice and it is on account of this that the Dorr mechanical rake classifier is such a satisfactory machine to dewater and classify the pulp before it is fed to the tube mill.

The Hardinge conical mill is a new type of grinding mill, a competitor of the tube mill, which is attracting attention. This mill consists of a short cylindrical section with conical sections of different lengths at each end. The cylindrical section is of considerably larger diameter than the tube mill which it is designed to replace. The most important claims for this conical mill are that "it has three times the capacity for the same power, requires one-fifth the pebbles, and has less wear on the pebbles and lining." Unfortunately this mill has not yet been tried extensively enough to provide accurate data, especially as to fine grinding, to thoroughly establish these claims. The most unique claim made for this mill is that it classifies its pulp and its pebbles, so that the larger pebbles work on the coarse sands and the smaller pebbles work on the fine sands. This is claimed to be a most efficient natural selection. (But the idea of natural phenomena in this machine working so beneficently in the right direction makes one stop and ponder over the almost human cussedness of some of the other machinery about the mill.) That the larger pebbles and the coarser sands tend to remain in that portion of the mill with the larger cross-section can be seen from a glass working model of the mill. It is undoubtedly true that a plain cylindrical tube mill would not give this sorting action when working dry, but it is also true that in a tube mill there is a certain amount of similar classification due to the action of the current of pulp through the tube. This is evidenced by the small worn pebbles which are found at the discharge end. There seems room for a reasonable difference of opinion as to the relative merits of having the finer sands worked on by smaller pebbles. But for grinding where 100-mesh is sufficiently fine the Hardinge mill has shown some astonishingly good results. It has not been tried out sufficiently for sliming to give the desired amount of data, and 100-mesh is not fine enough for the subsequent slime treatment.

In the Colorado tests referred to, the mills were started with a charge of only 3,000 pounds of pebbles and the required horsepower was 18.8. The power increased in almost exact proportion to the amount of the pebble charge, until the latter had reached 23,000 pounds, which filled the mill much fuller than even poor judgment would dictate. It would seem natural that the power consumed should increase thus with the added pebble load revolved, and this would seem to apply to the conical as well as to the tube mill. So that in this respect they would seem to be on the same footing. With these Colorado tests showing an increasing efficiency with the addition

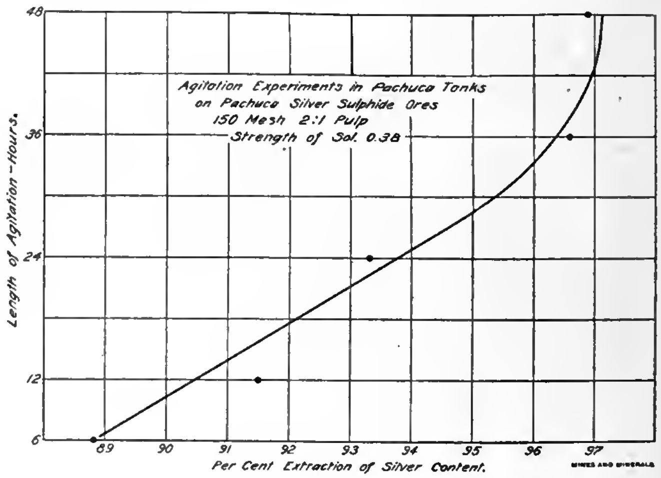

Fig. 4

of pebbles, from the initial charge of 3,000 pounds to a charge of 19,000 pounds, it would appear that the smaller charge of the conical mill must have an efficiency per pound very much in excess of the tube mill in order to give a greater relative efficiency, and very much greater than might naturally be expected.

The product from the tube mill is generally not of a wholly uniform grade, especially if the machine is being pushed a little for tonnage. The result is that a portion of the product needs

* "Fine Grinding of Ore by Tube Mills and Cyaniding at El Oro, Mex. Trans. A. I. M. E., Vol XXXVII.

† Mines and Minerals, June, 1908

to be reground. Therefore a classification is necessary. If the pulp from the grinding mill is as thick as it should be for the best grinding effect, it emerges too thick for classification without the addition of further water. Therefore this product is classified, usually in hydraulic cone classifiers, the slime going direct to the slime-treating department and the sand being returned to the tube mill for regrinding. If the head is not too great the sand is most easily and economically elevated to the tube-mill feed by means of the Frenier spiral pump, made of light sheet steel with sheet-steel discs forming the sides of the pump wheel. This wheel revolving in a hopper to which the coarse pulp is supplied, scoops up the pulp and forces it around through the spiral channel toward the center. When it reaches the center it emerges through the hollow trunnion, then through a flexible joint and thence to the delivery pipe and to the point of discharge. While this pump is very satisfactory for handling fine pulp, it has its limitations. The head against which it will work varies from 14 to 20 feet, depending upon the material handled and upon the altitude of the locality. Heavy coarse pulp is not a material to which this pump is adapted.

During the classification of the pulp subsequent to the tube milling the addition of classifying water has made the pulp too thin for cyaniding. The overflow from the classifiers also contains too much water, these two overflows are therefore brought together and are dewatered. The old style conical-bottom settling tank with its filling, settling, decanting, discharging, and flushing, and then a repetition of the cycle, is fast being relegated to abandoned practice. A continuous pulp thickener is displacing the old intermittent method. Present practice decrees that the pulp when submitted to the action of the cyanide solution shall have a consistency of about 1 : 1½ or 1 : 2. The Dorr continuous slime thickener has been developed for this particular service, and was fully described in September, 1909, Mines and Minerals. The capacity of this type of thickener depends upon the nature and density of the slime feed, and the amount of moisture desired in the thickened discharge. A tank 35 feet diameter by 12 feet deep, fed with as much thin slime as the tank would take and give a clear overflow, discharged 285 tons of thickened slime per day, containing 39 per cent., or 111 tons, of dry solids. At the Liberty Bell mine, in Colorado, a tank 33 feet diameter by 10 feet deep, fed with a pulp containing 120 tons of solids to 660 tons of solution, discharged at the bottom a thickened slime containing 120 tons of solids to 288 tons of solution, or a 1 : 4.2 pulp. The vertical shaft with the plows made 4.8 revolutions per hour and required .14 horsepower. Three tanks equipped with the thickening mechanism had the capacity of five of the same tanks used in the old intermittent method and made a considerable saving in the amount of labor required. At the Goldfield mill, thickeners were installed to handle the pulp from the agitators which contained 2½ tons of solution to 1 ton of dry slime and they discharged a thickened slime containing only 35 per cent. moisture. This is an example of the successful working of the machine over a wide range of conditions, delivering a pulp containing from 35 per cent. to 61 per cent. moisture. Except in the case of an extremely argillaceous slime, a long settling period is not necessary, and the old intermittent method ties up capital in equipment and in product without adequate return. The curve, Fig. 2, shows the results of a 24-hour settling test on a slightly argillaceous slime from ores at the Zambona mine in Mexico. During the first 2¼ hours readings were taken every 15 minutes, then every half hour until 6 hours had elapsed, after which only two readings were taken during the remainder of the 24 hours, no difference in the slime settling being noticed. During the first 30 minutes the consistency of the pulp increased in an almost straight line from 8.3 to 1 at the start, to 2½ to 1. From this point to a consistency of 1½ to 1 at the end of 3½ hours more the curve is very regular; after this point the curve for the remainder of the 24 hours is a straight line. It is obvious from this curve that the slime settled all that it would in 4 hours. At the end of 2 hours the slime had settled to a consistency of 1.7 to 1, which is perfectly satisfactory pulp to go to the cyaniding department, and also it had reached the limit of time which could profitably be spent settling it.

The Callow tank has justly come into considerable repute as a dewatering device for concentrating mills. This tank consists of an inverted conical shell of steel with a gooseneck discharge spout at the apex. The pulp is fed into the center of the now upturned base of the cone through a small cylindrical funnel which is only long enough to discharge the pulp below the top surface of the solution in the cone. The slime settles to the apex and flows continuously through the gooseneck while the clear water containing practically no slime overflows the rim into a launder connected with the water storage tanks. At the Goldfield combination mill during a test of concentrating machines the following data were obtained from the Callow tank: Flow to Callow tank, pounds per minute, 137.7; dry solids to Callow tank, pounds per minute, 16.36; water to Callow tank, pounds per minute, 115.5; overflow in clear water in per cent., 48.15; per cent. of solids in discharge, 22.62.

The pulp having the desired fineness of 200 and the desired consistency of about 1½ to 1 or 2 to 1, it is ready to be cyanided. One of the two devices which has made economical slime treat-

Fig. 5. The Oliver Filter

ment possible is the Pachuca tank. Like many other things extremely simple, its introduction was radical, even though its present form is the result of development. Agitation and aeration of the pulp had been tried by means of many different methods and devices, but without accomplishing the desired results commercially, until Brown, of New Zealand, built and experimented with a high tank of relatively small diameter equipped with an air lift. This tank, known in Australasia as the Brown tank, was soon introduced into Pachuca, Mexico, where it was developed so rapidly and adopted so widely that it has become known in this country and Mexco as the Pachuca, tank shown in Fig. 3. It consists of a plain cylindrical steel tank 13 feet diameter by 55 feet high. Inside the cylinder, extending from within about 30 inches of the top to within about 18 inches of the bottom, is a tube 18 inches in diameter, open at both ends. At the bottom of this tube is a small pipe through which is furnished compressed air. The tank is filled with pulp to the top of the tube or within 30 inches of the top of the tank. Compressed air at a pressure of 22 to 25 pounds per square inch is admitted at the lower end of the 18-inch tube, and by expanding carries the pulp up through the tube where it is discharged into the tank proper. The operation is continuous so long as the compressed air is supplied, in fact it is the old principle of the air lift and ejector applied in a rather

novel way. The result of this operation is a perfect agitation during which every particle of this slime is afforded the most intimate contact with the cyanide solution. The advantages or disadvantages of aeration as affecting the cyanide itself are a somewhat mooted question, but it has been found that by increasing the height of these tanks and thus increasing the aeration the cyanide consumption is lower than in tanks only moderately high, and very much lower than in low tanks. A tank 13 feet diameter by 55 feet high will hold a charge of about 100 tons of dry slime in a 1½ to 1 pulp. The free air required varies from 4 to 6 cubic feet per minute at an expenditure of about 2 horsepower. The time of the agitation depends upon the kind of ore and the economic point of extraction, because beyond a certain point it does not pay to increase the extraction even though it is mechanically and chemically possible. From experiments made by Grothe and Carter, of Mexico City, results of which have been given by them, the curve shown in Fig. 4 has been plotted which shows strikingly where the economic point was reached on the ores under treatment in this particular case. The curve is a straight line during the first 27 hours of agitation, during which time the extraction was in direct proportion to the length of time of agitation. After this the curve turns up very steeply, and the point at which the profitable extraction ceases is easily determined from the known conditions at the camp where the treatment is to take place. So far as known to the writer, there are only two installations of the Pachuca tanks in this country, at the Goldfield Consolidated, in Nevada, and at the Gold Roads, in Arizona. These are the only large cyanide plants erected in this country since the Pachuca tank came into vogue.

The second important improvement in the mechanics of the cyanide process is the perfection of the vacuum filter. Without it most of the low-grade ores would still be impossible of profitable treatment. The first type to come into successful practice was the leaf filter, as exemplified in the Butters. This filter consists of a number of leaves made of thin wooden frames covered on both sides with cocoa matting and canvas, the space between the canvas sides being connected with a vacuum system by piping through the top of the frame. These leaves are suspended in a tank into which the cyanided pulp is discharged. The problem now is to extract from this pulp all the gold-bearing cyanide solution. When the tank is filled with pulp so that the filter leaves are immersed the vacuum pumps are started and the gold solution is sucked through the filtering canvas and matting and is discharged into a gold-solution storage tank. The solid particles of the pulp adhere to the sides of the leaves forming a cake of slime. This process continues until the cake has reached a thickness beyond which it is not economical to continue. This thickness is from ¾ to 1½ inches. The pulp remaining in the tank is then drawn off and the tank filled with a weak solution of cyanide. During these operations a sufficient vacuum is maintained to prevent the cake from falling off the leaves. The weak solution is now drawn through the cake and is discharged into weak-solution storage tanks and the filter tank is filled with wash water. After the cake is thoroughly washed and the wash water remaining in the tank drawn off, the slime cake which is now more or less barren is discharged to the tailing dump. This tailing carries ordinarily about 30 per cent. wash water, whereas had the cake been discharged at the point where the drawing off of the gold solution was completed, this 30 per cent. moisture would have been the gold solution. Thus the advantage of washing the cake is clear.

The Moore filter process is similar to the Butters, except that instead of the filter leaves remaining in the tank with the filling and drawing off of the pulp and the various solutions, the Moore leaves are arranged in nests which are lifted from one tank compartment to another containing, respectively, pulp, wash solution, and wash water.

There are several modifications of the vacuum filter, but the one which at present is making greatest strides in application, due both to its efficiency and remarkably low first cost, is the Oliver continuous vacuum filter. The intermittent feature of the other processes is of course objectionable.

The Oliver filter, whose operation is continuous, has given astonishingly good results, is simple to operate, and requires probably smaller initial investment than any other. It consists of a large drum 11 feet 6 inches diameter by 8 feet wide, with open heads, mounted on a light cast-iron spider, as shown in Fig. 5, and is about two-thirds submerged in a wooden tank into which the pulp flows continuously. The drum makes a complete revolution in 5 minutes. It is covered with canvas and other filtering material supported by light framework within the drum. The circumference is divided into sections which are connected by pipes which lead through the hollow trunnions of the drum, by which it is supported and revolved, to the various pumps. Through that portion of the drum's surface which is submerged the gold solution is drawn by the vacuum pump while the slime cakes on the canvas cover of the drum just as on the leaves of other vacuum filters. As the drum revolves and a section emerges from the pulp the excess solution in the cake is drawn through and as this section reaches a point near the top of the path of revolution it encounters a spray of wash solution. At this point an ingenious automatic valve prevents the wash solution from mingling with the gold solution, each solution going to separate storage tanks. The section of the drum passes from the weak-solution wash to another spray of wash water and then just before it is about to be again submerged in the tank full of pulp a scraper fixed against the drum cleans off the now practically barren cake of tailing which drops into a hopper and thence goes to the tailing stacker. With the Oliver filter, the solutions are kept as separate as in any of the leaf filters, the tailing is as clean and carries as little moisture as in the other types, and the tailing is removed from the filter by a mechanical scraper.

The precipitation of the gold from the solution by means of zinc is the *sine qua non* of the process. Where formerly zinc shavings were used, now zinc dust is employed with very different equipment and results. At one time the precipitating room contained a series of boxes filled with zinc shavings through which the solution flowed. Now the zinc is fed in the form of dust to the gold cyanide solution before it is pumped to the precipitating plant. During its course through the pump it becomes intimately mixed and the pipe line is made sufficiently long to furnish time for precipitation to become complete while the emulsion is traveling through. The emulsion now consists of a barren cyanide solution in which the gold precipitate is in suspension, it is therefore delivered to filter presses from which the barren solution flows continuously while the precipitate is collected in the press in the form of a cake. At regular intervals the filter presses are opened and the cakes removed, melted down, and refined. By this method the gold precipitate is always locked up in the presses where it is perfectly safe. This filter press consists of a series of triangular cast-iron frames about 3 feet on the edge by 1 inch thick, supported on horizontal guides and clamped together by means of long longitudinal rods. Between these cast-iron frames are sheets of filtering canvas through which the solutions pass and between which the cake of gold precipitate accumulates.

This method of zinc dust precipitation is patented by C. W. Merrill, of the Black Hills, S. Dak., and the filter press used is his adaptation of the ordinary filter press used for clarifying mill solutions.

Mercury is produced in the district of Bachmut, state of Ekaterinoslav, Russia, from three mines belonging to the Auerbach company. From 90,000 metric tons of ore mined in 1910 360 metric tons of mercury was obtained. This ore according to the figures, carried but .88 pound mercury per ton, if all was recovered; a practical impossibility.

UTILIZING ZINC TAILINGS

Written for Mines and Minerals, by Lucius L. Wittich

In the Missouri-Kansas-Oklahoma zinc and lead district, more than 95 per cent. of the material taken from the ground and run through concentrating plants is waste, so far as metallic value is concerned, but the growing demand for concrete as building material is creating an ever-strengthening market for the mining waste, for it has been determined that the mining gravel, when properly mixed with sand, cement and water, forms a concrete that will wear indefinitely.

Business Development by Which Tailing and Refuse from Zinc Mines Are Used for Concrete

The present-day evolution of the tailing pile is illustrated by comparing the tailing pile, Fig. 1, and the structural framework of the modern Joplin, Mo., business block, Fig. 2, that was mostly made from it. The use of the mill waste in the $80,000 Union station is more in evidence than in the construction of the business block, for the concrete mixture constitutes the exterior walls of the structure, while in the business block, the framework will be covered with pressed brick and cut stone, and therefore will not be visible.

In the mining industry the necessity of reducing waste is paramount, and in the Joplin district the ore producers are awakening to the commercial value of mining debris that was regarded as almost worthless.

Perhaps no material used in modern construction has attracted the attention of the general public as has Portland cement, which forms the chief ingredient of concrete. The possible uses of this latter material are yet unknown.

Enormous heaps of waste tailing and veritable mountains of flint and lime boulders have accumulated since the first mining plant of the Joplin district was launched into operation back in the early seventies. During the last year alone, 14,000,000,000 pounds of material came from the crushing plants, exclusive of millions of tons of boulders that were not milled, and of this enormous tonnage that actually passed through the mills only 700,000,000 pounds were zinc-blende and lead. In other words, about 5 per cent. of the district's mill production was ore, while 95 per cent. was what might be termed waste, although much of this waste has played its part in beautifying the prosperous cities of Oklahoma, has been built into bridges and viaducts in Arkansas and Nebraska, and has helped build modern office structures and stations in Missouri.

As ballast for railroads the mining tailing is unexcelled; and white ribbons, indicating the roadbeds, stretch for hundreds of miles in every direction from the zinc and lead district. It is possible for the traveler to leave his home in the mining district, walk down steps made of concrete, then over sidewalks in which mill tailing plays a prominent part, then over macadamized roadways of crushed and packed gravel. He will purchase his ticket in a railroad station built almost entirely of the mining waste and will board his train only to be whisked over a roadbed, level as a dancing floor through the liberal use of tailing as ballast, and over concrete arches, rigid as though hewn from solid rock, while on either side, marking the boundary of the right of way, will stretch mile after mile of wire fencing, held firmly by posts that will defy the deleterious effects of weathering—for these posts have been constructed of waste mill tailing and cement.

In the construction of the new union station at Joplin, and this formula will apply for average building purposes, 15 parts out of 22 consist of waste products from the Joplin mines. In detail the formula was: 10 parts tailing, 5 parts "Chitwood" sand (mining debris from sludge mills), 3 parts river sand, and 4 parts Portland cement. A similar formula was followed in the preparation of a mixture that went into the large business establishment shown, the conglomerate mass being thoroughly mixed and moistened and placed in molds built of boards around spirals of steel reenforcement, delicate and fragile enough in themselves, but the whole forming the framework of a structure, which there is every reason to believe, will wear indefinitely.

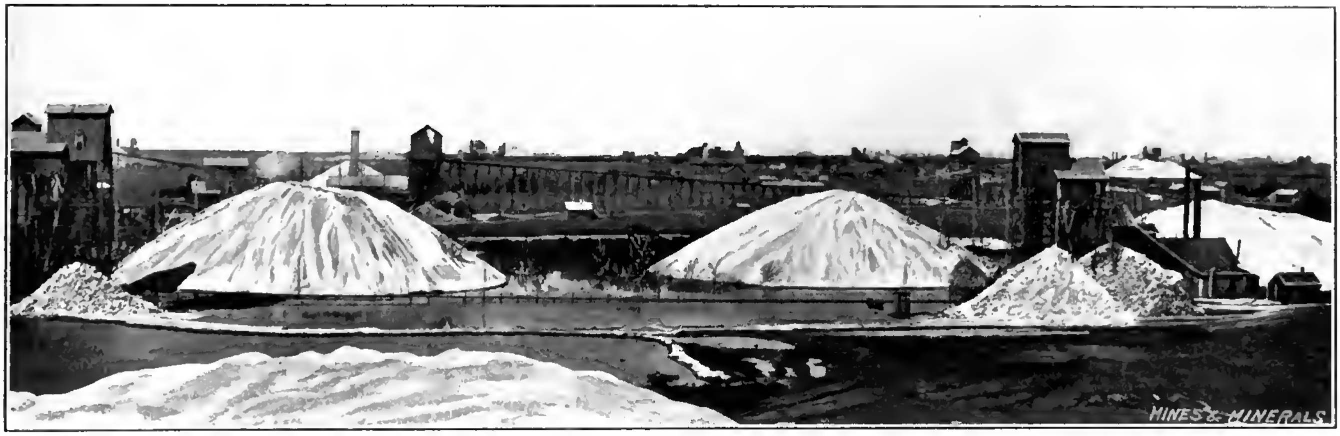

Fig. 1. Zinc Tailings That Were Converted Into a Skyscraper

For more than 30 years the Joplin district has been producing millions of tons of waste gravel annually, and thus the accumulation of this waste reaches the grand aggregate of more than 100,000,000 tons, with an estimated valuation of more than $20,000,000. In addition there are millions of tons of boulders on which it is impossible to place even an approximate valuation, but which are beginning to figure in the building progress of the immediate district, many handsome dwellings and other buildings and retaining walls having been constructed from this crude material. Boulders, glistening with calcite crystals or splotched with zinc or lead ores, are in greatest demand where an artistic finish is desired; and the effect secured from the use of such material is decidedly pleasing.

The outside demand for mine tailing has resulted in a number of "jobbers" entering the field and the new merchant or gravel wholesaler has become established. However, only those gravel heaps that are adjacent to railroads are in demand for average purposes, for the industry of shipping mining waste is yet in that stage where the supply is far in excess of the demand; hence the shipper is not forced to carry his quest far before finding the exact article that meets his requirements. Approximately 2,000,000 tons of waste mine gravel are now being used annually in building construction, railroad ballasting, road building, and in the manufacture of concrete merchandise. Yet, great as this tonnage is, it represents less than one-third of the waste mill material produced in the district in a year's

time. But the demand is growing rapidly; new industries are being created and new products composed of concrete are being manufactured; in fact, the demand for the tailing is growing much faster than the corresponding growth of the tailing production, despite the fact that each year sees an increasing production from the mines of the Joplin district. Therefore it is a question of time only before the margin between the production and the consumption narrows to a point that should materially increase the market price of the tailing.

At present, gravel for building purposes finds a ready market at prices ranging from 15 to 35 cents a ton (jobbers' figures), the average being about 20 cents a ton, which means that the district will waste, in 12 months time, a product from the concentrating plants valued at almost $1,500,000, of which only about $400,000 is reclaimed. To the producer and to the land owner the return is less, the price paid by the jobber seldom running more than 2 or 3 cents a ton in the pile, or from 6 to 8 cents a ton where the producer attends to the loading; yet this added income of approximately $100,000 is no small factor in computing the values of materials produced in the mining region in a year's time, especially when it is taken into consideration that comparatively few of the tailing piles of the district are situated adjacent to railroads or spurs, and that

Fig. 2. Concrete Building Made of Zinc Tailing

the $100,000 represents a profit gathered by comparatively few operators. It cannot be expected that the industry of wholesaling mine tailing should spring, like a mushroom, into full-fledged development in a night. Just as it required many years for the zinc industry of the Joplin district to attain recognition, so it is by degrees that the worth of the mill tailings is being realized. In the mining of metals, lead ore was the first and only metallic product produced for commercial purposes; zinc ore, known as "jack," was discarded as worse than useless; it was condemned as an impurity that penalized the value of the lead; it was discarded in thousands of tons, and for years the waste piles of the early camps were rich in purest zinc, wanting only a simple concentration treatment to convert the ore into a marketable product, especially desirable because of the choice quality of the zinc blende. And when at last a St. Louis chemist for the M. & H. Zinc Co. discovered the presence of the zinc and made public his discovery, it was only a short time before the production of lead ore took second place in the importance of the district's mineral resources; at the present time the mining zone of Missouri, Kansas, and Oklahoma is furnishing about 300,000 tons of zinc concentrates annually, compared to 50,000 tons of lead. Similar conditions have prevailed in other mining camps throughout the world. A recent striking example is found at Leadville, Colo., where the reported discoveries of carbonate of zinc deposits have recently been made.

What was true of zinc ore is now true of mine tailings. The commercial importance of the material has been overlooked up to a very recent date. The same thing is true of zinc ores carrying heavy percentages of sulphide of iron, which penalizes the zinc. Thousands of tons of iron-bearing ore are left untouched in mines, but it is not going beyond the bounds of reason to predict that within the course of a few years a new market will be created for this class of ore. Already the American Zinc, Lead and Smelting Co., the largest producing and smelting company in the district, is investigating conditions with the view of installing a Huff electrostatic separating plant, similar to the ones now in successful operation in Wisconsin and Colorado. If the company can be assured of 75 to 100 tons of concentrate per day, carrying 8 per cent. or more sulphide of iron, the plant is to be established. By-products of established value are now going to waste with every ton of Joplin zinc ore smelted. Few smelters utilize these by-products, although the aggregate value of materials going to waste will reach the hundreds of thousands of dollars annually. Among the more important by-products are cadmium, which is used in the manufacture of the finest paints; sulphuric acid, for which the demand is heavy; iron pyrites, the very material which lowers the value of the zinc and lead ores, and numerous other by-products of lesser value.

As a road-building material the merits of mine tailing have been appreciated for many years. The enterprising producer who first conceived the idea of converting the waste into macadam struck a keynote of popular progressiveness, with the result that scores of others followed his example until today Jasper County, Mo., ranks among the first counties of the state in the possession of hard, white roads that are moisture-proof, and which are as good for travel when the rain is pouring down as when the sun is shining.

The construction of concrete sidewalks, in which more than 50 per cent. of the material used is waste mine gravel, was the next step that added to the commercial value of the tailing and did more than any other one thing toward relegating to history the old-fashioned board walk of the small outlying village. Then, in quick succession, came the manufacture of concrete retaining walls, concrete curbing and guttering, and concrete skyscrapers—not of blocks but of solid mixture, welded together.

In view of the expanding field of mining operations, embracing new regions to the west in Oklahoma and to the east in the fastnesses of the Ozark Mountains, it is evident that the annual output of gravel for years to come must be enormous.

Flint and lime tailing, the former predominating, are brought from the ground and sorted, the boulders which contain little or no ore are discarded while all other material goes through sets of crushing devices and heavy rolls. Through gravity jigging the zinc blende and lead particles are separated from the chats, or tailing, which are discarded. As a certain percentage of ore, sometimes a very high percentage where milling practice is inadequate, is destined to escape in the tailing, the tailing mill has become common in the district. Here the waste from the first milling is rehandled and a further recovery of ore made. Recently, however, according to the Illinois Zinc Co., the alarming discovery has been made that tailing piles from many of the pioneer mills contain a much lower percentage of ore than when originally deposited, the deleterious effects of sulphuric acid waters intermingling with air having resulted in much of the zinc blende content being leached out. Tailing heaps, which at one time could have been retreated at a profit, have, in many instances, lost their value.

From the tailing mills, where the reclamation process is conducted without regrinding of the chats, the reworked tailings are especially desirable for use in concrete where important work is to be done, for from such tailing mills the recleaned gravel is freed from the finer particles, and the larger the individual pieces of gravel are the greater will be the demand for it in

concrete; but where the original tailings are reground in order that the ore separation may be made more perfect, the refuse is not so desirable for building purposes; but for cheaper grades of concrete, for road macadam or for railroad ballast, it still is good.

Tailing that passes through screens of ¾-inch mesh, after the finer particles have been eliminated, is used for the best qualities of concrete; from this the size of the mesh ranges down to ⅜ inch, the average of the entire district being about ½ inch. With the growth of the tailing shipping business, it is customary for jobbers to arrange with the producers for the tailing to be flumed directly into freight cars, ready for transportation. The method saves the cost of loading after the waste has been discharged from the mill; but where it does become necessary to load the gravel from heaps, various methods are employed the steam scoop shovel being widely used. Three types of this mechanical device are found in the district: the ordinary dipper, the "clam-shell" bucket, shown in Fig. 3, and the "orange peel" bucket. The "clam shell" operates at the end of a long steel beam and is different from the ordinary dipper in that it has two parts which grasp the material to be loaded, the big scoops opening like the shell of the clam after which the device is named. The "orange peel" has three shells that open to clutch the material to be lifted. Where any of these powerful machines are employed standard-gauge tracks are required, paralleling the railroad on which the freight cars to be loaded are stationed. The machines are self-propelling. Belt conveyers sometimes are employed to remove the gravel waste into freight cars, there being several distinct types of these machines in use in the district.

In the selection of tailing for concrete, color is of importance, and it is desirable to secure gravel that is as free as possible from sulphide particles, as iron sulphide and zinc blende have a tendency to leach if brought in contact with water and air. Blue or white flint particles, other considerations being equal, command the highest price; the rusty, saffron gravel, hinting of the presence of iron pyrite, is not used for building purposes if it is possible to secure the white or the blue. The sheet ground formation, as a rule, produces the best tailing as it consists of a fine-grained, deep blue, or white, chert, which when milled, separates almost perfectly from the zinc and lead ores. In mines where the ore is thinly disseminated through a big face of rock, the tailings show a tendency to be chatty, that is they are ore bearing, and if separation is made in a satisfactory manner it is necessary to grind the rock to a size which prohibits its use in concrete. Pure flint tailings are in strongest demand, although some maintain that a certain percentage of lime is desirable. The lime content should not exceed 30 per cent. Where it is desired to obtain lime for tailings that are purely flint, the stone quarries of the Carthage district, 18 miles east of Joplin, are a satisfactory source of supply. Analyses of stones taken from various places near Carthage, and some from Shoal Creek valley, near Joplin, show the material to be remarkably free from impurities. One test, for instance, showed: Silica (SiO_2) .21; alumina (Al_2O_3) .15; calcium carbonate ($CaCO_3$) 98.53; magnesium carbonate ($MgCO_3$) .88; total 99.77.

NO "SMOKE FARMERS" THERE

The Perth Amboy plant of the American Smelting and Refining Co. comprises a smelter, lead refining plant, electrolytic copper refining plant, electrolytic silver refining plant, and basic lined converters for Bessemerizing leady copper mattes. This plant refines about 7,500 tons of copper, 8,000 tons of lead, 3,000,000 ounces of silver, and 20,000 ounces of gold per month. To do this it smelts about 15,000 tons of ore and Bessemerizes about 1,500 tons of leady copper matte. Basic lined converters are the latest improvement in the metallurgy of copper.

ELECTRIC MOTORS SAVE MINE

The property of the Ernestine Mining Co. is located about 100 miles from Silver City, N. Mex., and includes ore bodies that make it one of the well-known individual holdings in the southwest. Its reputation is based upon the successful application of new methods of reducing low-grade ores, and partly upon the fact that prior to 1905 two companies had failed, with enormous financial loss, in their efforts to operate these mines.

Power was formerly generated by a Corliss engine, and distributed through belted line shafting. Pine wood, transported a distance of 10 miles on the backs of burros, at a cost of $10 per cord, is used for fuel. At some isolated points oil engines were installed, while in the mines proper, compressed air was used for operating the Ingersoll-Rand drills and also for an air-driven hoist between the upper and 800-foot levels. Acetylene gas was used for lighting.

When electrification was decided upon, Westinghouse apparatus, including generator, switchboard, motors, wiring, and lamps, were ordered complete. The generator is a three-phase, 220-volt, 60-cycle machine of 150-kilowatt capacity, and the total connected motor load aggregates 217 horsepower.

Cooper-Hewitt mercury vapor lamps were specified for the main building, metallic filament lamps for house lighting, and Nernst lamps for the company store. The excellent illumination of this store has given it the inside track in competition with

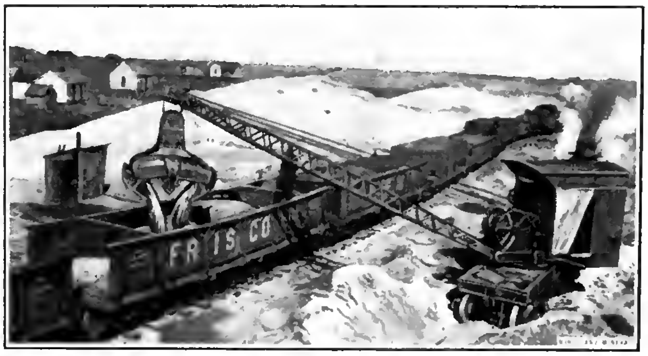

FIG. 3. LOADING TAILING FOR RAILROAD BALLAST, JOPLIN

the other stores, which do not enjoy the privilege of electric lighting from the private plant.

An incidental yet important advantage of electric drive lies in the ease with which a uniform consistency of slime can be maintained by observation of the electrical input to the pump motors. An ammeter is installed in each pump motor circuit and the reading noted under normal conditions; and change in the consistency of the slime increases or decreases the load on the motors and is quickly noted by the attendant. This plant was put into operation January 1, 1910, with the resulting improvement in operating conditions outlined below.

The tonnage has been increased by the addition of 20 new stamps weighing 1,050 pounds each and dropping 100 to the minute, replacing 20 stamps of 850 pounds each and dropping 96 to the minute. The 20 new stamps, and occasionally 10 of the old, are now run to meet the capacity of 90 tons per day, instead of 55 tons per day.

With this increased capacity and the electric drive, the power required has been increased only 38 per cent. over what the mill previously took when belt drives were used exclusively, and when the company was milling only 50 tons per day instead of 90 tons. In this increase is included the power used by the electric hoist, which was formerly air driven by an independent compressor.

The cost per horsepower year has been reduced $107.30. This results, with the amount of power now necessary to operate

the mill, in a net yearly saving in the fuel bill of $10,766. If with the increased capacity, the power per ton of ore handled were the same as with the old equipment, the yearly saving would be $13,905.

In addition to the above, the use of calcium carbide for lighting purposes has been eliminated and the gasoline engine has been replaced by a motor, making a net saving of $300 per month, or $3,600 per year.

As the electric hoist is used instead of compressed air, the total capacity of the air compressor is available for the drills, increasing considerably the amount of ore that can be mined per day, and also the amount of development work possible.

An additional interesting feature of the installation is the fact that, when the electric plant had been completed, the change from the belt to the electric drive necessitated the shutdown of the mill for only 15 minutes.

The actual result of practical value is demonstrated by a comparison of the cord-wood consumption, now and formerly. There is no increase in cord-wood consumption under the increased capacity of the mill; in other words, the company is mining and milling 35 tons per day more than formerly with no increase in fuel expense.

FINE CRUSHING WITH CONICAL MILL

The illustration, Fig. 1, is the flow sheet of a combination conical ball-and-pebble mill at a cyanide plant, and it will be noted that there is not a screen in the entire plant. The ore fed to the ball mill will not all pass a 2½-inch ring, yet this mill, installed for crushing to from 8 to 16 mesh, produced a product 33 per cent. of which passed 200 mesh, the oversize going to an 8-foot diameter conical pebble mill and 66 per cent. of its product passed 200 mesh even though the pebble mill contained a little more than one-half of its full charge of pebbles.

An interesting experiment with a ball mill was made in the presence of J. M. Callow in crushing a Butte lead-zinc ore which had all passed a Blake crusher. Steel balls were used, the mill making 32 revolutions per minute with an initial feed at the rate of 30 tons per 24 hours and a ratio of water to ore of 2.67 to 1. For comparison, a sample of the crusher run of this ore was recrushed in seven successive stages with rolls and hand screens, screening out the fines and returning only the coarse to the rolls after each screening, and the following results were obtained by the two processes:

	Once Through Hardinge Mill Per Cent.	Rolls 7 Returns Per Cent.
Held on 60 mesh	10.18	30.20
Held on 80 mesh	9.92	21.03
Held on 120 mesh	23.15	18.62
Through 120 mesh	40.32	21.34
Through 120 mesh as slime	16.83	8.81
	100.40	100.00

It will be noted that in the crushing with rolls an equivalent to seven screens was used, while in the conical mill the sizing was automatic and without any screen whatever. The latter only produced an excess of 8 per cent. as slime, which could have been materially lessened by the use of additional water or any one of three other adjustments to which the mill is adapted.

As to power and range of capacity of this smallest size of mill, the data given below are furnished by one of the largest iron companies in the world, which is testing the conical mill, grinding for concentration a very low-grade, hard, silicious, amorphous hematite: Mill used, 4½-foot diameter conical ball mill; charge of balls, 3,000 pounds; revolutions per minute, 30; power, less than 15 horsepower; capacity per hour, 7,850 pounds; size of feed, crusher product passing 1 inch; size of product, all but 2 per cent. passed 8 mesh.

The above shows considerably more than 5 tons per horsepower day, and is fully three times greater capacity than could be realized for similar crushing with stamps, rolls, or Chilian mills, and for simplicity of operation and freedom from necessity of oversight, there is absolutely no comparison.

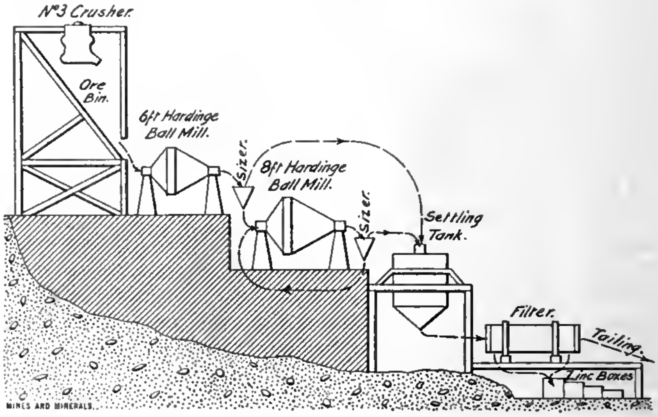

Fig. 1. Flow Sheet of Cyanide Plant

The Calumet Copper Co. is constructing three 8-foot diameter Hardinge mills that will be belt driven. Driving such large machines as these with a belt is an innovation that might be considered from the mechanical standpoint.

There is no question but that the conical mill has come to stay, in fact it has within the short period of 2 years found its way to Australia, New Zealand, Philippine Islands, South Africa, South America, Mexico, Canada, Norway, Sweden, and Belgium.

CYANIDE TREATMENT OF ORES IN MEXICO

Vice-Consul C. M. Leonard, Chihuahua

With the early completion and operation of two cyanide mills at Parral, by two American companies, that mining camp promises to renew its former activity, which for the past 3 years has been much curtailed, owing to the high cost of ore treatment and the presence of water in most of the mines.

Parral is a silver camp, the ores being silicious. Mining has been carried on there since 1640. Practically all of the mineralized ground in the district has been taken up, although many properties of much promise have not been developed. Labor is plentiful, good miners receiving only 75 cents per day, and common labor 50 cents. All values mentioned in this report are in gold.

The cost of mining and pumping is placed at $2.50 per ton. The normal output of the camp is about 25,000 tons per month, but it is conservatively estimated that this tonnage can be quadrupled with a cheaper method of treatment.

Based on the lixiviation process, the following statement shows the cost of treatment and the profit per ton: Average value of the ore, $12.50, but the percentage of extraction is only 80, reducing the net value to $10; cost of mining and milling, $2.50 and $5.50, respectively, leaving the net profit $2.

The cost and profit per ton by the cyanide process are given as follows: Percentage of extraction, 90; making the net value $11.25; cost of mining and milling, $5; leaving an estimated profit of $6.25; saving by cyanide process, $4.25 per ton.

The two American companies already mentioned are constructing cyanide mills of 300 and 400 tons daily capacity. It is expected the 300-ton mill will start in February, 1911. Much interest is manifested by mine owners at Parral in the result to be obtained by these mills, and if the process fulfils expectations other mills will be built, and many mines now idle will become good producers.

CONCENTRATION AT CALAMA, CHILE

*Written for Mines and Minerals, by F. A. Sundt**

Methods Used in Concentrating and Smelting Fine, Soft Copper Ores

The concentration plant of Humachuco belongs to the Compañia Poderosa de Chuquicamata, and is located at a short distance from Calama, Chile. It has the advantage of a branch line of the railroad. Its principal object is the concentration of the llamperas which are abundant in the mines of the company and too low grade for transportation. It produces 100 tons monthly of concentrated minerals of 17 per cent. copper and treats 16 tons daily of llamperas with 5 to 6 per cent. of copper. The concentration is performed on pyrite carrying copper and upon colored minerals, especially brochantite and atacamite. The last mentioned, which in their highest degree of purity are chemical combinations richer in copper than the iron, give a product of higher value but whose specific gravity is lower, and consequently the loss in the operation is also greater. The average loss in Humachuco reaches an average of 30 to 34 per cent. which quantity is not excessive if the low density of the concentrated minerals is taken into consideration. However great the loss may be, the method cannot be considered as a bad one. It must also be remembered that the plant in question was installed for minerals formerly considered of too low value to trêat and these products are occasionally furnishing a profit of from $4,000 to $5,000 per month to the owners.

There are 12 men employed at this plant, which has been so profitable for its owners they have accumulated a great supply of ore. This, together, with the quantities of llamperas which are thrown away at Chuquicamata on account of their low grade offer an excellent opportunity for capital.

The llamperas that can be concentrated at Huamachuco have to stand very high freight charges from Chuquicamata, being $3.05 per ton by rail, and $3.50 for the transportation in cars from the mines to the railroad.

The llamperas, on account of the matrix being easier to break than the mineral, are separated in the mines on flat or inclined bars 25 millimeters apart. The sulphide llamperas are mixed with colored ores. At Humachuco the llamperas are classified by means of revolving and cylindrical screens which give the following sizes: 25, 19, 12, 6, and 3 millimeters. The four larger sizes concentrate in screens. The product of 3 millimeters which forms the greater part is concentrated on two Ferrari vanning tables. There is a ball mill, No. 4, that works at night grinding some of the larger sizes, as the concentration of the tables is better than that of the screens. The mill produces 8 tons in 12 working hours with a screen of 2 millimeter openings. The grinding is carried on dry.

The two vanning tables treat 15 tons in 12 hours and produce 2.5 tons of concentrated minerals. No work is done at night on account of the limited capacity of the mill.

There are four screens which treat 6 tons in 12 hours and produce 1 ton of concentrated mineral.

The concentrated mineral contains sulphides and oxides of copper. The tailings from the tables, as well as from the screens, contain from 2.4 to 2.6 per cent. of copper. The tables make 120 vibrations per minute and like the screens they consume about .75 kilowatt.

The screens are made by Holman Bros., England, and do not have a filtering bottom. They are simple and have a movement of 60 vibrations per minute.

The water required for the concentration is elevated by three pumps through pipes 5 centimeters in diameter.

The power used is water. There is a wheel composed of troughs, measuring 3 meters in diameter by 120 in width. It is all made of iron and constructed at the factory of Orchard Bros., Antofagasta. It revolves 16 times per minute and furnishes 10.7 horsepower.

The cost of the wheel amounted to $1,000, and a like amount was spent in its installation.

The smelting plant of Chorrillos is situated a few minutes walk from Calama at an altitude of 2,300 meters. It belongs to the Compañia de Minas y Fundicion de Calama.† The principal business of this company is the operation of its mines at Chuquicamata, besides some other mines at Abra. Although the latter mines are not being worked, they formerly furnished the sulphur necessary in the smelter. Later on, the Chuquicamata mines produced the sulphur needed for matte in great quantities and as these mines are at a shorter distance from Chorillos, and do not contain water as do those of Abra, the preference has been given to them.

The smelters at Chorillos treat ores that average 10 per cent. copper. No poorer minerals could be found even in the midst of the desert of Chile. The Loa River furnishes the hydraulic power.

Chorrillos could have easily ranked among the great and modern copper smelting plants of Chile, for its production in previous years confirms this assertion. Chuquicamata, as it has been demonstrated before, could supply more than sufficient material to it.

The plant contains a section for copper smelting, and an installation for the conversion of matte to blister copper. There are also two tables for concentrating minerals. These two tables are considered as auxiliary to the other operations.

There is a rectangular blast furnace with seven tuyeres on each side with a crucible in the interior. Its area in the pipe section measures 3.60 × 1.05 meters. It has two series of jackets placed one above the other. The lower ones are inclined, and above the upper ones there are several meters of brickwork.

The furnace has a dust chamber of masonry resting on the ground. There are also two furnaces one of circular section and the other of octagonal section with eight lateral jackets in one series. They have only one fume pipe, dust chamber, and one metallic funnel. They have rectangular forehearths 2.10 × 1.45 meters. The furnace jackets are cooled by water.

The slag is carried away in cars of which there are five cone shaped and seven rectangular ones.

The converters are situated at a lower level than the furnaces so as to charge them by taking advantage of gravity. There are eight converters upon trunnions, revolved by hand. Four of them measure 2.40 meters in length by 1.70 meters in diameter with 14 pipes of 22 millimeters in diameter. The other four measure 2.30 meters in length and 2.17 meters in diameter and have 11 pipes. There are two converting sections. They have no fume chamber and the fumes are conducted away by means of two metallic hoods.

The three furnaces have only one air pipe. The air is delivered by two revolving blowers.

The converters are supplied with air by a Reidler compressor, having two coupled air cylinders with a diameter of 55 centimeters and a length of 1.12 meters. The compressors are water cooled.

The main furnace receives its power from a gas engine using producer gas. The engine was made by Fielding & Platt, Ltd., Gloucester, England, and has two coupled cylinders. It is a four-cycle engine with the mixture of gas and air exploded by the use of an electric igniter and is rated at 32 horsepower when making 160 revolutions per minute. The air for the starting device is compressed to 12 kilograms per square centimeter and the receiver contains a sufficient quantity for three starts. The gas producer is of the suction type using anthracite to produce the gas. It has a scrubber and a purifier. The steam necessary for the producer is made with the hot gases escaping from it. The producer requires only one man at a

* Injeniero de Minas, Professor Extraordinario de Metalurjia en la Universidad de Chile, Santiago, Chile.

† This company was formed in 1903 with a capital of £250,000. The home office is located at Valparaiso.

salary of $5 per day. The gas engine requires also a man with $7 salary per day.

The gas power is used when there is scarcity of water for the operation of the hydraulic motors which supply electric power.

The installation of the gas power plant cost $95,266.81.

There is a machine for briquetting the ore and dust, driven by belt attached to an electrical motor of 22 horsepower, 6.9 amperes, 2,000 volts, and 958 revolutions per minute.

There are two hydraulic power installations; one in the smelter, consisting of a small turbine which runs the concentrating machines, the other is the hydroelectric installation at Topater, distant about 3 kilometers. A canal from the lower river draws the water to a double turbine of horizontal axis. The turbine is of American construction, and has a capacity of 250 horsepower. It is connected by belt with a three-phase electric alternator of 2,000 volts. A man with a daily salary of $8 is sufficient for the generating station. At the receiving station, there is an alternator of 1,950 volts, 48 amperes, 180 horsepower, at 987 revolutions per minute. It drives the main shaft. These machines require a man with a daily salary of $6 and an assistant with $3. The complete hydraulic installation of Topater cost $102,015.40, according to the record in the books of the company, that is $400 per horsepower.

There are two Ferarri concentrating tables and a ball mill No. 4, with screens of 8-millimeter openings. The grinding is done dry in preference to using water.

The tables were used to concentrate the crushed quartz from the Abra Mine carrying 5 per cent. copper. The tailing composed of 85 per cent. silicon was used to line the converters. The concentrated mineral is pressed into briquets while the Chuquicamata crushed mineral with 8 per cent. copper is pressed directly.

There is a foundry containing a cupola that smelts 1 ton of iron per hour. There is a rectangular crane of 4 tons capacity. The jackets for the blast furnaces and the molds for the copper bars, as well as the castings for the converters are made here. The foundry employs 60 men.

Chorrillos smelters treat aluminum-silicate ores that require considerable coke and limestone flux. The smelting has cost as high as $25 per ton.

Limestone is obtained cheaply from the Calama quarries on the banks of the Loa. It costs $2.80 per ton delivered at the smelter and the principal work is to extract it. Chorrillos is located on a calcareous soil.

The bed of limestone on the banks of the Loa River has a thickness of from 30 to 50 meters. The limestone as a rule has a light color—yellowish and gray; is very compact and homogenous, and it is no doubt an excellent material for construction. In some parts it has a fibrous structure and is almost transparent.* It contains no more than 5 per cent. insoluble matter, and when calcined produces white lime. Quicklime is used in Chorrillos for the manufacture of briquets in the proportion of 10 per cent. to 90 per cent. concentrate and flue dust. The chalk of Calama used in the lining of the converters costs $6 per ton The clay of Lota costs 70 shillings per ton.

The gangue for the lining of the converters is quartz sand obtained when concentrating ore from San Jose del Abra It costs $24 per ton.

* Lorenzo Sundt, Estudios Geologicos y Topograficos del Desierto y Puna de Atacama, Vol. 1, 1909.

The coke has cost £3 11s. 4d. without dust, delivered at Chorrillos. The transportation charges are about 14s. 11d. Delivered at the mine. The anthracite costs £3 7s. 4d.

In 1908, 23,758 tons of ore was smelted and 1,199,660 kilograms of unrefined metal containing 590,604 tons of copper were sold. Besides, 1,319,844 kilograms of copper in bars were produced. In the first 6 months of 1909, the work at the smelters has been as follows: Smelted minerals, 13,029; unrefined mineral produced, 299,766 kilograms with 111,925 kilograms of copper; residuum, 101,112 kilograms with 37,751 kilograms of copper; bars of copper, 7,520 with 809,241 kilograms of copper; total produced, 875,317 kilograms.

The loss of copper figures 357 tons during this time, and it is considered equal to 16 per cent.

In June, 1909, the work of the smelter was as follows:

	Kilograms
Lime	990,170
Converter refuse	567,300
Oven refuse, after screening	19,950
Unrefined mineral siftings	89,100
Oven refuse	35,750
Pyrite flux	1,400,200
Sulphide, dross of metals	484,250
Light colored matte	556,400
Dark colored matte	303,550
Sulphide briquets	563,725
Clay colored briquets	250,000
Manganese flux	18,950
Total mineral	3,161,825
Coke	598,000
	Per Cent.
Lime from mineral	32.07
Unrefined mineral and dross	31.44
Coke from mineral	18.85
Coke from total	12.10
Bars	2,258

In the conversion 38 tons of Lota clay and 50 tons of chalk were used.

The converters produce 4 tons of copper. The lining is applied by hand. The clay is ground in mills, and is mixed with an automatic mixer in the same apparatus with the quartz. A very thin cloth is used to sift it. A mixture of two parts of sand and one part of Lota clay is used for the tuyeres and three parts of sand and one part of clay are used for the body of the converter.

DRIFTING RECORDS

The Vekol Mining Co., near Casa Grande, Pinal County, Ariz., is advancing a drift in hard blue limestone from the 120-foot level. The size of the drift is 8×6×4½ feet, and the working face is now about 500 feet from the shaft. The drilling is done with a Sullivan 2¾-inch air drill on a double screw mining column. Two drill runners recently had a contest to see which one could break the most rock in five shifts, with the results shown in Table 1.

Table 1

Shifts	1	2	3	4	5	Averages
Minutes to set up	26 min	16 min.	19	21	17	19.8
Number of holes drilled	11	11	12	10	12	11.2
Number of feet drilled	94	95	102	85	92	93.6
Average depth of holes in feet	8.54	8.6	8.5	8.5	7.66	8.36
Total working time	7 h. 54 m.	6 h. 25 m.	7 h. 15 m.	7 h. 10 m.	7 h. 2 m.	7 h. 9 m.
Feet of advance per shift	7′	6′ 11″	6′ 9″	5′ 1″	5′ ½″	6′ 2″

The time for setting up included the time required by the men in walking from the shaft station on the 120-foot level until the air was turned on at the drill. The total working time included setting up, drilling, tearing down, loading, and blasting. Seventy-five pounds of 1¼-inch powder were used per round of holes. A Sullivan straight-line, two-stage compressor furnished power for the drills at 110 pounds receiver pressure.

The above information was furnished by W. J. Forbach manager of the Vekol Mining Co.

THE GEOGRAPHY OF PETROLEUM

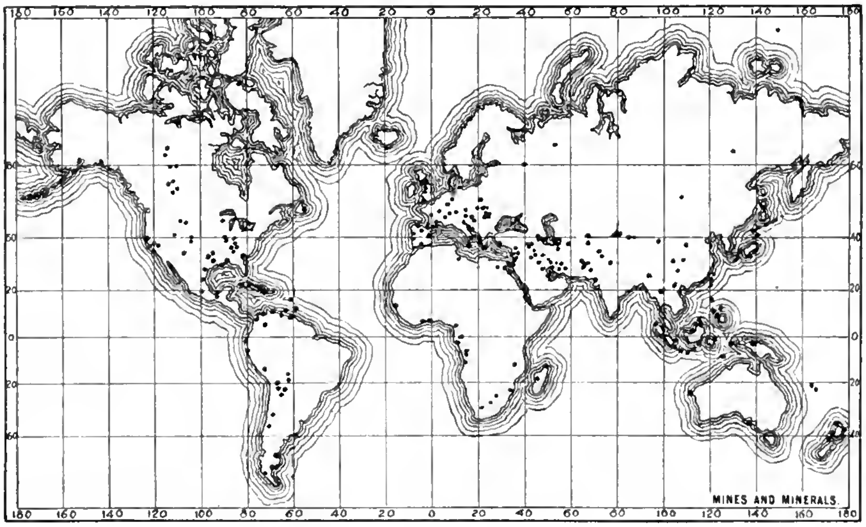
Written for Mines and Minerals

Qualities and Relative Quantities Produced by the Different Countries of the World

It is only a little more than 50 years since Colonel Drake drilled his first oil well near Titusville, Pa. While it is supposed that the Chinese antedate this discovery, the fact remains that they did not make practical use of their oil as did the Americans, for which reason the discovery of petroleum, so far as mankind is concerned, was made in Pennsylvania.

Since the discovery of petroleum, the United States has been the largest producer, manufacturer, and distributor of petroleum products, and seems destined, for some years at least, to occupy that enviable position, although there are now large quantities of oil produced in other countries. It is a strange coincidence that the best petroleum so far discovered, from a commercial standpoint, was the first discovered; and it is also a coincidence that it should be near the Atlantic seaboard so that it might be exported readily.

The first most abundant source of supply was Pennsylvania, but gradually that field became exhausted until now the first quality oil is obtained mostly from New York, West Virginia, and Ohio. This oil comes from the Devonian geological period known as the age of fishes. The next most important field, so far as quality is concerned, is known as the Lima-Indiana oil field. Before the advent of the gushers in Texas and California, this field was almost as prolific as the Appalachian field, which now includes New York, Pennsylvania, Eastern Ohio, West Virginia, and Kentucky, and will probably be further extended in time on the west side of the Appalachian mountain system. In 1896, Ohio as an individual oil producer took the lead from Pennsylvania; in 1903, California wrested the title for the most productive state from Ohio and has since continued to lead, while Ohio has been passed by Texas in 1904, Kansas and Illinois in 1906 and Oklahoma in 1907. While the Appalachian field is not now so productive as some others, the value of its oil exceeds that of the other fields individually. This is due to its nearness to the Atlantic seaboard and to the quality of its oil, which so far has seldom been equaled and never surpassed. Appalachian oil comes from the Devonian rock system, known as the age of fishes, and it is probably derived from the ancient fishes indirectly by natural chemical phenomena.



Map of World Showing Petrolem Regions

About 1885 what is known as the Lima-Indiana oil field was discovered. This field, as stated, reached its zenith about 1904 and then declined. Oil from this field carries considerable sulphur, which makes it more expensive to refine, for which reason it never did command the price of that of the eastern field, at one time its only competitor. By treating the oil with copper oxide, Mr. Frasch was able to rid it of sulphur and today it brings a fairly good price. It has a paraffin base and comes from the Trenton rock formation during which period there were large quantities of shell fish and trilobites in existence. It is probable that the oil of this horizon originated from their organisms in much the same way as the Appalachian oil was formed.

The Illinois oil field was discovered about 1889 and has been developed rapidly, being in 1909 the third most productive state. The principal oil-bearing sands belong to the upper and lower coal measures but in some places the Chester rock group of the subcarboniferous contains oil. Undoubtedly Southern Indiana will contain oil not far beneath its coal measures, and in case it does Western Kentucky will also. This statement is not made haphazardly but is based on oil indications obtained from various sources that have been submitted to the writer. The specific gravity of crude petroleum is mainly important as measuring the relative yield of light and heavy oils on distillation. The light oils, such as naptha, benzol, etc., are distilled from the petroleum at less heat than kerosene and lubricating oils. The Illinois oil, while it has a paraffin base the same as Pennsylvania and Ohio-Indiana oils, and carries less than 1 per cent. of sulphur, grades from 28° to 32° Baumé, consequently it has a low market value and oil grading so low as 28° Baumé is generally considered a fuel oil.

The production of the various states for 1910, as compared with their respective crude oil outputs during 1909, will be gathered from Table 2, the figures being in barrels of 42 gallons,

Illinois produced nearly three times as much oil in 1909 as Pennsylvania, nevertheless its total market value was but \$5,300,000 more.

Table 1 is made up from the United States Government statistics for 1909. It gives the production by states; the average price per barrel of 42 gallons during 1909; the increase in production over the year 1908 is preceded by +; the decrease by −; the per cent. of the total production from each state; the per cent. of the total value; and the total value. The Mid-continent field, which includes Missouri, Kansas, and Oklahoma, produced 49,804,922 barrels of oil in 1909, which averaged 36.8 cents per barrel and netted \$18,314,355, or practically \$2,900,000 more than Pennsylvania, with an output of 9,299,403 barrels. The oil in this field comes from the coal measures of the Carboniferous period, and while practically from the same horizon as the Illinois oil, has less market value owing to its having an asphaltic base. It varies considerably in specific gravity. The oil below 30° Baume sold for 28 cents per barrel and that above 30° B. for 38½ cents a barrel on the average. While it may be possible that location influences the selling price of this oil, it should on quality bring the same price as Louisiana or Texas oil.

The Gulf oil field includes Louisiana and Texas. Louisiana production comes mostly from the Caddo field in the northwestern corner of the state, which is in all probability a continuation of the Beaumont field.

Texas has two producing fields one termed the Corsicana or Northern Texas and the other the Beaumont or Coastal Texas; another, south of San Antonio, is not yet developed. The Louisiana oil and the Coastal Texas oil come from the Pleistocene formation of the Cenozoic period. It has an asphaltic base, but

on account of its location averaged 71.2 cents per barrel. There has been a decrease in production of about 66 per cent. in the Gulf oil field during the past 4 years. In 1905 the production was 36,526,000 barrels, in 1909 it was 11,912,000 barrels. It gained notoriety from the gushers at Spindle Top, from the oil-speculating schemes inaugurated on the strength of the gushers, and afterwards the fire which wasted the oil.

California enjoys the reputation of having the deepest oil wells in the world (4,400 feet), the greatest single producing wells, the most expensive wells to drill, and of being the greatest of all oil producers, both at home and abroad. The most remarkable well, the Lakeview, started in March 4, 1910, flowing 10,000 barrels daily; this increased to 40,000 barrels; July 20, the well declined to 31,000 barrels; July 30, to 22,000 barrels with 3 per cent. water; and in December it spouted less than 10,000 barrels and about 56 per cent. water. Mayo well came in with 30,000 barrels; Pioneer-Midway with 20,000 barrels; Union Oil Co. with 25,000 barrels; Santa Fe, 20,000 barrels; American Oilfields, 30,000 barrels; Union Oil Co., 30,000 barrels; Midway Five Oil Co., 24,000 barrels; Midway Premier, 30,000 barrels when it came in, and 2,500 barrels at the end of the year. A number of these gushers sanded and went out of business soon after being brought in. California oil comes from the Cretaceous

Mexico produced 2,288,742 barrels of high-grade oil which on the Isthmus of Tehuantepec has a gravity of 30° B. Owing to the oil war between the Waters-Pierce and the Pearson interests, 27,554,581 barrels of crude petroleum were shipped into Mexico and refined. Recent reports from Tampico,* January 8, 1911, credit that state with a well flowing 100,000 barrels daily. The well is 30 miles south of the famous Dos Bocas gusher, which was credited with a like production, then caved in, and next got on fire.

Petroleum is found in the Piura and Tumbes department of Northern Peru. Here the Lobitos, Negritos, and Zorritos districts produced 1,240,015 barrels out of a total of 1,316,118. The petroleum deposits of Lake Titicaca district in Southern Peru, near Pusi, in Huancane province, are expected to prove of more importance than those in Northern Peru.

Trinidad was prospected for pretoleum in 1909, not only because of seepages of oil and gas, but because of the success attained in Mexico in searching for oil near asphalt deposits. Oil has been found at Guayo.

Barbados contains small quantities of petroleum in connection with asphalt deposits.

In Venezuela crude oil is found in two classes according to Consul R. J. Totten.

Table 1. Production of Petroleum in the United States in 1909

State	Barrels	Average Price Per Barrel	Increase in Production	Per Cent. of Total Quantity	Per Cent. of Total Value	Total Value
California	54,433,010	$ .564	+21.35	29.89	23.92	$30,675,267
Oklahoma	47,859,218	.364	+ 4.50	26.28	13.59	17,428,990
Illinois	30,898,339	.640	− 8.28	16.96	15.43	19,788,864
West Virginia	10,745,092	1.642	+12.83	5.90	13.76	17,642,283
Ohio	10,632,793	1.244	− 2.08	5.84	10.31	13,225,377
Texas	9,534,467	.712	−14.92	5.23	5.30	6,793,050
Pennsylvania	9,299,403	1.659	− 1.33	5.11	12.03	15,424,554
Louisiana	3,059,531	.661	−47.15	1.68	1.58	2,022,449
Indiana	2,296,086	.870	−30.07	1.26	1.56	1,997,610
Kansas	1,263,764	.389	−29.86	.69	.38	491,633
New York	1,134,897	1.665	− 2.17	.62	1.46	1,878,217
Kentucky	639,016	.811	−12.20	.35	.40	518,299
Colorado	310,771	1.022	−18.14	.17	.25	317,712
Wyoming	27,887	1.655	+24.55	.02	.03+	44,478
Michigan		1.362	−62.28			
Missouri		1.362	−62.28			
Utah		1.665	+24.55			
Totals	182,134,274	$ .704		100.00	100.00	$128,248,783

system of the Mesozoic period; it is a thick heavy oil with an asphaltic base and therefore most suitable for fuel. The gravity varies from 12° to 26° B. The other states producing oil in

Table 2

Producing Field	1910 Barrels	1909 Barrels
California	74,300,000	58,190,000
Mid-continental	53,500,000	46,800,000
Illinois	35,000,000	30,900,000
Pennsylvania fields	26,000,000	25,000,000
Texas and Lousiana	14,900,000	12,500,000
Indiana and Ohio	5,000,000	6,600,000
Colorado, Kentucky, Tennessee, Wyoming, and smaller fields	1,500,000	1,700,000
Total	210,200,000	181,690,000

small quantities are Colorado, Missouri, Michigan, New Mexico, Wyoming, and Utah.

It is probable that oil will be found in other states, but quite improbable that it will be found east of the Alleghany Mountains, in states above North Carolina.

The production of oil in Canada came mostly from Ontario, but a small quantity came from New Brunswick. In 1909 the total production was 420,755 barrels worth $1.33 per barrel. Oil is said to have been tapped in small quantity at Parson's Pond, Newfoundland It is to be hoped that this is true, as that country needs it for fuel and light.

One has a specific gravity of .8837 at 15° C. and flows readily. On distillation .5 per cent. was driven off below 120° C.; .5 per cent. below 170°; 14 per cent. between 170° and 235° C. (illuminating oil); 28 per cent. between 235° and 270° (heavy illuminating oil); 51 per cent. between 270° and 370° (lubricating oil, etc.); and 6 per cent. coke. The thick oil was like tar, and gave no gasoline or burning oil.

Oil has been found in the northern part of Argentina, and in Patagonia.

Chili is said to have an oil well near Carelmapu flowing 500 barrels per day.

South America seems to have oil in almost every country, although at present is not a great producer owing to its latent development in this line.

The principal competitors of American petroleum are the Russian and Java oil fields.

In Russia the two principal fields are Baku and Grosny, on the Apsheron Peninsula, in the Black Sea. In 1909 the total production from these two districts was 65,970,350 barrels.

Recently considerable booming of the Maikop field, in Kuban province, in Southern Russia, has been carried on in London. News from this field is confined to indirect talk, apparently to keep alive the interest in the share market.

The production of petroleum in Galicia in 1909 amounted to 14,932,799 barrels, thus making this part of Austria-Hungary of importance to Europe.

*See Mines and Minerals, February, 1911.

Roumania has steadily increased its output of petroleum until in 1909 its production amounted to 9,321,138 barrels, and in 1910 there was an increase of about 25 per cent. Roumania is well supplied with refineries, there being more money in the manufacturing than the uncertain producing end. This shows the fine Italian hand of the Standard Oil Co. is being copied in Roumania, from which a cargo of kerosene was sent to America.

In 1909 Alsace-Lorraine, Prussia and Bavaria produced 1,018,837 barrels of petroleum. Italy produced 57,564 barrels in 1909; Japan, 1,879,542; and Formosa, 132,867 barrels. Borneo, Java, and Sumatra, the Dutch East Indies produced 11,041,852 barrels of petroleum and are keen competitors of the United States oil in the East.

Oil has been discovered in the Philippine Islands of Tayabas and Cebu, but has not been developed. It is high in volatile hydrocarbons, has a paraffin base, is free from sulphur and is supposed to come from Tertiary blue slates. The production of oil in New Zealand is about 4,000 gallons weekly, and that comes from a depth of 3,030 feet.

The preliminary figures of the American petroleum exports during 1910 have been issued by the Bureau of Statistics, Washington. These figures show the total exportation during 1910 of 1,397,000,000 gallons valued at $81,571,000. Compared with the figures for 1909 there is a falling off in quantity of 100,000,000 gallons and a reduction in value of over $11,000,000.

ILLINOIS RESCUE STATION COMMISSION

The Mine Rescue Station Commission of the state of Illinois has issued a Report to the Governor and General Assembly of the work accomplished from August 1, 1910, to December 31, 1910. The Governor of Illinois appointed on this Commission the following men:

Representing the United Mine Workers of Illinois: Charles Bennett, La Salle, Ill.; Charles Krallman, Glen Carbon, Ill.

Representing the Mine Operators of Illinois: John L. Schmidgall, Murphysboro, Ill.; J. W. Miller, Gillespie, Ill.

Representing the Mine Inspectors of Illinois: Hector McAllister, Streator, Ill.

Representing the Federal Bureau of Mines: J. A. Holmes, Washington, D. C.

Representing the Mining Department of the University of Illinois: H. H. Stoek, Urbana, Ill.

Immediately after the organization on August 2, 1910, the Commission held a conference with the state architect and authorized him to draw up plans for three rescue stations in accordance with suggestions submitted to him by the Commission.

After several meetings of the Commission in Chicago and Springfield, it was decided to locate the rescue stations at the following places: At La Salle, for the northern part of the state; at Springfield, for the central part of the state; at Benton, for the southern part of the state.

In order to secure suitable men for the positions of superintendent and assistants at the three rescue stations, Richard Newsam was appointed manager of the stations, and with the sanction of the Commission adopted a rule that only those holding an Illinois certificate as mine manager would be eligible for appointment as superintendent of a rescue station, and only those holding an Illinois certificate as mine manager or mine examiner would be eligible to appointment as assistant at a rescue station.

As a result of the preliminary theoretical and practical tests, the following appointments were made:

La Salle station: Superintendent, Thomas English, of Streator; assistant, Peter Donnelly, of Streator.

Springfield station: Superintendent, G. H. Walmsley, of Peoria; assistant, Charles Swan, of Danville.

Benton station: Superintendent, J. C. Duncan, of Murphysboro; assistant, Frank Rosbottom, of Peoria.

These men were trained at the Urbana station of the United States Bureau of Mines, and after 2 weeks were sent to the United States Bureau of Mines at Pittsburg, where they were given further training in rescue and first-aid methods. After returning to Urbana they were given additional training in first-aid to the injured.

During the period of their training all the men accompanied R. Y. Williams and James Webb, of the United States Bureau of Mines, to the Electric mine in Danville, Ill., to assist in fighting a mine fire. On December 10, three of the men accompanied Mr. Webb to Middletown, Ill., and assisted him in fighting a mine fire there. The men in charge of the Illinois stations therefore have had an unusually thorough theoretical and practical training.

An essential part of the rescue equipment at each station is the mine rescue car which stands on a switch at the station and is equipped with rescue apparatus and ready upon call to be taken to the scene of an accident as soon as a locomotive can be attached. Two of the cars were fitted out and contributed by railways, and the third was purchased for $750 from the Pullman company, and refitted at the railroad shops in Peoria.

The rescue stations are intended to serve two distinct purposes. First, to furnish a trained rescue corps of men to assist at a mine in case of accident. Second, to train men in the use of rescue appliances so that ultimately there will be at every mine in Illinois a corps of men who can enter a mine with a suitable rescue outfit.

Each station can accommodate from 12 to 15 men in training at one time, and the Commission recommends that this number should be at each station at all times receiving instruction in rescue appliances and rescue methods.

EARTHQUAKES AND COLLIERY EXPLOSIONS

F. Napier Denison, F. R. M. S., has interested the Victoria, B. C. Board of Trade in the establishment of an observatory to record seismic disturbances. From observations made by Mr. Denison an average of 76 earthquakes were recorded in Victoria yearly, and of these 36 occurred within a radius of 1,000 miles of Victoria. Mr. Denison stated that since 1898 he had kept a constant record of earth unrests on the local seismograph. He had been able to an extent, by the collection of statistics, to establish a certain relation between periods of great seismic unrests and colliery disasters. He pointed out that the greatest number of these disasters occurred when the pendulum reached its greatest westerly swing. In the records of correlation obtained the greatest westerly turn of the pendulum was during the months of November and December of last year, and coincident with this the greatest number of colliery disasters during the last 12 years occurred.

Of 114 explosions in North America, in which more than 5 lives were lost, 48 of these occurred upon the day or within 24 hours of some great earth unrest. Of 9 European explosions, in which similarly more than 5 lives were lost, 77 per cent. of these occurred on the day or within 24 hours of a great earthquake.

In a letter, T. R. Stockett, general manager of the Western Fuel Co.'s mines, at Nanaimo, said that the peculiar coincidence of Mr. Denison's records and colliery statistics warranted further investigation, and that the Dominion government might well extend the local facilities for studies of this important subject.

In elaborating on his theory Mr. Denison did not wish it understood that earthquakes were the direct cause of disasters in collieries. During the time of maximum disturbances he pointed out that the earth undergoing tremendous strains, and stress at different points would cause changes in rock strata that would lead to the escape of gases which would only need ignition to cause explosions and subsequent disasters.

THE PROTECTION OF SURFACE OVER COAL MINES

OWING to the extent of the coal mining operations under the city of Scranton, and the value of the surface and buildings thereon, the question of the protection of the surface and surface improvements is such that on the initiative of Hon. J. Ben Dimmick, former mayor of the city, the city councils and the school board jointly engaged Messrs. William Griffith and Eli T. Conner, both well-known and able mining engineers to make an exhaustive investigation of the hundreds of acres of mine workings under the city, and to suggest plans for the proper support of the surface. In addition, the voluntary services of the following gentlemen were secured as an advisory board to supplement the suggestions of Messrs. Griffith and Conner: John Hays Hammond, W. A. Lathrop, L. B. Stillwell, D. W. Brunton, and Dr. R. A. F. Penrose, Jr.

Messrs. Griffith and Conner, after several months work and study, submitted a voluminous and comprehensive report to the advisory board, which recently met in Scranton, and on their approval of it, they submitted it to the mayor, councils, and school board. A summary of the conditions found to exist and the recommendations of Messrs. Griffith and Conner are published in another column. That the work of the two able engineers would be conscientiously and ably done was predicted by the writer when he with others familiar with their ability urged their appointment. That their report and maps are worth infinitely more to the city than the fees paid them, is a statement which we make without fear of contradiction from any mining engineer or mine official of experience and common sense.

The method suggested by Messrs. Griffith and Conner—flushing the worked-out areas full of culm, sand, gravel, ashes, or other available material—is what we predicted it would be. Of course there are details regarding the methods of treating various areas suggested in the report that could only be suggested after personal examinations of the areas in question by the engineers. These details, however, are among the most valuable portions of the report.

In their report Messrs. Griffith and Conner mention that the method of protection they suggest is largely and successfully used in France and Germany. They might also have called attention to the fact that it has been and is now being successfully used at Shenandoah, Pa., by the Philadelphia & Reading Coal and Iron Co. In fact, the late Mr. R. C. Luther, when chief mining engineer of that company, was the first man to suggest flushing anthracite mine workings full of culm to protect the surface, and the first work of the kind done anywhere, was in the western section of the town of Shenandoah, some 25 or 30 years ago, and the writer was at the time an assistant to Mr. John H. Pollard, resident engineer, under whose personal direction the surveys were made, the bore holes put down and the work was accomplished.

Descriptions of this operation, and of similar opera-

tions on somewhat smaller scales in other portions of the anthracite region were published in Mines and Minerals, read by subscribers in France and Germany, and the method was adopted in those countries. A peculiar and interesting fact in this connection is that in the former country the method is known as the *Scranton Method* probably because its use was first brought to the attention of the French engineers by this journal, published in Scranton.

THE LESSON OF THE PRICE-PANCOAST DISASTER

On another page we publish an absolutely correct account of the Price-Pancoast mine disaster with a map showing the affected mine area, ventilation plan, etc. It has been prepared with a mind free from prejudice and all sentiment has been eliminated, so that there might be a plain statement of facts that would serve a useful purpose in suggesting means for the prevention of other mine disasters.

There is no positive evidence as to what started the fire, and we base our belief that the coal oil lamp in the Dietz lantern exploded, on the fact that it was the only probable agent that could possibly start the fire.

Such lanterns have been used for many years in mines, just as coal-oil lamps have been used in homes. In proportion to the number of lamps used in homes, the number of explosions is very small. When the lamp is encased as in the Dietz lantern there is very much less chance for an explosion than there is in the case of an ordinary house lamp. Nevertheless there is a chance of explosion, and the starting of a mine fire which may soon get beyond immediate control. Therefore the use of coal-oil lamps, of any type, in mine workings should be deprecated. In fact no great hardship would be entailed if their use was prohibited by law.

Progressive mine managers are now making inside engine rooms, pump houses, etc., of steel and masonry, masonry, brick, or concrete. However, there are in practically all large mines, engine rooms, pump rooms or offices for foremen, similarly constructed to the engine room at the Price-Pancoast. Such engine or pump rooms are safer from fire than those built entirely of wooden planks, and we do not recollect another instance in which a fire starting in such a room caused so great a conflagration or so much loss of life. It is therefore evident, that if an engine room such as that at the Price-Pancoast mine could, through a few unfortunate circumstances, initiate such a fire, the more flimsy shanties sometimes used in mines as engine rooms, pump rooms, and offices, are an element of great danger, and their use should be terminated as quickly as possible. It is not always practicable to construct inside engine and pump rooms and offices of masonry, brickwork, or concrete, and it is not always necessary to do so, but it should be done wherever it is practicable, and the flimsy plank or board shanties should be prohibited.

THE PREVENTION OF MINE ACCIDENTS

In an address recently made at the Case School of Applied Sciences, in Cleveland, Ohio, Dr. Joseph A. Holmes, Director of the Federal Bureau of Mines, endorsed strongly the position maintained for many years by Mines and Minerals, in regard to the selection of state mine inspectors. In the course of his address Doctor Holmes said: "The selection of state mine inspectors by popular vote must be stopped if there is to be a reduction of accidents in the coal and metal mines of the United States. The state mine inspectors should have greater permanence in office and freedom from political and other outside influences. Their selection and continuance in office should depend upon their training and experience. They should be examined by a non-partisan board of mining men. They should be appointed upon the recommendation of such a board from the applicants that have shown the highest skill and best experience. Under no circumstances should they be selected by popular vote. In other words, politics should have nothing whatever to do with their selection or their continuance in office. The inspectors should have better support in the way of compensation. In fact, the salary and other conditions should be such as to enable the state to secure the best possible type of men for this important work."

He also recommended "the use at each mine of a limited number of men well trained and experienced concerning the best methods of using explosives, electricity, the handling of gases and coal dust, the methods of timbering with a view to preventing falls of roof, the methods of preventing and extinguishing mine fires, and the methods of rescue and first-aid work. These trained men can serve to good advantage as special inspectors or foremen.

"There must be active, determined cooperation between the miners and the mine management and the state mine inspectors in the enforcement of the mine rules and regulations, and the punishment of every person, whether mine worker or mine manager, who disobeys these rules and regulations."

We heartily concur in all that Doctor Holmes says regarding the selection of state mine inspectors and their compensation. In regard to the latter, we have always claimed that the salaries of the state mine inspectors should be at least $3,000 per year, if men of proper caliber are to be secured for the positions and retained in the service of the state. In many instances men of superior ability as mine inspectors have resigned their positions to accept superintendencies of mines at larger salaries than the inspectorship paid. In other words, mine owners paid more for real mining ability than the state did, and as a result the state lost the services of men who should have been retained as inspectors.

Doctor Holmes' statement as to the desirability of a limited number of well trained and experienced men at each mine is also sound. Such men are located at

each mine in states requiring the employment of certificated mine foremen, assistant foremen, and fire bosses, but unfortunately, many mining states do not have laws requiring the employment of such men in official positions. When the states without such laws enact and enforce them, a great step toward remedying present conditions will have been taken. With first-class inspectors and properly qualified and certificated mine officials, the cooperation between the miners, the mine management, and the state mine inspectors, in the enforcement of rational mine rules and regulations, which Doctor Holmes rightly considers essential, can easily be secured.

BOOK REVIEW

Motion Study, by Frank B. Gilbreth. Published by the D. Van Nostrand Co., New York. The price of this book is $2 net. According to the writer tremendous savings are possible in the work of everybody. They are not for one class, they are not for the trades only, they are for the offices, schools, colleges, stores, households, and the farms; but the possibilities of benefits from motion study in the trades are particularly striking, because all trades, even at their present best, are badly bungled. At first glance the problem of motion study seems an easy one. After careful investigation it is apt to seem too difficult and too large to attack. There is this to be said to encourage the student however: First, the study of one trade will aid in finding the result for all trades. Second, work once done need never be done again. The final results will be standards. The book is divided into five chapters and is an interesting book in that it shows how workers may not only lessen their work but increase their capacity at the same time.

Elementary Chemistry for Coal-Mining Students, by L. T. O'Shea, M. Sc., Sheffield, B. Sc., London, Professor of Applied Chemistry in the University of Sheffield. The author has been delivering popular and more or less systematic courses of lectures to mine foremen and other coal-mine workers, who have little or no knowledge of chemistry, but are desirous of learning something of the subject which may be useful to them in their daily occupation. The work has been prepared with the object of meeting the wants of these as well as other students of coal mining. It is really a compilation of those parts of chemistry, pure and applied, that are cognate to the coal-mining industry and does not pretend to be a textbook of chemistry. While there is considerable of higher chemistry in the book, there is much which is elementary and practical. There are 15 chapters and an appendix, in all 319 pages. The following is a synopsis of the subjects treated: The Air or Atmosphere, Pressure of a Gas and Atmospheric Pressure, Water and Hydrogen, Atoms and Molecules, Sulphur, Carbon, Flame and the Safety Lamp, The Oxides of Carbon, Coal, By-Products and Their Recovery, Explosives, Explosion in Gases, The Effect of Temperature and Pressure on the Density and Volume of Gases, and the Diffusion of Gases, Chemical Calculations, Useful Tables, Index. The price of the book is $1.80 net.

Elements of Geology, by Eliot Blackwelder, Associate Professor of Geology, University of Wisconsin, and Harlan H. Barrows, Associate Professor of General Geology and Geography, University of Chicago. Published by the American Book Co., New York, N. Y. The book contains 475 pages and 485 illustrations. The price is $1.40. There are 25 chapters and an index and the book is divided into two parts—Physical Geology and Historical Geology. It is exceedingly well illustrated, and the illustrations help much toward aiding the student in geology to an understanding of the subject.

Biennial Report of the State Geologist, by H. A. Buehler, Director of the Missouri Bureau of Geology and Mines, Jefferson City, Mo. The investigations made in the preparation of this report are, coal deposits, iron ores, lead and zinc deposits of the Aurora area, geology and structural materials of Jackson County, the geology of Phelps County, and ore deposits of the southern Ozark region.

Forestry Wood Industries, Vol. V, 1911, of the West Virginia Geological Survey, by A. B. Brooks; also Bulletin No. 2, 1911, Levels, Coal Analyses. While the former book pertains to the lumber business, coal mining and lumbering are so closely connected in many instances that the subject is of interest to both industries. The book teems with information, and Mr. White is to be congratulated on obtaining Mr. Brooks as forester on this subject. "Bulletin Two" is a cloth-bound book of 385 pages, divided into two parts, the first giving levels in the various parts of the state and the other analyses of the coal beds in the different geological horizons. A list of the publications of the West Virginia Geological Survey and the prices can be had by addressing the Secretary of State, Charleston, or Dr. I. C. White, Superintendent of the West Virginia Geological Survey, Morgantown, W. Va.

BOOKS RECEIVED

United States Geological Survey Publications, Washington, D. C. Bulletin No. 445, Geology of the Pegmatites and Associated Rocks of Maine, including Feldspar, Quartz, Mica, and Gem Deposits, by Edson S. Bastin; The Production of Iron Ore, Pig Iron, and Steel, by Ernest F. Burchard; The Production of Sand-Lime Brick in 1909, by Jefferson Middleton; The Production of Gems and Precious Stones in 1909, by Douglas B. Sterrett.
